In baffled stirred reactors at sufficiently high speeds, entrainment of the gas bubbles into the liquid surface occurs. Alternatively, in unbaffled vessels, vortex formation occurs, which at high impeller speeds causes bubbles to entrain into the liquid phase. Under certain conditions, at high impeller speeds, a spray of liquid droplets in the gas phase also occurs. The three phenomena are called surface aeration, as depicted in Figures 11.46a and b. They depend on the impeller design, location, and speed of agitation. The important characteristics of surface aerators are the critical impeller speed for the onset of surface aeration, the intensity of surface aeration, power consumption, mass transfer coefficient, gas holdup, solid suspension, and so forth. Little information has been published on the heat transfer and solid suspension aspects of surface aerators. A characteristic feature of surface aeration is that the impeller has to be provided at the liquid surface to ensure a high intensity of surface aeration. With a single gas-inducing impeller, drawbacks often occur such as poor mixing in the rest of the reactor, poor dispersion of gas, and poor solid suspension/heat transfer characteristics. All difficulties can be eliminated by providing one or more impellers below the surface aerating impeller. The hydrodynamics and performance characteristics of such multiple-impeller surface aerators are similar to those of multiple-impeller gas-inducing systems. The recommended correlations are given by Patwardhan and Joshi (1998).

11.4.3.10.3 Jet-Loop Reactors

In a jet-loop reactor, liquid or gas and liquid are pumped into the reactor through a nozzle at either the top or the bottom. The jet of liquid or gas and liquid leaving the nozzle provides the energy for mixing and dispersion of the two phases. The unreacted gas can be recycled to the nozzle, forming a loop. In addition, the liquid may also be forced to circulate within the reactor (with the help of a draft tube) or externally (using a pump). Such reactors are referred to as jet-loop reactors, as shown in Figure 11.47. Jet-loop reactors can be further classified according to the construction of the nozzle as either injector or ejector. In injector nozzles or two-fluid nozzles, the gas is sparged along with the liquid through the nozzle. Intense gas-liquid mixing occurs in the nozzle, creating a fine dispersion. The gas-liquid dispersion exits the nozzle, and the gas is further dispersed in a draft tube. Unreacted gas escapes into the head space and can be either vented or recycled to the injector nozzle. Ejector nozzles, on the other hand, can suck gas from the atmosphere or from the reactor head space. The liquid (primary fluid) is pumped through a nozzle at high velocity. Based on Bernoulli's principle, a vacuum is created in the suction chamber. The gas (secondary fluid) therefore is sucked into the suction chamber. The liquid jet and the gas are mixed, and a gas-liquid

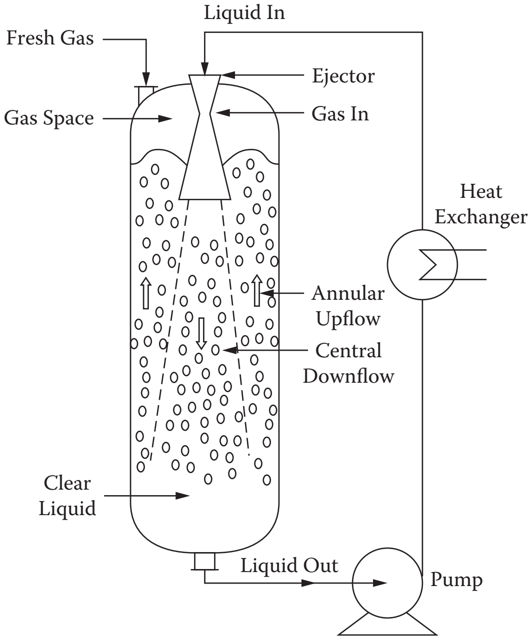

FIGURE 11.47 Jet-flow reactor.

dispersion is created in the mixing tube. The diffuser section at the end of the mixing tube helps in pressure recovery and compresses the gas-liquid mixture to the discharge pressure. The entire assembly (nozzle, mixing tube, and diffuser) is collectively called the *ejector*. The gas-liquid dispersion issuing from the ejector is sent to a separator, a reactor vessel, or a holding tank, which provides additional gas-liquid contact. The liquid jet performs two functions: it provides the momentum necessary for circulation of the vessel contents to ensure good mixing, and it disperses the entrained gas into small bubbles producing a large interfacial area. The unreacted gas escapes back into the head space, which can again be entrained into the ejector. Bhutada and Pangarkar (1987, 1989) investigated the effects of nozzle and ejector geometry, operating conditions, and physicochemical properties on the rate of gas entrainment and fractional gas holdup. These were found to be independent of the shape of the entry section of the nozzle. With a decrease in the mixing tube length, the rate of gas entrainment increases, whereas the fractional gas holdup is almost independent of the length. A pressure recovery diffuser section improves the rate of gas induction and the fractional gas holdup. The effects of geometrical parameters on the mass transfer characteristics need to be investigated systematically and related to the gas holdup and rate of gas entrainment.

11.4.3.10.4 Rotating Biological Contactors (RBC)

An RBC consists of a number of plastic disks mounted on a rotating horizontal shaft, and it is placed in a concrete tank containing the liquid to be treated. During rotation, the disk surface withdraws a thin film of liquid from the tank and transfers it through the gas space (i.e., air). This thin liquid film on the disk surface absorbs oxygen from the air, thereby providing gas-liquid contact. A pictorial representation of this reactor is shown in Figure 11.48. The RBC system provides high interfacial area per unit volume of contractor, resulting in efficient aeration. Vaidya and Pangarkar (1985) solved the simplified Navier–Stokes equation for a Newtonian fluid, assuming a half-immersed disk vertically withdrawn from a pool of liquid; various radial points on the disk had different linear speeds ($r\omega$) and hence different film thicknesses. Using computed profiles, the conservation equation for the gas phase was solved in addition to the mass transfer coefficient.

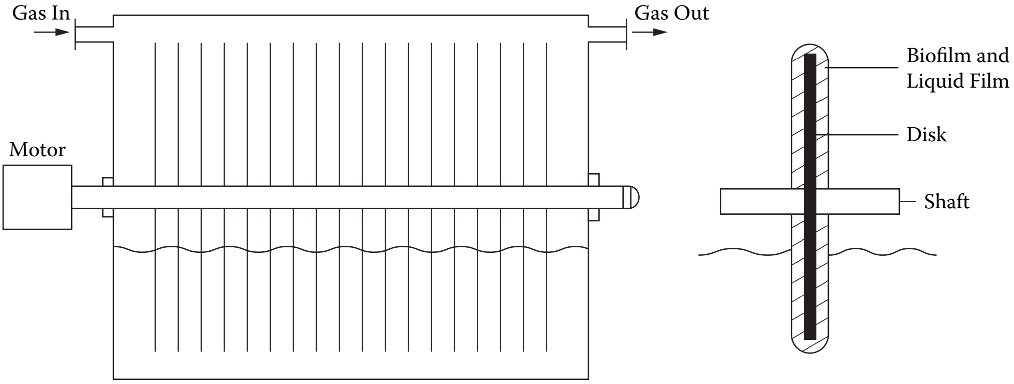

FIGURE 11.48 Rotating-disc reactor.

11.4.4 Potential Energy (Film Contactors)

As described in Section 11.4.1, most energy is supplied through the liquid phase as potential energy. Packed columns, trickle-bed reactors, falling-film reactors/evaporators, and wiped-film evaporators (and their variants, such as agitated-film and thin-film) fall into this category. In these cases, liquid flows in the form of a film and thus occupies only a very small fraction of the reactor/contactor volume (less than 10 to 20%) as compared to class 1 and class 2 equipment. Since the liquid phase occupies a small fraction of the equipment, only a low phase pressure drop results. However, it gives low values of interfacial area and mass transfer coefficient as compared to class 1 and class 2 equipment. In all film reactors (except wiped-film reactors to some extent), the design of the liquid distributor (and in some cases the liquid redistributor) is very crucial.

11.4.5 Comparison of Gas-Liquid Reactors

It is instructive to compare gas-liquid reactors (from all the classes) on the basis of capacity, turndown ratio (*L/G*), liquid-phase axial mixing, gas-side pressure drop, mass transfer coefficient, effective interfacial area, heat transfer coefficient, and the number of theoretical stages. Table 11.26 presents such a comparison using ratings 1 to 5 (poor to excellent). This table should be useful to design engineers.

11.5 CASE STUDIES

11.5.1 Introduction

We now consider 12 case studies that include simple homogeneous liquid-phase reactions, complex homogeneous gas-phase reactions, gas-solid catalytic and noncatalytic reactions, gas-liquid simple and complex reactions, gas-liquid-solid (noncatalytic) reactions, gas-liquid-solid (catalytic) reactions, and solid-solid reactions. The scope and coverage of each case study are summarized in Table 11.27. In the first, homogeneous reactions are considered. For these relatively simple reactions, the possibility of optimum design is discussed.

In the case of multiphase reactions, mass transfer and/or chemical reactions occur in series and/or parallel. Depending on the relative rates of these steps, the rate-controlling step is likely to be either one or a combination of two or more steps. The rate-controlling step may depend on the type of reactor. Furthermore, within a given reactor, it may change with location because of possible variations in the concentrations of different species, total pressure, temperature, and system properties. Hence, some case studies include a discussion of the rate-controlling step and estimation of the overall rate of reaction. Pertinent literature is cited in each case.

TABLE 11.27
List of Case Studies Covered with Brief Descriptions

No.	Case Study	Coverage
1	Homogeneous liquid-phase simple reaction: $A \rightarrow R$	The design of pipeline, coil, and heat exchanger (reaction on tube or shell side) reactors and their optimization are illustrated and discussed.
2	Homogeneous gas-phase complex reaction: Oxidation of NO using ozone	The reaction involves several intermediate, side and end products. For all these species, the concentration profiles in a pipeline reactor are obtained. The ozonation of NO is shown to be very fast and the importance of mixing of ozone is brought out.
3	Gas-solid (catalytic) reaction: Modeling of a complex reaction on a deactivating catalyst (a model scheme)	The chlorination of tetrachloroethane successively to the penta and hexa chlorides on a deactivating catalyst is used as a good complex model system for illustrating the application of rigorous statistical methods for model discrimination using a powerful discriminatory criterion.
4	Gas-solid (catalytic) reaction in fixed-bed NINA and adiabatic reactors: Reduction of nitrobenzene to aniline	The general principles of modeling a vapor-phase reaction on a solid catalyst in a fixed-bed reactor are illustrated by applying them to the specific case of nitrobenzene reduction to aniline. Several models of varying complexity are discussed.
5	Comparison of selected fluid-bed models for predicting the conversion in the catalytic reduction (by hydrogen) of nitrobenzene to aniline	The design of a fluidized-bed reactor for the same reaction as under (4) is discussed. Five important models are used to design the reactor and the results are compared. A brief discussion of a few other (more complex) models is also included.
6	Gas-solid (noncatalytic) reaction: Development of a solid sorbent for cleaning coal followed by modeling of the reaction involved and a conceptual reactor design	A problem of paramount environmental importance is the cleaning of coal gas for industrial use, such as in electrical power generation by the new IGCC process. The development of a calcium-based adsorbent for this purpose is described followed by the postulation of a possible reactor configuration.
7	Gas-liquid reaction: Air-oxidation of sodium sulfide (a simple reaction with typical problems of gas-liquid reactions)	For an industrially important system, oxidation of black liquor, six reactor types are designed. A comparison of all these six reactors is presented in terms of reactor dimensions (fixed cost) and power consumption (operating cost).
8	Gas-liquid reaction: Absorption of NO_x gases in the manufacture of nitric acid (a system with multiple complexities)	Absorption of NO_x gases in water is an important step in nitric acid manufacture. The absorption process involves multiple complexities. The design of a plate column, which incorporates many of these complexities, is discussed.
9	Gas-liquid-solid (noncatalytic) reaction: Oxydesulfurization of coal in a slurry reactor	A brief discussion of the rate-controlling step in coal oxydesulfurization is given on the basis of the shrinking core model. A three-phase slurry reactor is designed by including the nonideal behavior of the solid phase.
10	Gas-liquid-solid (noncatalytic) reaction with the particle size diminishing to less than the diffusion film thickness: Carbonation of lime	In this three-phase reaction, the solid phase undergoes a chemical reaction. The rate-controlling step is shown to vary with particle size. The case of particles smaller than the diffusion film thickness is considered, and a procedure is given for optimizing the production capacity of a given reactor.
11	Gas-liquid-solid (catalytic) reaction: Hydrogenation of an organic compound	A conventional stirred tank reactor and a self-inducing reactor are designed. Self-induction is shown to enhance the overall rate of reaction. A procedure is described for optimum design.
12	Solid-solid reaction followed by a gas-solid reaction: Manufacture of chlorosilanes	Silicon reacts with cuprous chloride autocatalytically to form a solid known as η-phase, which then catalyzes the reaction between silicon and methyl chloride to form methyl chlorosilanes. Mass transfer effects are neglected to illustrate the mechanism of this unique reaction and equations are developed for predicting the final product size distribution.

For sound process design, we need values of numerous design parameters such as fractional phase holdups, pressure drop, dispersion coefficients (the extent of axial mixing) of all the compounds, heat and mass transfer coefficients across a variety of fluid-fluid and fluid-solid interfaces depending on the type of multiphase system, type of reactor, and the rate-controlling steps. To clarify the scope of the case studies selected, their salient features are next listed.

Examples of several classes of industrially important multiphase reactions were given in Section 11.3. The case studies are chosen to represent different classes of reactions. Thus, we cover reactions ranging from simple homogeneous to quite complex multiphase reactions.

The rate-determining step is particularly important when a choice has to be made between competing mechanisms for a given reaction. One case study illustrates a rigorous statistical procedure.

In available texts, emphasis is often on the design of a single (often arbitrarily selected) reactor for a given reaction. In some case studies presented here, several reactor configurations are considered for a single reaction, and an optimum configuration (along with appropriate geometrical details) is recommended. Such a study can nontrivially alter reactor choice and performance.

Several models are sometimes available for the design of the reactor. Thus, in one case study, designs are made using several models, and a comparative assessment is presented.

Capital and operating costs are central to reactor selection. This aspect of design is illustrated in two case studies.

It is theoretically possible to include all considerations mentioned above in just two or three case studies. This has the disadvantage of severely restricting their breadth. Therefore, we decided to spread these considerations over 12 carefully selected case studies.

At the end of each case study, general remarks are given that bring out the lessons learned. Furthermore, at the end of the case studies we give our recommendations (morphology) for the selection and design of reactors.

Case Study 11.1 Homogeneous Liquid-Phase Simple Reaction: $A \rightarrow R$

Nomenclaure for Case Study 11.1

A	reactant
A_A	available area of heat transfer available (m^2)
A_H	area of heat transfer (m^2)
$[A]$	concentration of reactant A
$[A]_0$	inlet concentration of A
$[A]_e$	exit concentration of A (mol/m^3)
A_S	shell area (m^2)
a_S	cross-sectional area for shell-side flow (m^2)
B	baffle spacing (m)
C	clearance (m)
C_{PC}	heat capacity of coolant (kcal/kg K)
D	diameter of tube (m)
D_C	diameter of coil helix (m)
Do	outer diameter of tube (m)
D_S	shell diameter (m)
$\mathbf{D}$	dispersion coefficient (m^2/s)
d_E	equivalent diameter of the shell (m)
f	friction factor (–)
f_C	friction factor for a coil (–)
f_P	permissible stress for steel (N/m^2)
f_S	friction factor on shell side (–)
G_S	shell-side mass velocity ($kg/m^2/s$)
H	height (m)
ΔH	heat of reaction (kcal/kmol)

h	height coordinate (m)
h_C	tube-side heat transfer coefficient of a coil (W/m^2 K)
h_S	shell-side heat transfer coefficient (W/m^2 K)
h_T	tube-side heat transfer coefficient (W/m^2 K)
k_A	first-order rate constant (1/s)
k_T	thermal conductivity (W/m K)
L_T	length of pipe (m)
M_C	mass flow rate of coolant (kg/s)
N_B	number of baffles
N_T	number of tubes (–)
Nu_L	Nusselt number for laminar flow (–)
Nu_T	Nusselt number for turbulent flow (–)
Pe	Peclet number (–) Pe = $DV\rho C_p/k$
P	pressure (N/m^2)
Pr	Prandtl number (–)
Pr_C	Prandtl number of coolant (–)
Pt	tube pitch (m)
ΔP	pressure drop (N/m^2)
ΔP_C	pressure drop of coil (N/m^2)
ΔP_S	shell-side pressure drop (N/m^2)
ΔP_T	tube-side pressure drop (N/m^2)
Q	volumetric flow rate (m^3/s)
Q_H	heat load (W, kcal/s)
R	product
Re	Reynolds number (–)
r_A	rate of reaction (mol/m^3/s)
Re_S	shell-side Reynolds number (–)
Re_T	tube-side Reynolds number (–)
R_{ST}	ratio of shell area to tube area (–)
S	area of cross section (m^2)
$(\Delta T)_{LM}$	logarithmic mean temperature difference (K)
T_{Ce}	coolant outlet temperature (K)
T_{C0}	coolant inlet temperature (K)
T_0	inlet temperature (K)
T_e	outlet temperature (K)
ΔT	temperature difference (K)
$\bar{t}$	residence time (s)
t_s	shell thickness (m)
t_T	tube thickness (m)
U	overall heat transfer coefficient (W/m^2 K)
u	average velocity (m/s)
V	reactor volume (m^3)
V_C	volumetric flow rate of coolant (m^3/s)
W_R	weight of pipe (kg)
W_S	shell weight (kg)
X	fractional conversion (–)

Greek

μ_C	viscosity of coolant (Pa·s)
μ_W	viscosity at the wall (Pa·s)
η	safety factor
ρ	density (kg/m^3)
ρ_C	density of coolant (kg/m^3)
ρ_S	density of steel (kg/m^3)

Subscripts

C	coil/coolant
E	equivalent
e	outlet
o	inlet
S	shell side
T	tube side

The Problem

A continuous reactor is to be designed for a homogeneous liquid-phase reaction $A \rightarrow R$. The reaction is first order with respect to A, and the rate is given by

$$-r_A = k_1[A] \tag{CS1.1}$$

where k_1 = 0.00167 s^{-1}. The heat of exothermic reaction is –209 kJ/gmol. The flow rate of the reactant is 0.01 m^3/s. The concentration of A at the inlet of the reactor is 1 kmol/m^3, and a conversion of 99% is desired. Find the volume of the reactor if the same reaction is to be performed in a (1) backmixed reactor and (2) plug-flow reactor (PFR). Calculate the optimum length-to-diameter ratio for a plug-flow reactor. Also examine the alternative configurations, i.e., (3) a coil reactor and (4) a shell-and-tube heat exchanger type reactor.

Data

Density (ρ) = 1000 kg/m^3; specific heat (C_P) = 4180 J/kg K; viscosity (μ) = 1×10^{-3} Pa·s; Prandtl number (Pr) = 5; number of working hours per year = 8000; cost of electric power = 0.03 \$/kWh; cost of mild steel = 0.4 \$/kg; density of steel = 8000 kg/m^3; permissible stress for steel (f_P) = 8.5×10^7 N/m^2; design pressure of the reactor = 0.5×10^6 N/m^2.

Solution

1. Completely Backmixed Reactor

Assumption: isothermal operation

Data: $[A]_0$ = 1 kmol/m^3, x = 0.99, F = 0.01 m^3/s, outlet concentration,

$$\begin{aligned}[A]_e &= [A]_0(1-X) \\ &= 0.01 \text{ kmol/m}^3\end{aligned} \tag{CS1.2}$$

For a backmixed reactor, the residence time is given by the following equation:

$$\begin{aligned}\bar{t} &= V/Q = ([A]_0 - [A]_e)/k_1[A]e \\ &= 59281 \text{ s}\end{aligned} \tag{CS1.3}$$

Therefore, the reactor volume, $V = \bar{t} \times Q = 59400 \times 0.01 = 593 \text{ m}^3$

2. Plug-Flow Reactor: Pipeline Reactor

The operation is assumed to be isothermal. To start with, we assume plug flow, a condition that is validated later. For a plug-flow reactor, the residence time is given by

$$\bar{t} = V/Q = -(1/k_1)\ln(1-X)$$
$$V = Q \times \bar{t} = 0.01 \times [-(1/0.00167) \times \ln(1-0.99)] = 27.63 \text{ m}^3 \quad \text{(CS1.4)}$$

Thus, the ratio of backmixed reactor (CSTR) volume to plug-flow reactor (PFR) volume is 594/27.63 = 21.5. The CSTR not only has 21.5 times the PFR volume, it also needs sufficient impeller power to achieve backmixing. Obviously, from fixed as well as operating costs points of view, PFR is a better option. However, let us now consider the length-to-diameter (L_T/D) ratio for PFR behavior.

For the case of turbulent flow in a pipeline, the dispersion coefficient ($\boldsymbol{D}$) is given by (Taylor, 1953)

$$\boldsymbol{D} = 5.05\ u\ D\ (f/2)^{0.5} \quad \text{(CS1.5)}$$

The Peclet number is

$$Pe = uL_T/\boldsymbol{D} \quad \text{(CS1.6)}$$

PFR behavior is attained when Pe exceeds 10. However, considering the end effects, it is desirable to select a higher number (say, 50) for which the length-to-diameter ratio can be estimated from Equations (CS1.5) and (CS1.6) and that works out to be 12.5. Thus, the plug-flow condition is satisfied when $L_T/D > 12.5$ for a given volume of a PFR. For selection of optimum L_T/D, the following points need to be considered: (1) pressure drop, (2) heat transfer area of the wall, and (3) fixed cost. Let us estimate these for $L_T/D = 1000$:

$$V = (\pi/4)D^2 L_T$$
$$= (\pi/4)D^2(1000D) = (\pi/4)D^3 \times 1000 \quad \text{(CS1.7)}$$
$$D = (4V/1000\pi)^{1/3} = 0.327 \text{ m}, \ L_T = 327 \text{ m}$$

Area of cross section,

$$S = (\pi/4)D^2$$
$$= 0.084 \text{ m}^2 \quad \text{(CS1.8)}$$

Average velocity,

$$u = Q/S = 0.119 \text{ m/s} \quad \text{(CS1.9)}$$

Reynolds number,

$$\text{Re} = Du\ \rho/\mu$$
$$= 0.327 \times 0.119 \times 1000/10^{-3} = 38913 \quad \text{(CS1.10)}$$

Friction factor,

$$f = 0.08\,\text{Re}^{-0.25} \\ = 0.0057 \tag{CS1.11}$$

Dispersion coefficient $\boldsymbol{D}$ = 5.05 $uD(f/2)^{0.5}$ = 0.0104 m^2/s
Peclet number $Pe = uL_T/\boldsymbol{D}$ = 3742
Peclet number is very high (>50), which confirms the assumption of plug flow.

Pressure drop,

$$\Delta P = 2\,f\;L_T\;u^2\;\rho / D \\ \Delta P = 161\ \text{N/m}^2 \tag{CS1.12}$$

$$\text{Power} = \text{Q} \times \Delta P \\ = .01 \times 160 = 1.61\ \text{W} \tag{CS1.13}$$

Annual electric energy required = (1.6 W/1000) × (8000 h/year) = 12.8 kWh

Annual operating cost = 12.8 kWh × 0.03 \$/kWh = \$0.4

Estimating the fixed cost of the reactor:

Thickness,

$$t_T = PD / 2\,f_P \eta \\ = 0.5 \times 10^6 \times 0.327 \left[2 \times 8.5 \times 10^7 \times 0.9 \right] \tag{CS1.14}$$

t_T = 0.0011 m ~ 1.1 mm, which is very low. In addition, we need to have some corrosion allowance:

Assuming a minimum thickness of 4 mm, t_T = 0.004 m

Weight of the material required,

$$W_R = \pi D L_T t_T \rho_s \\ = \;3.142 \times 0.327 \times 327 \times 0.004 \times 8000 = 10750\ \text{kg} \tag{CS1.15}$$

Cost of reactor = W_R × unit cost of material = 10750 kg × 0.4 \$/kg, i.e.,
Fixed cost = \$4300

Considering 20% of the fixed cost as the annualized cost (depreciation cost),

Total annualized cost = operating cost + 20% of fixed cost = 0.4 + 0.2 × 4300 = \$860/year

Since the reaction is exothermic, heat transfer must be considered. The total heat load is

$$Q_H = Q([A]_0 - [A]_f)(-\Delta H) = 0.01 \text{ m}^3/\text{s} \times (1 - 0.01) \text{ kmol/m}^3 \times (209 \times 10^6) \text{ J/kmol} = 2.069 \times 10^6 \text{ W}$$

$$\text{Heat transfer area, } A_H = \pi D L_T = \pi \times 0.327 \times 327 = 336 \text{ m}^2$$

Estimation of the heat transfer coefficient:

$$Pr = Cp\ \mu/k_T = 5 \text{ (given)}$$

$$k_T = C_P\ \mu/5 = 0.836 \text{ W/m K}$$

$$h_T D/k_T = 0.023\ Re^{0.8}\ Pr^{0.33} = 0.023 \times (38913)^{08} \times (5)^{0.33} = 183.85$$

$$h_T = 183.85\ k_T/D = 183.85 \times 0.836/0.327 = 469.8 \text{ W/m}^2 \text{ K}$$

Assuming this heat transfer coefficient to be the controlling heat transfer resistance, the overall heat transfer coefficient $U = 469.8$ W/m^2 K. Since the reactor is a plug-flow reactor, the concentration of A is high along its entrance length, so the rate of reaction and hence the rate of heat generation are also high. Toward the end of the reactor, the rate of heat generation will be less. However, for simplicity, we calculate the driving force on the basis of log mean temperature difference. The rate of heat transfer is given by

$$Q_H = UA_H \left(\Delta T\right)_{LM} \tag{CS1.16}$$

Substitution of Q_H, U, and A_H for (L_T/D) of 1000, gives the log mean temperature difference:

$$(\Delta T)_{LM} = Q_H/UA_H = 2.069 \times 10^6/(469.8 \times 336) = 13.1°\text{C}$$

This is a reasonable driving force for fixing the temperature of the heat transfer fluid. It can be seen from Table CS1.1 that for a reasonable $(\Delta T)_{LM}$, the L_T/D ratio needs to be greater than 500 or the length greater than 200 m.

The above calculations are repeated for various L_T/D ratios with the help of a computer. The results are shown in Table CS1.1; for low L_T/D ratios, the fixed cost of the pipeline is the same. This is explained below:

$$\text{Weight of empty pipe, } W_R = \pi D L_T t_T \rho_s = PD/2\ f_P \eta$$

$$\begin{aligned} W_R &= \pi D L_T \left(PD/2\, f_P \eta\right) \rho s \\ &= \left(1/2\right)\left(\pi D^2 L_T\right)\left(P/f_P \eta\right)\rho_S = 2V\left(P/f_P\eta\right)\rho_S \end{aligned} \tag{CS1.17}$$

Thus, W_R is constant for a given reactor volume V.

However, at higher L_T/D ratios, the calculated thickness of small diameter pipelines is also small. At least a minimum thickness of 4 mm of the pipeline is required. Hence, at higher L_T/D ratios, the weight of the empty pipe is

TABLE CS1.1
Sensitivity Analysis of Length-to-Diameter Ratio for the Pipeline Reactor

$$W_R = \pi D L_T t_T \rho_S = \pi D L_T (0.004)\rho_S = 0.004\pi D^2 (L_T / D)\rho_S$$

$$= 0.004\pi[\{4V / \pi(L_T / D)\}^{1/3}]^2 (L_T / D)\rho_S \tag{CS1.18}$$

$$= 0.004\pi(4V / \pi)^{2/3} \rho_S (L_T / D)^{1/3}$$

Thus, the fixed cost of the pipeline increases with increase in the L_T/D ratio. As L_T/D increases, the velocity and pressure drop increase. Hence, the operating cost increases. Thus, the total annualized cost increases with increase in the L_T/D ratio. However, for plug-flow behavior, L_T/D greater than 12.5 is needed. Furthermore, for the transfer of exothermic heat, sufficient heat transfer area is needed. The total annualized cost is \$973 for an L_T/D of 500, which gives a reasonable driving force for heat transfer (25°C). At higher L_T/D ratios, the total annualized cost is higher, and at lower L_T/D ratios, the $(\Delta T)_{LM}$ is too high. Hence, we choose the case with L_T/D of 500 as the optimum for the pipeline reactor (D = 0.413 m, L_T = 206 m).

For simplicity, various assumptions were made, including the major assumption of isothermal behavior even though a temperature profile is expected due to the exothermic reaction. Also, in reality, one has to consider the cost of the reactor as well as the costs of the heat transfer system, fabrication of reactor, and insulation in the fixed cost. The cost of pressure drop should include a multiplying factor to account for pump efficiency. The operating cost should include the cost of pumping and recooling of the heat transfer medium and so on. Even for the simple case considered here, there is a need for optimization. The procedure can be extended to increasingly complex situations by progressively eliminating the above-mentioned assumptions.

At this stage, one very important point may be noted. The selection of the optimum L_T/D ratio depends on the available heat transfer area. Furthermore, the length of 327 m is rather large. Therefore, let us use a coil reactor for managing the reactor length and conserving the floor space and also a shell-and-tube exchanger (as reactor) for imparting flexibility in the selection of heat transfer area.

3. Helical Coil Reactor

Let us continue with the case of L_T/D = 500, the same as that of the pipeline reactor with a diameter of 0.413 m. Considering the helix diameter to be 10 times the pipe diameter, D_C = 4.13 m.

$$\text{Perimeter of the coil} = \pi D_C = 12.97 \text{ m} \tag{CS1.19}$$

Number of turns of the coil required = total length/perimeter = 206/12.97 = 16

The pressure drop is higher due to helical flow (Srinivasan et al., 1968):

$$\text{Re} = Du\rho / \mu = 3.08 \times 10^4$$

$$\text{The coil friction factor, } f_C = 0.08\text{Re}^{-0.25} + 0.01(D / D_c)^{0.5} \tag{CS1.20}$$

$$= 9.2 \times 10^{-3}$$

$$\text{Pressure drop, } \Delta P_C = 51.3 \text{N/m}^2$$

Annual power consumption = 51.3 N/m^2 × 0.01 m^3/s × 8000 h/yr/1000 = 4.21 kWh

Annual power cost = 4.21 kWh × 0.03 \$/kWh = \$0.13

From Table CS1.2, fixed cost = \$3422

Total annualized cost = 0.13 + \$3422 × 0.2 = \$684.53

However, there is an enhancement in the heat transfer, too, compared to the pipeline reactor (Kern, 1950):

$$h_C / h_T = (1 + 3.5\ D / D_C)$$
$$h_C / h_T = 1.35 \tag{CS1.21}$$

Therefore, the $(\Delta T)_{LM}$ requirement is reduced to 25.00 × h_T/h_C = 18.52°C or a lower L_T/D ratio may be selected.

4. Multitubular Reactor

The same reaction can be performed in a multitubular reactor (with a shell-and-tube heat exchanger configuration). Two possibilities exist: the reactant is on the tube side or on the shell side. Both are considered below.

Reactant on the Tube Side

Tube-Side Calculations

Number of tubes:
Besides the diameter of the tube, the number of tubes, N_T, is also assumed and, correspondingly, the length required is

$$L_T = V / [(\pi / 4) D^2 N_T] \tag{CS1.22}$$

If we consider 25 tubes with an inner diameter of 0.154 m and an outer diameter of 0.168 m, the length of the tube becomes $L_T = 27.63/[(\pi/4) \times 0.154^2 \times 25] = 59.3$ m.

Such a long tube needs many 1-1 shell-and-tube exchangers in series or a multipass exchanger with many passes on the tube side. A 1-1 type heat exchanger is considered here for simplicity.

Pressure Drop:

$$S = (\pi / 4) \times 0.154^2 = 0.0186\ \text{m}^2$$
$$u = Q / S N_T \tag{CS1.23}$$

$$u = [0.01\ \text{m}^3/\text{s}]/[0.0186\ \text{m}^2 \times 25] = 0.021\ \text{m/s}$$

Reynolds number $Re = Du\rho/\mu = 3306$

Friction factor $f = 0.08\ Re^{-0.25} = 0.011$

Dispersion coefficient $\boldsymbol{D} = 5.05\ uD(f/2)^{0.5} = 0.00121\ \text{m}^2/\text{s}$

Peclet number $Pe = uL_T/\boldsymbol{D} = 1028$ (>>50), which confirms our assumption of plug flow

TABLE CS1.2

$$\text{Pressure drop } \Delta P = 2\, fL_T\, u^2\, \rho/D = 3.7 \text{ N/m}^2$$

$$\text{Power} = Q \times \Delta P = 0.01 \times 3.7 = 0.037 \text{ W}$$

Heat Transfer Coefficient:
The tube-side Reynolds number is in the transition regime between laminar and turbulent flows ($2100 < Re < 4000$): using the Sieder–Tate equation for laminar flow ($Re < 2100$),

$$\left(\frac{h_T D}{k_T}\right) = 1.86\left(\text{Re}\,\text{Pr}\frac{D}{L_T}\right)^{1/3}\left(\frac{\mu}{\mu_W}\right)^{0.14} \tag{CS1.24}$$

At Re = 2100, substituting the values of Re, Pr, D, and L_T in Equation (CS1.24), the Nusselt number for laminar flow is 5.6. At the other extreme, for turbulent flow, the Nusselt number is given by

$$\left(\frac{h_T D}{k_T}\right) = 0.023\,\text{Re}^{0.8}\,\text{Pr}^{1/3}\left(\frac{\mu}{\mu_W}\right)^{0.14} \tag{CS1.25}$$

Assuming the value of $(\mu/\mu_W)^{0.14} \sim 1$, Re = 4000, and Pr = 5, the Nusselt number is 29.8. Using interpolation of the log-log relation of the Nusselt number and Reynolds number in the transition regime ($2100 < \text{Re} < 4000$),

$$\frac{\ln(h_T D/k_T) - \ln(5.6)}{\ln(29.8) - \ln(5.6)} = \frac{\ln(\text{Re}) - \ln(2100)}{\ln(4000) - \ln(2100)} \tag{CS1.26}$$

At Re = 3306, Nu = 18.18. Substituting for D and k_T in the Nusselt number ($h_T D/k_T$), the heat transfer coefficient, $h_T = 99$ W/m^2 K.

Shell-Side Calculations

Flow Rate of the Cooling Medium:
Assume the cooling medium to be chilled water with an inlet temperature $T_{C0} = 7°C$, density (ρ_C) = 1000 kg/m^3, specific heat (C_{PC}) = 4180 J/kg K, viscosity (μ_C) = 1×10^{-3} Pa·s, Prandtl number (Pr_C) = 5.

Assuming an outlet temperature (T_{Ce}) of 27°C,

$$Q_H = M_C C_{PC}(T_{Ce} - T_{C0}) \tag{CS1.27}$$

Mass flow rate of the chilled water required is $M_C = Q_H/\{C_{PC}(T_{Ce} - T_{C0})\} = 26.1$ kg/s

Chilled water volumetric flow rate $V_C = M_C/\rho_C = 0.026$ m^3/s

Shell Diameter:
Assuming a triangular pitch of the tubes, with a pitch of $P_T = 1.33 \times D_O$

$$P_T = 1.33 \times 0.168 = 0.224 \text{ m}$$

The ratio R_{ST} of shell area/tube area is given by

$$R_{ST} = \frac{\frac{1}{2} P_T 0.86 P_T}{\frac{1}{2}\frac{\pi D_O^2}{4}} \tag{CS1.28}$$

$$= 1.095\left(P_T / D_O\right)^2 = 1.95$$

$$\text{Shell area} \quad A_S = R_{ST} \times \text{tube area}$$

$$A_S = R_{ST} \times N_T \times S \tag{CS1.29}$$

$$= 1.95 \times 25 \times 0.0186 = 0.91 \text{ m}^2$$

With this cross-sectional area, the shell diameter, D_S, is found to be 1.08 m. Providing an additional 0.3 m to the diameter of the shell, (so that the outermost tubes are away from the shell), D_S = 1.08 + 0.3 = 1.38 m.

Pressure Drop:
Let baffle spacing B = (0.8 times of D_S) = 1.1 m:

$$\text{Number of compartments in the shell} = L_T/B \tag{CS1.30}$$

$$L_T/B = 59.3/1.1 = 54$$

Number of baffles N_B = 54 – 1 = 53:

$$B = L_T / (N_B + 1) \tag{CS1.31}$$

$$= 1.098 \text{ m}$$

Clearance,

$$C = P_T - D_O \tag{CS1.32}$$

$$= 0.056 \text{ m}$$

Cross-sectional area for shell side flow as is given by

$$a_S = \frac{D_S C}{P_T} B \tag{CS1.33}$$

$$= 0.40 \text{ m}^2$$

The mass velocity is given by

$$G_S = M_C / a_S \tag{CS1.34}$$

$$d_E = 4\frac{\frac{1}{2}P_T 0.86 P_T - \frac{1}{2}\frac{\pi D_O^2}{4}}{\frac{1}{2}\pi D_O} \tag{CS1.35}$$

G_S = 65.1 kg/m^2/s, and the equivalent diameter (d_E) of the shell is given by

$$d_E = 0.158 \text{ m}$$

Reynolds number,

$$\begin{aligned} \text{Re}_S &= d_E G_S / \mu c \\ &= 10263 \end{aligned} \tag{CS1.36}$$

Friction factor, $f_S = 0.08\ \text{Re}^{-0.25} = 0.008$:

$$\Delta P_S = \frac{f_S G_S^2 D_S \frac{L_T}{B}}{2\rho_C d_E} \tag{CS1.37}$$

Pressure drop on the shell side ΔP_S is given by

$$\Delta P_S = 8 \text{ N/m}^2$$

$$\text{Power} = Q_C \times \Delta P_S = 0.207 \text{ W}$$

$$\left(\frac{h_S D}{k_T}\right) = 0.36\,\text{Re}^{0.55}\,\text{Pr}^{1/3}\left(\frac{\mu}{\mu_W}\right)^{0.14} \tag{CS1.38}$$

Shell-Side Heat Transfer Coefficient:
Assuming $(\mu/\mu_W)^{0.14} \sim 1$ and substituting the values of Re, Pr, D, and k_T in the above equation, the calculated value of the shell-side heat transfer coefficient h_S = 524W/m^2 K.

Overall Heat Transfer Coefficient (U):
For simplicity, considering only the shell- and tube-side resistances (neglecting dirt factors), the overall heat transfer coefficient U is given by

$$\frac{1}{U} = \frac{1}{h_T} + \frac{1}{h_S D_O / D} \tag{CS1.39}$$

$$U = 88 \text{ W/m}^2\text{ K}$$

Check for Adequacy of Heat Transfer Area:
Initially it was assumed that the chilled water outlet temperature is 27°C. The log mean temperature difference is given by

$$\Delta T_{LM} = \frac{(T_e - T_{Ce}) - (T_0 - T_{Ce})}{\ln\left[(T_e - T_{co})/(T_0 - T_{Ce})\right]} \tag{CS1.40}$$

where T_0 and T_e are the inlet and outlet temperatures of the reaction mixture (process fluid), respectively. Assuming the shell side to be isothermal, $T_0 = T_e = 50°C$, $(\Delta T)_{LM} = 32°C$:

$$A_H = \frac{Q_H}{U\Delta T_{LM}} \tag{CS1.41}$$

The required heat transfer area is then calculated as

$$A_H = 734.7 \text{ m}^2$$

Actual available area (A_A) of the shell-and-tube exchanger = $A_A = N_T \pi D L_T = 717.4 \text{ m}^2$.

$A_A/A_H = 0.97$. Since the value of A_A/A_H is different from 1, the number of tubes needs to be changed and the whole procedure repeated to finally obtain a value of 1. The final solution is: number of tubes = 23, shell I.D. = 1.34 m, tube length = 63.7 m. The details of this reactor are given in Table CS1.3.

Cost Evaluation

Annual operating cost:
For case 1 in Table CS1.3,

Power (shell side + tube side) = 0.238 + 0.045 = 0.283 W

Annual electric energy required = (0.283 W/1000) × (8000 hr/year) = 2.3 kWh

Annual operating cost = 2.3 kWh × 0.03 $/kWh = $0.07

To estimate the fixed cost, let us calculate shell and tube weights.

Shell thickness:

$$\begin{aligned} t_S &= PD_S/2f_P\eta \\ &= (0.5\times10^6)\times1.34/[2\times(8.5\times10^7)\times0.9] = 0.0045 \text{ m} \sim 4.5 \text{ mm} \end{aligned} \tag{CS1.42}$$

In addition, we need a corrosion allowance, say 3 mm. Thickness $t_S = 0.0075$ m.

Weight of the material of construction required is

$$\begin{aligned} W_S &= \pi D_S L_T t_S \rho_S \\ &= 3.142\times1.34\times63.7\times0.0075\times8000 = 15{,}784 \text{ kg} \end{aligned} \tag{CS1.43}$$

$$\begin{aligned} \text{Weight of tubes} &= N_T \pi D L_T t_T \rho_S \\ &= 40819 \text{ kg} \end{aligned} \tag{CS1.44}$$

[a] LMTD = log mean temperature difference.

For simplicity, we consider only the cost of the shell and tubes. In reality, however, one has to consider the tube sheets, head, nozzles, baffles, and cost of fabrication.

$$\text{Cost of reactor} = \text{Total weight} \times \text{unit cost of material}$$

$$= (15784 + 40819)\ \text{kg} \times 0.4\$/\text{kg} = 56603 \times 0.4 = \$22641$$

$$\text{Fixed cost} = \$22641$$

Considering 20% of the fixed cost in the annualized cost,

$$\text{Total annualized cost} = \text{Operating cost} + 20\%\ \text{of fixed cost}$$

$$= 0.07 + 0.2 \times 22641 = \$4773$$

In Table CS1.3, various options are given with respect to the coolant outlet temperature. For a lower outlet temperature of the coolant, the following occur: higher coolant flow rate and an increase in the operating, and hence the total, annualized cost. Also, the use of 0.204 m I.D. tubes (case 4, Table CS1.3) instead of 0.154 m I.D. tubes leads to lower fixed cost and hence lower total annualized cost ($4199).

Reactant on the Shell Side

When the reactant is on the shell side, the volume of the reactor is approximately

$$V = (\text{Volume of empty shell}) - (\text{Volume of tubes}) \tag{CS1.45}$$

when we neglect the volume of baffles, spacer rods, and so forth. In this case, the design steps to be followed are as follows. (1) Assume diameter D, number of tubes N_T, and tube thickness. (2) Based on triangular (or square) pitch, calculate the shell diameter D_S. (3) From a knowledge of the shell cross-sectional area and tube cross-sectional area, calculate the length of the reactor for the desired volume. (4) Assume coolant inlet and outlet temperatures. (5) Calculate the coolant flow rate for the desired heat duty. (6) Calculate the tube-side pressure drop and heat transfer coefficient. (7) Assume baffle spacing and calculate the shell-side pressure drop and heat transfer coefficient. (8) Calculate the overall heat transfer coefficient and log mean temperature difference. (9) Calculate the heat transfer area required and compare it with the area available. (10) Vary N_T or D. Repeat steps 1 to 9 until $A_A/A_H = 1$. (11) Cost evaluation: since most steps are described in the previous case (reactant on the tube side), one case is presented briefly below (refer to case 10 in Table CS1.3).

1. Assume 43 tubes with I.D. = 0.154 m, O.D. = 0.168 m, $N_T = 43$, $D = 0.154$ m, $D_0 = 0.168$ m, pitch = $1.33 \times D_0 = 0.223$ m.
2. By following a procedure similar to that given in the previous case for reactant on the tube side, the shell diameter (D_S) works out to be 1.7 m.
3. Since the reactor volume is the difference between the empty shell volume and the volume of the tubes based on O.D., the reactor length is obtained as

$$L_T = \frac{V}{\frac{\pi}{4}\left(D_s^2 - N_T D_O^2\right)} \tag{CS1.46}$$

$$= 20.76\ \text{m}$$

4. Assume chilled water (coolant) inlet temperature T_{C0} = 7°C and outlet temperature T_{Ce} = 25°C.
5. Mass flow rate of the chilled water required is $M_C = Q_H/\{C_{PC}(T_{Ce} - T_{C0})\}$ = 29.1 kg/s.
6. Tube-side pressure drop and heat transfer coefficient:

   Re_T = 5662, pressure drop = 3.4 N/m², heat transfer coefficient h_T = 213 W/m² K

7. Shell-side pressure drop and heat transfer coefficient: Since the reactant is on the shell side, assume low baffle spacing so that the flow may be assumed to be plug.
   Assume baffle spacing of $0.2 \times D_S$ = 0.34 m
   Shell-side pressure drop = 11 N/m²
   Heat transfer coefficient h_S = 525 W/m² K
8. Overall heat transfer coefficient and log mean temperature difference:
   For simplicity, considering only the shell- and tube-side resistances (neglecting the dirt factor),

   $$U = 148 \text{ W/m}^2\text{ K}$$

   Log mean temperature difference is given by Equation (CS1.40), where T_0 and T_e are the inlet and outlet temperatures of the reaction mixture (process fluid), respectively. Assuming the tube side to be isothermal, $T_0 = T_e$ = 50°C, $(\Delta T)_{LM}$ = 32.77°C.

   $$A_H = \frac{Q_H}{U\Delta T_{LM}} = 427.27 \text{ m}^2$$

9. Required heat transfer area is calculated from the actual area available A_A of the shell-and-tube exchanger as $A_A = N_T \pi D L_T$ = 427 m².
10. A_A/A_H = 0.999 ~ 1. This is a good match. If the value of A_A/A_H was found to be very different from 1, then the number and/or diameter of tubes would need to be varied and the whole procedure repeated to finally obtain a value of 1.
11. Annual operating cost:
    Shell-side power required = $Q \times \Delta P_S = 0.01 \times 11 = 0.11$ W
    Tube-side power required = $Q_C \times \Delta P_T = 0.029 \times 3.4 = 0.1$ W
    Power (shell side + tube side) = 0.21 W
    Annual electric energy required = (0.21 W/1000) × (8000 hr/year) = 1.68 kWh
    Annual operating cost = 1.68 kWh × 0.03 $/kWh = $0.05

Fixed cost of reactor:

Shell thickness, $t_S = PD_S/2f_P\eta = (0.5 \times 10^6) \times 1.7/[2 \times (8.5 \times 10^7) \times 0.9]$ = 0 .0056 m ~ 5.6 mm.
In addition, since we need to have some corrosion allowance, say 3 mm, thickness t_S = 0.0086 m.
Weight of the material of construction required = $\pi D_S L_T t_S \rho_S$ = 7698 kg.
Weight of tubes = $N_T \pi D L_T t_T \rho_S$ = 24409 kg. For simplicity, we consider only the cost of the shell and tubes. In reality, however, one also has to consider the tube sheets, head, nozzles, baffles, and cost of fabrication.

Cost of reactor = Total weight × unit cost of material = (7698 + 24409) kg × 0.4$/kg = $12842.

Fixed cost = $12842.

Total annualized cost = operating cost + 20% of fixed cost = 0.05 + 0.2 × 12842 = \$2568.6.

For the case of reactant on the shell side, it can be seen from a comparison of cases 7 to 12 of Table CS1.3 that use of tubes of 0.204 m I.D. and coolant outlet temperature of 20°C gives the lowest annualized cost (\$2398). Hence, it is the optimum configuration. Also, Table CS1.3 shows that having the reactant on the shell side gives a lower annualized cost.

Lesson

The superiority of the plug-flow reactor over other reactors for many reactions is often taught in undergraduate CRE courses. The importance of this simple fact is quantitatively illustrated, but it is later shown that such a straightforward (known) result is not directly useful in practice. Although plug-flow behavior gives minimum volume, it is important to establish the critical length-to-diameter ratio to obtain plug-flow conditions. The selection of L/D ratio also depends on the operating cost (which is related to pressure drop) and the fixed cost. It is also shown that plug-flow behavior is advantageously reached by using a coil reactor, which also saves floor space. Since the reaction is generally accompanied by large heat effects, various geometrical alternatives and their cost implications must be considered.

Case Study 11.2 Homogeneous Gas-Phase Complex Reaction: Oxidation of NO Using Ozone

The Problem

Flue gases from thermal power plants and industrial boilers are a major source of pollution. The polluting components are mainly nitric oxide, NO, and sulfur dioxide, SO_2. The solubility of NO in water is limited, but it can be oxidized to N_2O_5 using ozone. N_2O_5 readily reacts with water to form nitric acid. In the present problem, only the oxidation step is considered.

Fu et al. (2000) have reported rate constants for the following reaction scheme:

$$NO + O_3 \rightarrow NO_2 + O_2 \qquad \text{(CS2.R1)}$$

$$2\,NO_2 + O_3 \rightarrow N_2O_5 + O_2 \qquad \text{(CS2.R2)}$$

$$2\,O_3 \rightarrow 3O_2 \qquad \text{(CS2.R3)}$$

$$SO_2 + O_3 \rightarrow SO_3 + O_2 \qquad \text{(CS2.R4)}$$

$$CO + O_3 \rightarrow CO_2 + O_2 \qquad \text{(CS2.R5)}$$

$$NO + 1/2\,O_2 \rightarrow NO_2 \qquad \text{(CS2.R6)}$$

$$N_2O_5 + H_2O \rightarrow 2HNO_3 \qquad \text{(CS2.R7)}$$

$$SO_2 + N_2O_5 \rightarrow SO_3 + 2NO_2 \qquad \text{(CS2.R8)}$$

As a typical case, the mass flow rate of the gas from a power plant is 2,543,629 kg/h, inlet temperature is 50°C, and pressure is 1.1×10^5 N/m^2. A pipeline reactor is to be designed to give a conversion of total NO_X to N_2O_5 of 99%. The gas composition at the inlet to the reactor (flue gas

+ ozone) is as follows: NO- 389 ppm, NO_2– 39 ppm, HNO_2– 6 ppm, N_2O_5– 0 ppm, HNO_3– 1 ppm, O_3– 663 ppm, O_2– 6.5297 mol%, SO_2– 1944 ppm, CO– 0 ppm, CO_2– 11.9815 mol%, SO_3– 0 ppm, CO– 0 ppm, HNO_3– 1 ppm, O_3– 663 ppm, H_2O– 6.9974 mol%, N_2– rest. The theoretical requirement has been estimated on the basis of NO and NO_2 conversion.

Solution

The following assumptions are made: (1) Ozone and flue gas are thoroughly mixed in a short distance using a proper distributor. (2) Gas moves in plug flow. (3) Gas follows ideal gas law. (4) There are no radial gradients of temperature, concentration, and density. (5) The reactor is operating at steady state.

Component balances across a differential length can be established for O_3, O_2, NO, NO_2, N_2O_5, HNO_3, H_2O, SO_2, CO, and SO_3, and ten first-order ordinary differential equations are written. For the solution of this set of simultaneous differential equations, the Runge–Kutta fourth-order method was employed. The integration along the volume of the reactor was performed using the feed composition as the inlet boundary condition. The outlet boundary condition was specified to be 99% conversion of the total inlet NO_x to N_2O_5.

The level of ozone affects the reactor volume. The rate of ozonation of NO being fast, NO is consumed almost instantaneously, forming NO_2. NO_2 concentration decreases due to the formation of N_2O_5. The residence time required for 99% conversion is 7.4 s. The effect of percentage excess of ozone on reactor performance for 99% conversion of total inlet NO_X (NO and NO_2) can be easily calculated.

Lesson

The abatement of NO_x pollution is an important environmental problem that has alternative technologies. This case study focuses on technology that won the McGraw-Hill 2001 Kirkpatrick Award. The main reaction involves the ozonation of NO_X to give N_2O_5, followed by absorption in water/$Ca(OH)_2$. While Case Study 11.1 illustrates a detailed procedure for determining the geometric specifications for a simple reaction, the present study outlines a design methodology for a complex system and tells us that such a study is not only relevant but almost inescapable. Because this case study pertains to the treatment of exhaust gases, it demands very low pressure drops, even at high volumetric gas flow rates. Although not considered in this case study, the injection methodology of ozone in flue gases using a distributor should be such that the length required for mixing of ozone (in flue gases) is negligible compared to the length of the reactor.

Case Study 11.3 Gas-Solid (Catalytic) Reaction: Modeling of a Complex Reaction on a Deactivating Catalyst (a Model Scheme)

Nomenclature for Case Study 11.3

(Some symbols are defined in the text; some are self-evident statistical terms.)

A_1, A_2, A_3	chemical species
f_1, f_2, f_3, f_4	functions
h	proportionality constant defined by Equation (CS3.13)
$\boldsymbol{I}_r$	$(r \times r)$ identity matrix
$\boldsymbol{K}, \boldsymbol{K}_1, \boldsymbol{K}_3$	vectors of rate constants, equilibrium constants, etc.
m	total number of models
n	total number of experiments at any stage
P	fouling complex
$P_{n+1,v}$	posterior probability of the vth model
$P_{n,v}$	prior probability of the vth model
p	total number of parameters

r	total number of responses
$\underline{r}, \underline{r}_1, \underline{r}_2$	reaction rates defined by Equations (CS3.1), (CS3.5), and (CS3.6)
S	multiresponse sum of squares function defined by Equation (CS3.7) a determinant
s	total number of independent variables
s^{11}, s^{12}, s^{22}	elements of the determinant S
t	on-stream line
$\boldsymbol{U}$	utility function defined by Equation (CS3.17)
$\boldsymbol{V}$	$(r \times r)$ precision matrix of responses
$\mathbf{X}_v^i$	$(n \times p)$ matrix of partial derivatives of the ith response in vth model
$\boldsymbol{x}$	vector of independent variables
$\boldsymbol{x_k}$	an $(s \times 1)$ vector of the kth experimental setting or kth design vector
y_k^i	observed value of the ith response in the kth experiment
$\boldsymbol{y}_k$	vector of observation in the kth experiment
$\boldsymbol{Z_{n+1,v}}$	$r \times p$ matrix of partial derivatives, where components are defined by Equation (CS3.1)
$z_{k,u,\ell}^i$	partial derivative of the ith response with respect to the ith parameter in the uth model using the kth experiment
z_{n+1}^i	partial derivative of $\eta_{n+1,v}^i$ with respect to th parameter evaluated after nth experiment

Greek

$\alpha^{i,j}$	(i, j)th component of $\boldsymbol{V}^{-1}$
ε_k^i	error in the ith response in the kth experiment
ε_k	$\gamma \times 1$ vector of experimental errors for kth experiments
η_k^i	true value of the ith response using the kth experimental settings $\boldsymbol{x}_k$
η_k	$r \times 1$ vector of true responses in kth experiment
$\hat{\eta}_{n+1,v}$	$r \times 1$ vector of calculated responses using vth model after n experiments using current best estimates of parameters
$\phi_{n+1,u}$	$(r \times r)$ precision matrix of the uth model after the $(n + 1)$th experiment
Ω	catalyst activity

As shown in Section 11.1.2.2, hyperbolic (LHHW) models are usually the most appropriate for reactions occurring on solid catalysts. These are nonlinear models whose parameters can be determined using statistical methods. Several examples are available.

An equally important system of reactions is one where the catalyst becomes deactivated either intrinsically or through deposition of carbonaceous products. The modeling of such systems becomes involved where deactivation has to be coupled with LHHW kinetics. Another complicated situation can arise where the reaction occurring on the deactivating catalyst is complex but each step can be represented by power law kinetics. In the present case study, we consider such a reaction to illustrate the application of rigorous statistical methods to complex reacting systems.*

The Problem

Tetrachloroethane chlorinates as follows using activated silica gel as catalyst (by-product HCl is not shown):

$$\underset{(A_1)}{C_2H_2Cl_4} \xrightarrow[\text{cat}]{Cl_2} \underset{(A_2)}{C_2HCl_5} \xrightarrow[\text{cat}]{Cl_2} \underset{(A_3)}{C_2Cl_6} \qquad \text{CS3.R1}$$

The catalyst deactivates with time. The rate of deactivation and level of activity depend on the variety of silica gel used. Basic kinetic data for this reaction were obtained by Prasad and

* Basic knowledge of statistics is assumed in describing this case study.

Doraiswamy (1974) on a particular variety of silica gel in a fixed-bed reactor. The role of catalyst deactivation was studied by obtaining kinetic data at various times. Fortunately, by-products were negligible. This case study describes the reaction-deactivation kinetics and proposes a complete model using appropriate statistical methods. The emphasis will be on the use of a suitable algorithm for sequential updating of the models until one of them emerges as the "best."

Procedure

For model discrimination to be accomplished sequentially, leading to the selection of the "best" model, the following data/techniques are essential:

1. Experimental rate data in a suitable form.
2. A set of plausible models containing the true model.
3. An efficient method of parameter estimation.
4. A good sequential design strategy.
5. A powerful discriminatory criterion.

Experimental Data

For the reaction under consideration, values of the reaction rate as a function of concentration and catalyst decay time may be obtained by numerical differentiation of the experimental data obtained by Prasad and Doraiswamy (1974) at various space velocities and catalyst decay times in a fixed-bed reactor. The bed length was maintained small enough to give isothermal conditions to within 2°C. It was also ensured that the feed velocity was high enough, and the particle size small enough, to eliminate external and internal diffusion effects, respectively. The kinetic parameters, including decay time, will vary with the type of silica gel used. The data obtained for the silica gel used are summarized in Table CS3.1.

Models

Vapor-phase catalytic chlorination of A_1 on activated silica gel at 200°C is accompanied by slow deactivation of the catalyst. A_1 is successively chlorinated to A_2 and A_3. Trace quantities of by-

products formed (trichloroethylene and tetrachloroethylene) may be neglected. The following assumptions are made:

1. Both the reaction steps in the above scheme are first order.
2. The catalyst activity decreases uniformly for both reaction steps.
3. The fouling product is the result of an unwanted side reaction involving reactants or products.
4. The catalyst decay is slower than the reaction rate by several orders of magnitude.

The last mentioned assumption allows the use of separable kinetics. Thus the reaction rate model in a deactivating system may be written as two simultaneous equations:

$$\underline{r} = f_1[\mathbf{x},\mathbf{K}]f_2[\Omega] \tag{CS3.1}$$

$$\frac{d\Omega}{dt} = f_3[\mathbf{x},\mathbf{K}]f_4[\Omega] \tag{CS3.2}$$

where $\underline{r}$ is the rate of reaction; f_1, f_2, f_3, and f_4 are some functions depending on the system; $\mathbf{x}$ is the vector of controlled variables such as concentrations of species, temperature, and so on; $\mathbf{K}$ is the vector of rate constants, equilibrium constants, reaction orders, and so forth; t is the catalyst decay time; and Ω is the activity of the catalyst defined as

$$\Omega = \frac{\underline{r}|t = t}{\underline{r}|t = 0} \tag{CS3.3}$$

If assumption 4 is valid, Equation (CS3.2) may be independently solved and substituted in Equation (CS3.1).

For the reaction under consideration, several combinations of series and parallel fouling schemes may be chosen, involving either one or more of A_1, A_2, A_3 or one or more of $A_1 + A_2$, $A_2 + A_3$, $A_3 + A_1$, or $A_1 + A_2 + A_3$. The different forms of the function f_3 in Equation (CS3.2) resulting from these fouling reactions are summarized in Table CS3.2. Furthermore, f_2 and f_4 are assumed to be given by

$$f_2[\Omega] = f_4[\Omega] = \Omega \tag{CS3.4}$$

f_1 consists of two functions for the present system in which observations are made on two independent responses, namely, rate of disappearance of A_1 and rate of formation of A_2. Thus,

$$\underline{r}_1 = -\mathbf{K}_1 y_1 \Omega \tag{CS3.5}$$

$$\underline{r}_2 = [\mathbf{K}_1 y_1 - \mathbf{K}_2 y_2]\Omega \tag{CS3.6}$$

Using different forms for f_3, Equation (CS3.2) may be solved and substituted in Equations (CS3.5) and (CS3.6) to yield expressions for different models. These are included in Table CS3.2.

Method of Parameter Estimation

The method of parameter estimation depends on the models involved. All models listed in Table CS3.2 are nonlinear and algebraic. One might employ the Gauss–Newton method of nonlinear least

TABLE CS3.2
The Rival Models

Model No.	Fouling Reactions	Expressions for f_3 in Equation (CS3.2)	Model Equations for	
			$\underline{r}_1$	$\underline{r}_2$
1.	$A_1 \rightarrow P$	$-\mathbf{K}_3 y_1$	$-\mathbf{K}_1\, y_1\, \exp[-\mathbf{K}_3\, y_1\, t]$	$[\mathbf{K}_1\, y_1 - \mathbf{K}_2\, y_2]\, \exp[-\mathbf{K}_3\, y_1\, t]$

10.	$A_2 \rightarrow P$ $A_3 \rightarrow P$	$-\mathbf{K}_3[1 - y_1]$	$-\mathbf{K}_1\, y_1\, \exp[-\mathbf{K}_3(1 - y_1)\, t]$	$[\mathbf{K}_1\, y_1 - \mathbf{K}_2\, y_2]\, \exp[-\mathbf{K}_3(1 - y_1) t]$
11.	$A_1 \rightarrow P$ $A_2 \rightarrow P$ $A_3 \rightarrow P$	$-\mathbf{K}_3[y_1 + y_2 + (1 - y_1 - y_2)]$ $= -\mathbf{K}_3$	$-\mathbf{K}_1\, y_1\, \exp[-\mathbf{K}_3 t]$	$[\mathbf{K}_1\, y_1 - \mathbf{K}_2\, y_2]\, \exp[-\mathbf{K}_3 t]$

Main reaction is $A_1 \rightarrow A_2 \rightarrow A_3$

squares but, for the present two-response system, the resulting equations are quite involved. Hence, the following least squares objective function may be minimized using the "complex" method of Box (1965):

$$S = \det \begin{bmatrix} s^{11} s^{12} \\ \\ s^{12} s^{22} \end{bmatrix} \tag{CS3.7}$$

where s^{ij} is the sum of cross products of residuals of the ith and jth responses.

A Good Sequential Design Strategy

Basic Equations

Any experimental program involving r dependent and s independent variables and p parameters in the kth experiment may be described by algebraic equations,

$$y_k^i = \eta_k^i\left(\mathbf{x}_k, \mathbf{K}\right) + \varepsilon_k^i, \qquad i = 1, 2, \ldots r \tag{CS3.8}$$

where $\mathbf{x}_k$ is an $(s \times 1)$ vector of independent variables for the kth experiment, is a $(p \times 1)$ vector of model parameters, η_k^i is the true value of the ith response for the kth experimental settings $\mathbf{X}_k$, y_k^i is the observed value of the ith response, and ε_k^i is the experimental error for the ith response, also for the kth experiment. The uth model for all the responses may be written in vector form as

$$\mathbf{y}_k = \eta_k(\mathbf{x}_k, \mathbf{K}) + \varepsilon_k^i \tag{CS3.9}$$

If the ith component of the (r × 1) vector of nonlinear functions η_k is expanded in Taylor's series about an estimate $\hat{\mathbf{K}}_u$ of the parameters and truncated after the first partial derivatives, Equation (CS3.8) may be written for the $(n + 1)$th experiment as

$$\varepsilon_{n+1}^{i} = y_{n+1}^{i} - \eta_{n+1,u}^{i}\left(\mathbf{x}_{n+1}, \mathbf{K}\right)$$

$$= y_{n+1}^{i} - \hat{\eta}_{n+1,u}^{i}\left(\mathbf{x}_{n+1}, \hat{\mathbf{K}}_{u}\right) - \sum_{\ell=1}^{p} z_{n+1,u,\ell}^{i}\left(K_{\ell} - \hat{K}_{\ell u}\right) \quad \text{(CS3.10)}$$

$$i = 1 \ldots r$$

where $\hat{K}_{\ell u}$ is the lth parameter in the $(p \times 1)$ vector of parameters for the uth model estimated using the first n experiments, and $z_{n+1,u,\ell}^{i}$ is given by

$$z_{n+1,u,l}^{i} = \delta\eta_{n+1,u}^{i}\left(\mathbf{x}_{n+1}, \mathbf{K}\right) / \delta K_{l} \Big| \mathbf{K} = \hat{\mathbf{K}}_{u}$$

$$i = 1, \ldots r \quad \text{(CS3.11)}$$

$$u = 1, \ldots m$$

Bayesian Discrimination

Since competing models exist, Bayes' theorem provides a sound statistical method of discriminating between them. This theorem defines the posterior probability of the uth model after $(n + 1)$ experiment as the product of the prior probability and the likelihood

$$P_{n+1,u} = P_{n,u} L_{n+1,u}\left(\mathbf{K}_{u} \mid \phi_{n+1,u}, \mathbf{y}_{n+1}\right) / h \quad \text{(CS3.12)}$$

where $P_{n+1,u}$ is the posterior probability of the uth model after y_{n+1} data have been collected; $P_{n,u}$ is the prior probability, i.e., the probability before performing the $(n + 1)$th experiment; $\phi_{n+1,u}$ is the $(r \times r)$ precision matrix for the predictions made by the uth model after $(n + 1)$ experiments; $L_{n+1,u}$ $(\mathbf{K}_{u}|\phi_{n+1,u},\mathbf{y}_{n+1})$ is the likelihood of the uth model after data $\mathbf{y}_{n+1}$ are obtained; and h is the proportionality constant given by

$$h = \sum_{v=1}^{m} P_{n,v} L_{n+1,v}\left(\mathbf{K}_{V} \mid \phi_{n+1,v}, \mathbf{y}_{n+1}\right) \quad \text{(CS3.13)}$$

For a system of r responses, the likelihood is given by (Hill, 1966)

$$L_{n+1,v}\left(\mathbf{K}_{V} \mid \boldsymbol{\phi}_{n+1,v}, \mathbf{y}_{n+1}\right) = \frac{\left|\boldsymbol{\phi}_{n+1,v}\right|^{-1/2}}{\left(2\pi\right)^{r/2}} \times$$
$$\exp\left[-\frac{1}{2}\left(\mathbf{y}_{n+1} - \hat{\boldsymbol{\eta}}_{n+1,v}\right)^{T} \boldsymbol{\phi}_{n+1,v}^{-1}\left(\mathbf{y}_{n+1} - \hat{\boldsymbol{\eta}}_{n+1,v}\right)\right] \quad \text{(CS3.14)}$$

where $\hat{\boldsymbol{\eta}}_{n+1,v}$ $(r \times 1)$ is the vector of responses for the $(n + 1)$th experiment predicted using the vth model and the previous best estimates of parameters. The precision matrix $\boldsymbol{\phi}_{n+1,v}$ is found from

$$\boldsymbol{\phi}_{n+1,v} = \mathbf{V} + \mathbf{Z}_{n+1,v}\mathbf{M}_{v}^{-1}\mathbf{Z}_{n+1,v}^{T}, \quad v = 1, 2, \ldots m \quad \text{(CS3.15)}$$

where $\mathbf{Z}_{n+1,v}$ is the $(r \times p)$ matrix of partial derivatives whose (i,ℓ)th element is given by Equation (CS3.11), $\mathbf{M}_v^{-1}$ is the $(p \times p)$ precision matrix of parameters of the vth model, and $\mathbf{V}$ is the precision matrix. $\mathbf{M}_v$ is given by

$$\mathbf{M}_v = \sum_{i=1}^{r}\sum_{j=1}^{r} \alpha^{ij} \mathbf{X}_v^{i^T} \mathbf{X}_v^{j}, \quad v = 1,2,\ldots m \tag{CS3.16}$$

where α^{ij} is the (i, j)th component of $\mathbf{V}^{-1}$ and $\mathbf{X}_v^i$ is the $(n \times p)$ matrix of partial derivatives of the ith response for the vth model whose (k,ℓ)th element is obtained from Equation (CS3.11) by replacing subscript $(n + 1)$ with k. Since Equation (CS3.12) is basic to the Bayesian procedure, the probabilities of all the models are sequentially updated by collecting additional data until one model emerges with the highest probability.

A Powerful Discriminatory Criterion

Often, no single model emerges as the most probable. In such a case, the next experiment should be performed at a setting of independent variables that maximizes the divergence between competing candidates. This is done by using a discriminatory design criterion, which is some suitably defined function of the vector of independent variables $\mathbf{x}_k$, called the *utility function* $U(\mathbf{x}_k)$. Several criteria have been proposed (Reilly and Blau, 1974). The Box–Hill (1967) criterion is perhaps the most commonly used and is given by

$$U(\mathbf{x}_k) = \frac{1}{2}\sum_{u=1}^{m}\sum_{v=u+1}^{m} P_{n,u}P_{n,v}\Big[Tr\big(\boldsymbol{\phi}_u\boldsymbol{\phi}_v^{-1} + \boldsymbol{\phi}_v\boldsymbol{\phi}_u^{-1} - 2I_r\big) + (\boldsymbol{\eta}_u - \boldsymbol{\eta}_v)^T\big(\boldsymbol{\phi}_u^{-1} + \boldsymbol{\phi}_v^{-1}\big)(\boldsymbol{\eta}_u - \boldsymbol{\eta}_v)\Big] \tag{CS3.17}$$

where $U(\mathbf{x}_k)$ is the utility function for the kth set of independent variables $\mathbf{x}_k$, $P_{n,u}$ is the posterior probability of the uth model after n experiments, $\boldsymbol{\phi}_u$ is the $(r \times r)$ precision matrix for the predictions made by the uth model after n experiments, and $\boldsymbol{\eta}_u$ is the $q \times 1$ vector of predicted responses for the uth model using the kth set of independent variables $\mathbf{x}_k$. This criterion weighs the divergences over the inverse of the precision matrix so that large divergences due to imprecisely known parameters do not contribute significantly to the utility function. The object is to find the ${}^{\max}_{k}U(\mathbf{x}_k)$ that determines the next best experiment to be performed to maximize divergence between rival models. Hence, several new sets of $\mathbf{x}_k$ can be randomly generated to evaluate U_{max}.

A Sequential Discrimination Algorithm

A computational algorithm for sequential discrimination among rival models is presented in Figure CS3.1.

Choice of Model for the Present System (see Prasad and Rao, 1977)

The eleven models given in Table CS3.2 can be compared taking an initial probability of 1/11 or 0.0909 for each and with an initial set of six experiments taken at random from Table CS3.1. Ten sequential experiments (total of 16 experiments) were performed (Table CS3.3), at the end of which one of the models (model 9) attained a probability of 0.912, compared to 0.088 for the nearest rival (model 1). The probabilities of the other models are negligibly small, even after the first discriminatory experiment.

The computations show that the given system represents an example of series-parallel deactivation:

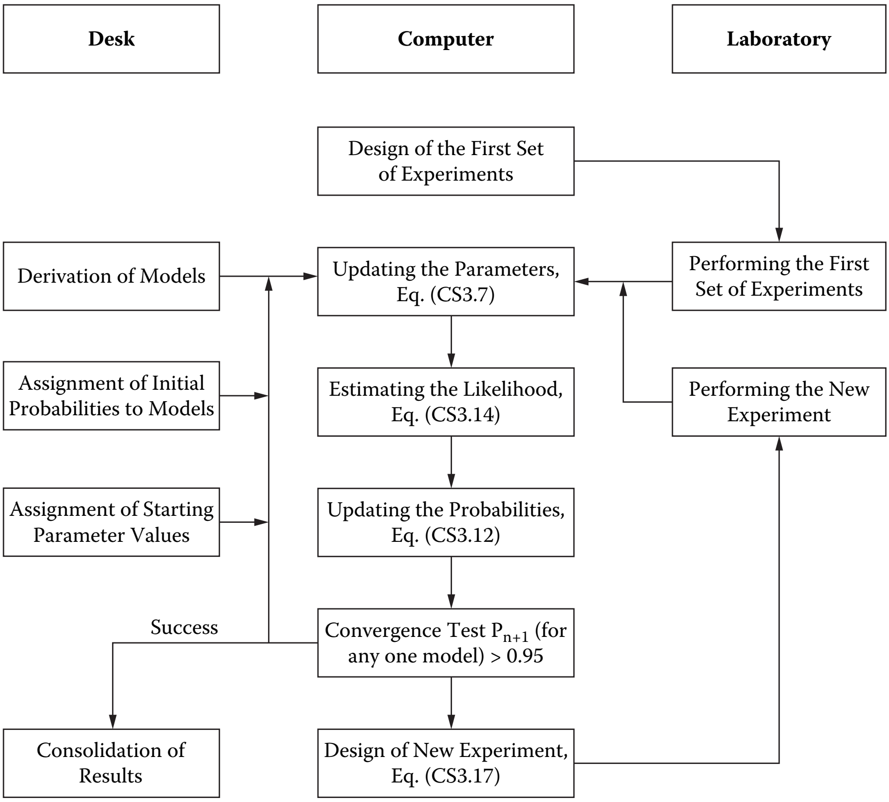

FIGURE CS3.1 A computational algorithm for sequential discrimination among rival models.

TABLE CS3.3
Posterior Probabilities of Models Using the Box-Hill Criterion

Discrimination Stage	Total Number of Experiments	Posterior Model Probability[a]	
		P_9	P_1
1	7	0.502	0.483
2	8	0.513	0.487
3	9	0.623	0.377
4	10	0.656	0.344
5	11	0.730	0.270
6	12	0.794	0.206
7	13	0.833	0.167
8	14	0.849	0.151
9	15	0.902	0.098
10	16	0.912	0.088

Computation stopped

[a] The posterior probabilities of the remaining models are negligibly small. Hence they are not reported here.

$$A_1 \to A_2 \to A_3 \qquad \text{CS3.R2}$$

$$A_1 \to P \qquad \text{CS3.R3}$$

$$A_3 \to P \qquad \text{CS3.R4}$$

with the rate equations

$$\underline{r}_1 = -\mathbf{K}_1 y_1 \exp\left[-\mathbf{K}_3\left(1-y_2\right)t\right] \qquad \text{(CS3.18)}$$

$$\underline{r}_2 = \left(\mathbf{K}_1 y_1 - \mathbf{K}_2 y_2\right)\exp\left[-\mathbf{K}_3\left(1-y_2\right)t\right] \qquad \text{(CS3.19)}$$

where y_1, y_2 are the mole fractions of A_1 and A_2 in the product mixture. The values of the parameters $\mathbf{K}_1$, $\mathbf{K}_2$, and $\mathbf{K}_3$ are

$$\mathbf{K}_1 = 0.933 \text{ h}^{-1}$$

$$\mathbf{K}_2 = 0.136 \text{ h}^{-1}$$

$$\mathbf{K}_3 = 0.549 \text{ h}^{-1}$$

Lesson

This case study describes a statistical method for modeling a complex reaction. A model reaction occurring on a deactivating catalyst, in which the fouling reactions generate the complexity, is chosen for illustration, but the procedure is equally applicable to any complex reaction scheme with or without fouling, catalytic or noncatalytic. While a great reliance on statistics is not always needed, this study tells us that the statistical method can identify the controlling step. On the other hand, it does not consider the possibility that the true rate-determining mechanism may have been omitted from the list of candidates. Thus, any statistical procedure of this kind, so common in chemical engineering, is no more than one of convergence to the "best" and not a direct postulation of a model from first principles and validated by experiments.

When this procedure is applied to LHHW models, caution should be exercised in claiming a model to be the "best." The need for this increases with the number of unknown parameters, since several models may then show almost equal convergence. In general, it is advisable to confine the methods to models with no more than three or four unknown parameters. Furthermore, it should be ensured that all data points are of equal precision.

Case Study 11.4 Gas-Solid (Catalytic) Reaction in Fixed-Bed NINA and Adiabatic Reactors: Reduction of Nitrobenzene to Aniline

Nomenclature for Case Study 11.4

A	nitrobenzene
$[A]$	concentration of A (kmol/m^3)
B	hydrogen
$[B]$	concentration of B (kmol/m^3)
C_P	heat capacity [kcal/kg (reactant gases)°C]
C_{pm}	molar heat capacity (kcal/kg °C)

$\boldsymbol{D}_{A,er}$	effective radial diffusivity of A (m^2/s)
d	diameter (m)
E	activation energy for reaction (kcal/mol)
E_{ad}	activation energy for adsorption (kcal/mol)
F	flow rate of A (kmol/s)
$-\Delta H_r$	heat of reaction (kcal/mol)
h	heat transfer coefficient (kcal/m^2 °C s)
K_B	adsorption constant of B (m^3/mol)
K^o_B	Arrhenius constant for K_B (m^3/mol)
$k_{T,er}$	effective radial thermal conductivity (kcal/m °C s)
k_w	reaction rate constant (kmol/g cat s)
k^o_w	Arrhenius constant (m^3/g cat s)
R_g	gas law constant (kcal/mol K)
r	radial coordinate (m)
$-r_A$	rate of disappearance of A (kmol/m^3 s)
$-r_{wA}$	rate of disappearance of A (kmol/kg cat s)
S	cross-sectional area (m^2)
T	temperature (°C or K)
u	velocity (m/s)
W	weight of catalyst (kg)
x_A	conversion of A (–)
y_A	mole fraction (–)

w	wall; weight based
0	initial (entrance)

NINA Reactor

Aniline is produced by the catalytic reduction (with hydrogen) of nitrobenzene in a fixed-bed reactor according to the reaction

$$C_6H_5NO_2(A) + 3H_2(B) \rightarrow C_6H_5NH_2 + 2H_2O \qquad \text{CS4.R1}$$

The rate equation is given by

$$-r_{wA} = \frac{k_w[A]}{\left(1 + K_B[B]^2\right)}, \text{mol/g cat s} \qquad \text{(CS4.1)}$$

where

$$k_w = k_w^o \exp\left(-\frac{E}{R_g T}\right), \text{ cm}^3/\text{g cat s} \tag{CS4.2}$$

$$K_B = K_B^o \exp\left(\frac{E_{ad}}{R_g T}\right), \text{ cm}^3/\text{mol} \tag{CS4.3}$$

Assuming a pseudohomogeneous two-dimensional reactor model with plug flow of fluid and constant properties, calculate the axial concentration and temperature profiles at several radial positions along the axis of a single tube. Use the following property/parameter values (Doraiswamy, 2001):

$[A]_0 = 7.1 \times 10^{-4}$ mol/L, $(-\Delta H_r) = 180$ kcal/mol, $\rho_s = 2.18$ g/cm^3, $\varepsilon_B = 0.312$, $C_p = 0.49$ cal/g (reactant gases) °C at 200°C, $k_{T,er} = 1.4$ cal/m °C s, $h_w = 9.5 \times 10^{-4}$ cal/cm^2 °C s, $\mathbf{D}_{A,er} = 4.74 \times 10^{-4}$ cm^2/s, $\rho = 0.0944$ g/L, $u = 40$ cm/s, $k^\circ{}_w = 9.46 \times 10^{-3}$ L/g catalyst s, $E = 2631$ cal/mol, $K^\circ{}_B = 10.7$ cm^3/mol, $E_{ad} = 8039$ cal/mol. $T_0 = 160$°C, $T_w = 100$°C.

Solution

Before proceeding with the solution, it is instructive to list the governing equations for a number of simple and complex situations. These situations have already been described in Section 11.4, and Table 12.2 of Doraiswamy and Sharma (1984) lists the more important equations. Case A2-a of this table is the so-called basic model that incorporates enough complexity to make the design sufficiently realistic and yet is relatively easy. The homogeneous nonisothermal nonadiabatic (NINA) model allows one to compute temperature and concentration profiles within the reactor tube. The equations for this model are

$$\mathbf{D}_{A,er}\left(\frac{\partial^2[A]}{\partial r^2} + \frac{1}{r}\frac{\partial[A]}{\partial r}\right) - u\frac{\partial[A]}{\partial z} - (-r_A) = 0 \tag{CS4.4}$$

$$-k_{T,er}\left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r}\frac{\partial T}{\partial r}\right) - u\rho C_p\frac{\partial T}{\partial z} + (-\Delta H_r)(-r_A) = 0 \tag{CS4.5}$$

with boundary conditions

$$\begin{aligned}
&\frac{\partial[A]}{\partial r} = 0 \quad \text{at } r = 0,\ z > 0\\
&[A] = [A]_0 \quad \text{at } r > 0,\ z = 0\\
&\frac{\partial T}{\partial r} = 0 \quad \text{at } r = 0,\ z > 0\\
&-k_{T,er}\frac{\partial T}{\partial r} = h_w(T - T_w) \quad \text{at } r = 0,\ z = 0
\end{aligned} \tag{CS4.6}$$

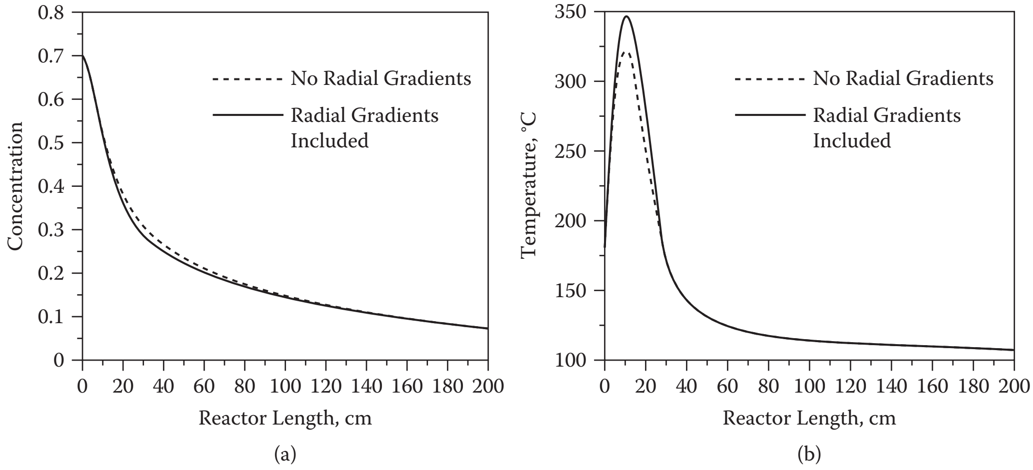

FIGURE CS4.1 Computed concentration and temperature profiles in the multitubular reactor for the catalytic reduction of nitrobenzene to aniline.

Using the data given above, the equations were solved (Doraiswamy, 2001) to obtain axial concentration and temperature profiles at different radial positions. From these profiles, an average value was calculated for the entire cross section for a given axial position. The resulting plots of the average temperature and concentration as functions of reactor length are shown as continuous lines in Figure CS4.1. For comparison, the results of computations of the model without radial gradients are described by

$$u\frac{d[A]}{dz}+(-r_A)=0 \tag{CS4.7}$$

$$u\rho C_P\frac{dT}{dz}+\frac{4U}{d_T}(T-T_w)-(-\Delta H_r)(-r_A)=0 \tag{CS4.8}$$

with boundary conditions

$$[A]=[A]_0,\ T=T_0 \quad \text{at } t=0 \tag{CS4.9}$$

are also included. The axial temperature maximum occurs close to the entrance. Also, there is very little difference between the one- and two-dimensional models. The desired conversion of 99.7% is achieved in a length of 8.3 m, whereas a length of 1.9 m provides a 90% conversion.

Extension to Adiabatic Operation

It is also possible to operate the aniline reactor adiabatically, as in the earliest reactors used in Germany. As mentioned in Section 11.4.2.4.2, adiabatic reactors are usually operated as multistage reactors with interstage cooling. Since the present reactor is reasonably exothermic, a single reactor can be used, provided a large excess of hydrogen is employed such that the hydrogen-nitrobenzene ratio is as high as 50:1 to 80:1. Without going into numerical details, we shall illustrate the procedure (see Doraiswamy, 2001, for details). Let us use the same rate equation as for the NINA reactor. However, we express the concentrations in terms of partial pressures; hence the numerical values of the rate and adsorption constants will be different.

Assuming a hydrogen-nitrobenzene ratio of 60:1, the rate equation can be recast as

$$-r_{wA} = \frac{k_w^o \exp\left(-E/2T\right)\left(\dfrac{1-X_A}{61-X_A}\right)}{\left[1+K_B^o \exp\left(E_{ad}/2T\right)\left(\dfrac{X_A}{61-X_A}\right)\right]^2} \tag{CS4.10}$$

A material balance on A gives

$$F_{A0}dX_A = (-r_{wA})dW \tag{CS4.11}$$

or

$$F_{A0}dX_A = (-r_{wA})\rho_b(l-\varepsilon_b)Sdz \tag{CS4.12}$$

and an energy balance gives

$$F_{A0}(-\Delta H_r)dX_A = F_{t0}C_{pm}dT \tag{CS4.13}$$

where F_{t0} is the total flow rate of the inlet gases. In view of the large excess of hydrogen, F_{t0} can be assumed constant.

From Equations (CS4.12) and (CS4.13), we can write

$$dX_A = \left[\frac{\rho_b\left(1-\varepsilon_b\right)S\left(-r_{wA}\right)}{F_{A0}}\right]dz \tag{CS4.14}$$

$$dT = \left[\frac{\left(-\Delta H_r\right)\rho_b\left(1-\varepsilon_b\right)S\left(-r_{wA}\right)}{F_{t0}C_{pm}}\right]dz \tag{CS4.15}$$

or

$$dX_A = \alpha dz \tag{CS4.16}$$

$$dT = \beta dz \tag{CS4.17}$$

Equations (CS4.16) and (CS4.17) are coupled ordinary differential equations in conversion and temperature. They can be solved for the initial conditions

$$z = 0, \quad X_A = 0, \quad T_0 = 473 \text{ K}$$

using the Runge–Kutta fourth-order method for different tube diameters and ratios [note that Equation (CS4.10) will be slightly different for different ratios].

The results (not given here) show that (1) conversion and temperature decrease with the reactor length with an increase in H_2–$C_6H_5NO_2$ ratio, and (2) for a given ratio, conversion and temperature rise throughout the reactor length with an increase in reactor diameter. Hence, in general, larger diameters and lower ratios are favored.

Lesson

The present case study outlines a modeling procedure for a catalytic reaction but places it in context by including it as one of 12 case studies chosen to cover a variety of reactions. The main lesson here is that a relatively complex model often does little better than its simplest counterpart. While all models should be explored, the suitability of the simplest one should always be considered.

The choice between NINA and adiabatic reactors is not easy for moderately to highly exothermic reactions. The values of the adiabatic temperature change ATC and temperature sensitivity given by

$$ATC = \frac{(-\Delta H_r)\, y_{A0}}{C_{pm}}$$

$$TS = (-r_{wA}) \frac{E}{R_g T^2}$$

are useful indicators. ATC is usually in the range of 90 to 800 K, and TS is in the range of 2 to 20. Values in the lower half of the ranges would suggest a preference for adiabatic operation. Another important consideration is the cost of recycling the large excess of hydrogen used in adiabatic operation. The fixed cost depends on the number of stages (not considered here; see Froment and Bischoff, 1990; and Doraiswamy, 2001). Detailed calculations should be done on NINA and several adiabatic configurations. The final selection should be made from the two or three "best" alternatives that may emerge, based on convenience as the final test. Catalyst life is usually not a problem, since it is quite robust. If it lasts for a year or more, it is usually preferable to replace it rather than regenerate it. *A priori,* the present reaction is a candidate for more than one mode of operation.

Case Study 11.5 Comparison of Selected Fluid-Bed Models for the Catalytic Reduction (by Hydrogen) of Nitrobenzene to Aniline

Nomenclature for Case Study CS11.5

A	nitrobenzene
A_{be}	bubble-emulsion interfacial area (m^2)

f	fluidization
mf	minimum fluidization

The Problem

Aniline is produced by the hydrogenation of nitrobenzene on a solid catalyst as was shown in CS4.R1 (Case Study 11.4). Kinetic data for this reaction using a copper-based catalyst were obtained during pilot plant studies at the National Chemical Laboratory. Although an LHHW model was proposed, it was also possible to fit a simpler, power law equation to the data, with a rate constant of 1.2 s^{-1}. The purpose of the present case study is to calculate the conversions obtained for this reaction in a fluid-bed reactor using several available models. Although more rigorous models have been proposed that account for bubble size distribution, volume change, and other complicating features of a fluidized bed, simpler models are usually quite adequate. In this study, we compare the predictions of the following five models: Davidson, Kunii–Levenspiel, Miyauchi, Fryer–Potter, and Jayaraman–Kulkarni–Doraiswamy. As the catalyst maintains its initial activity for over a year, a batch fluidized bed is used, and the catalyst is replaced after it begins to lose its activity.

To put the five models in perspective, and to understand the complications that may arise in more rigorous modeling, we conclude this case study with a brief discussion of a few complex models.

Data

The following data (calculated, assumed, or experimentally obtained) will be used:

Minimum fluidization velocity $u_{mf} = 2$ cm/s, feed velocity at inlet $u_0 = 30$ cm/s, bubble diameter $d_b = 10$ cm, initial (fixed-bed) height $L_0 = 1.4$ m, reaction rate constant $k_v = 1.2$ s^{-1}, bed voidage

at minimum fluidization $\varepsilon_{mf} = 0.6$, temperature = 270°C, diffusion coefficient of gas $\mathbf{D} = 0.9$ cm²/s, density of catalyst $\rho_c = 2.2$ g/cm³, reactor diameter $d_T = 3.55$ m, solids fraction in the wake $s_{wb} = 0.33$.

Solution

The original references provide more details of the models. The solutions below illustrate only the use of the model equations. However, the main features are sketched in Figure CS5.1.

Davidson Model

The first hydrodynamic model proposed for fluid-bed reactor design (see Davidson and Harrison, 1963) is simple but is the basis of most models developed since. A sketch of the model appears in Figure CS5.1a. Three main groups are involved: U for fluidization, K_0 for reaction, and Y for mass transfer. Equations can be derived both for plug flow and mixed flow of emulsion gas. The simpler mixed-flow model is usually adequate (with predictions close to those of the plug-flow model) and is given by

$$\left[1 - X_A\right] = Ue^{-Y} + \frac{1 - Ue^{-Y}}{K_0 + \left[1 - Ue^{-Y}\right]} \quad \text{(CS5.1)}$$

where

$$U = l - u_{mf} / u_0$$
$$K_0 = k_v L_{mf} / u = k_v L_f (l - \delta) / u_0 \quad \text{(CS5.2)}$$
$$Y = Q_{be} L_f / u_b V_b$$

The bubble velocity u_b is the real bubble velocity and is the sum of the slip velocity of bubbles u_{br} and the velocity at which the bed itself moves; it is given by

$$u_b = 0.711 \times (gd_b)^{1/2} + [u_0 - u_{mf}] = 98.4213 \text{ cm/s} \quad \text{(CS5.3)}$$

where g = 981 cm/s², and $V_b = \pi d_b^3 / 6 = 523.33 \text{ cm}^3$
The quantity Q_{be} appearing in the group Y is the sum of the volumetric flow between the bubble and emulsion phases induced by circulation (q) and diffusive flow ($k_g A_{be}$),

$$Q_{be} = q + k_G A_{be} \quad \text{(CS5.4)}$$

where

$$k_G = 0.975 \mathbf{D}^{1/2} [g / d_b]^{1/4} = 2.91 \text{ cm/s}$$
$$A_{be} = \pi d_b^2 = 3.14 \times 10^2 = 314 \text{ cm}^2 \quad \text{(CS5.5)}$$
$$q = 0.75 u_{mf} \pi d_b^2 = 471 \text{ cm}^3/\text{s}$$

Substituting for k_g and A_{be} in Equation (CS5.4),

$$Q_{be} = 471 + 9.14 \times 314 = 1384.74 \text{ cm}^3/\text{s}$$

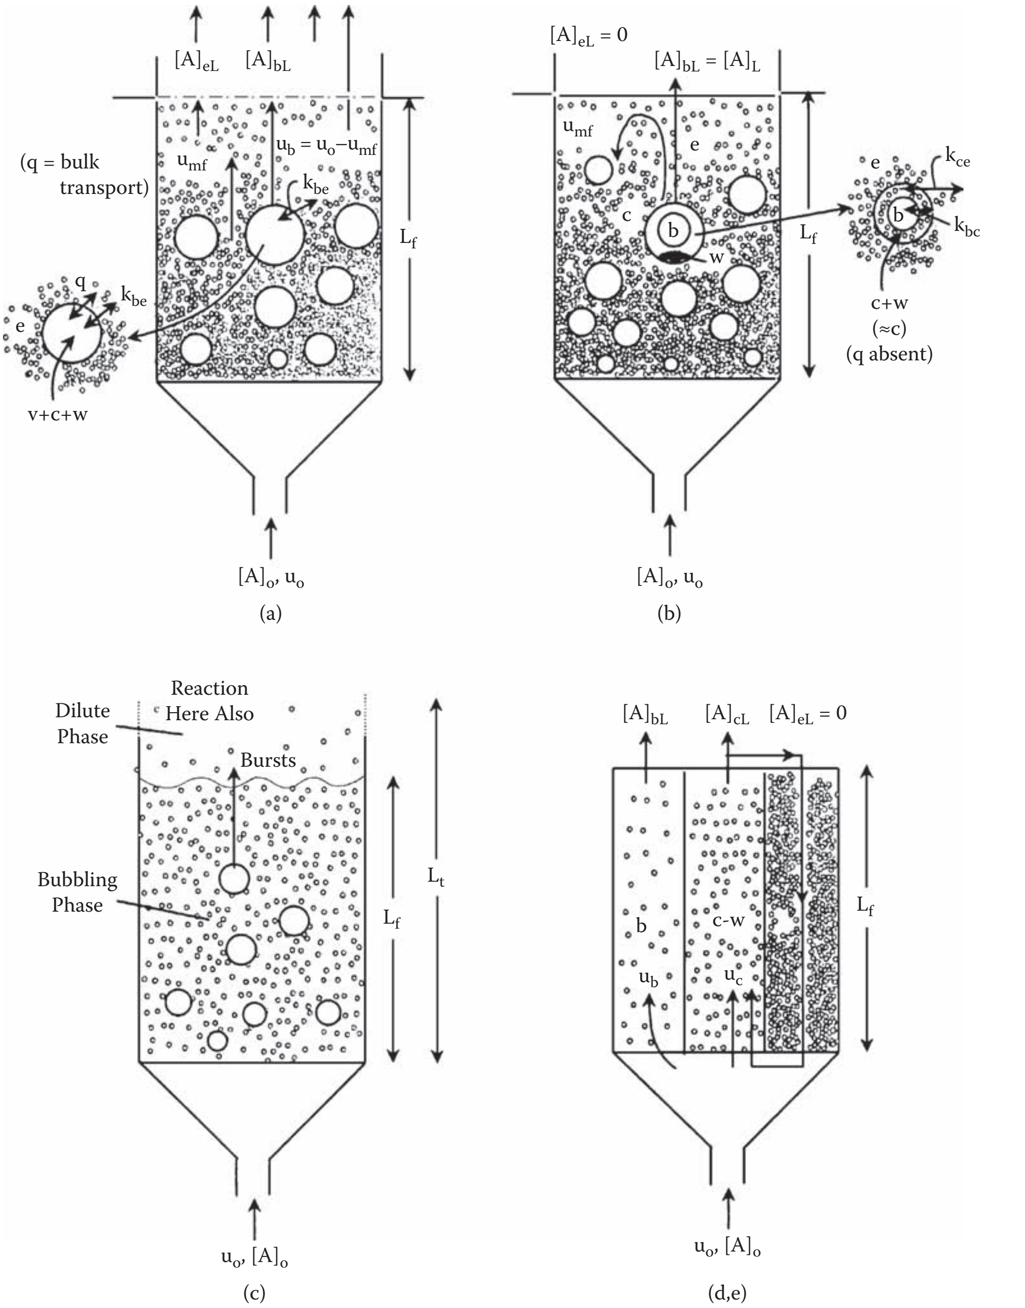

FIGURE CS5.1 Schematics of several fluidized-bed reactor models: (a) Davidson model, (b) Kunii-Levenspiel model, (c) Miyauchi model, (d), (e) Fryer-Potter and Jayaraman-Kulkarni-Doraiswamy models.

L_f is related to L_0 by the following relationship (Kunii and Levenspiel, 1969):

$$L_f = \left(\frac{1-\varepsilon_B}{1-\varepsilon_{mf}}\right)\frac{L_0 u_b}{u_{br}} \tag{CS5.6}$$

where

$$u_{br} = 0.711\left(gd_b\right)^{1/2} = 70.4213\,\text{cm/s}$$

$$L_f = 290 \text{ cm} \tag{CS5.7}$$

$$\delta = \left(u_0 - u_{mf}\right)/u_b = 0.2845$$

The quantities U, K_0, and Y are then easily calculated giving

$$U = 0.9333,\ K_0 = 8.3,\ Y = 7.79$$

Substituting the parameter values calculated above in Equation (CS5.1),

$$\left(1-X_A\right) = 0.9333\exp\left[-18.83\right] + \frac{1-0.9333\exp\left(7.79\right)}{8.2999+\left[1-0.933\right]\exp\left(7.79\right)} = 0.119$$

giving conversion X_A = 88.1%.

Kunii–Levenspiel (K–L) Model

The main postulates of the K–L model (Kunii and Levenspiel, 1968a, b; 1991) are sketched in Figure CS5.1b. The bubble develops a "cloud" of particles around it as it moves upward at a velocity

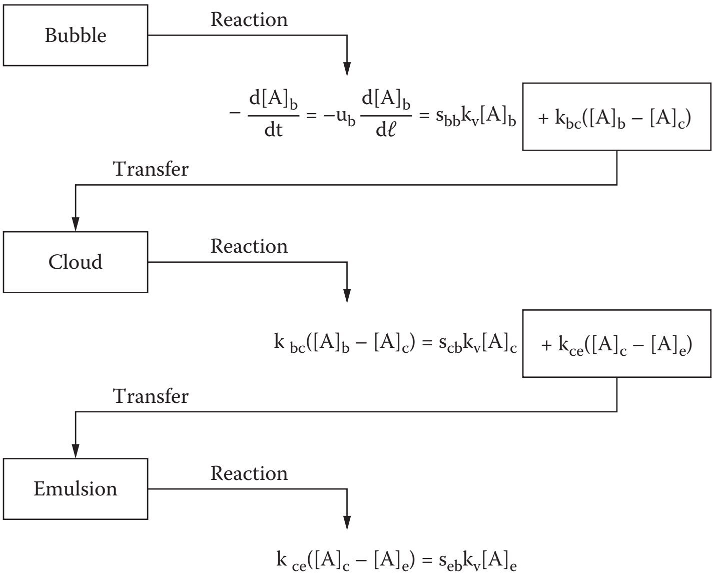

FIGURE CS5.2 Schematic representation of calculations for the Kuni–Levenspiel model. (From Doraiswarmy, L. K., 1991.)

greater than the emulsion gas velocity. The thickness of the cloud is a function of the bubble velocity, which in turn depends on the size of the bubbles and of the fluidizing particles. In a bed of small particles with large bubbles (with corresponding high velocities), a cloud of thickness calculated as

$$\frac{r_c - r_b}{r_b} \cong \frac{u_f}{u_{br}} = \frac{1}{\alpha}$$
$$\frac{r_c}{r_b} = \left(\frac{\alpha+2}{\alpha-1}\right)^{1/3} \left(\text{more rigorous}\right) \tag{CS5.8}$$

develops around each bubble. The bubble gas does not circulate through the rest of the bed. The gas exchange is by diffusive transfer with no bulk circulation (unlike in the Davidson model, which has both). Furthermore, as already mentioned in Section 11.4.2.5.1, as the bubble moves upward, suction is created at the bottom of the bubble; solid particles are drawn into that region and lodged there. This is known as the *wake* and, for purposes of mass transfer, it is assumed to be fully mixed with the cloud-phase components. Because there are now two operative phases in the bubble-cloud-wake unit (bubble and cloud/wake), mass transfer between the emulsion and this unit occurs by two consecutive steps (unlike in the Davidson model, where only one step is involved): between emulsion and cloud, and between cloud and bubble/cloud/wake. For simplicity, the gas and solid particles are assumed to be fully mixed in each of the phases, cloud/wake and bubble. Reaction occurs in all three phases, and the extent of reaction in each phase depends on the solids fraction in that phase. These solid fractions are defined as

$$s_{bb} = \frac{\text{volume of solids in bubbles}}{\text{volume of bubbles}} \tag{CS5.9}$$

$$s_{cb} = \frac{\text{volume of solids in clouds/wake}}{\text{volume of bubbles}} \tag{CS5.10}$$

$$s_{eb} = \frac{\text{volume of solids in emulsion}}{\text{volume of bubbles}} \tag{CS5.11}$$

$$s_{wb} = \frac{\text{volume of solids in wake}}{\text{volume of bubbles}} \tag{CS5.12}$$

Hence, several reaction and mass transfer steps occur in the overall scheme as shown in Figure CS5.2. Assuming that only the bubble gas exists in the bed (the emulsion gas is assumed to circulate within the bed), mass balances can be written as shown in the figure. All these equations can be algebraically combined and rearranged to give the following design equation:

$$1 - X_A = e^{-K_f} \tag{CS5.13}$$

where K_f represents a composite constant given by

$$K_f = \frac{L_f k_v}{u_b}\left[s_{bb} + \cfrac{1}{\cfrac{k_v}{k_{bc}} + \cfrac{1}{s_{cb} + \cfrac{1}{\cfrac{k_v}{k_{ce}} + \cfrac{1}{s_{eb}}}}} \right]$$

$$s_{bb} \approx 0.05 \tag{CS5.14}$$

$$k_v = 1.2 s^{-1}$$

Values of k_{be} and k_{ce} can be calculated using the Kunii–Levenspiel equations:

$$k_{bc} = 4.5\left(\frac{u_{mf}}{d_b}\right) + \frac{5.85 g^{1/4}\mathbf{D}^{1/2}}{d_b^{5/4}} = 2.6466 \text{ s}^{-1} \tag{CS5.15}$$

$$k_{ce} = \left(\frac{6.78\varepsilon_{mf}\mathbf{D}u_b}{d_b^3}\right)^{1/2} = 0.60 \text{ s}^{-1} \tag{CS5.16}$$

The other terms appearing in Equation (CS5.14) may be estimated as follows:

δ = 0.2845 (already calculated)

$$s_{cb} = (1-\varepsilon_{mf})\left[\frac{3u_{mf}/\varepsilon_{mf}}{u_b - u_{mf}/\varepsilon_{mf}} + s_{wb}\right] = 0.1916 \tag{CS5.17}$$

$$s_{eb} = \frac{(1-\varepsilon_{mf})(1-\delta)}{\delta} - s_{cb} - s_{bb} = 0.5678 \tag{CS5.18}$$

Thus, from Equation (CS5.14),

$$K_f = 1.51$$

and from Equation (CS5.13),

$$1 - X_A = e^{-K_f} = e^{-3.3149} = 0.0363$$

$$X_A = 0.7790$$

or conversion = 77.90%

Miyauchi Model

As was pointed out earlier (Figure CS5.1c), it is often desirable to account for conversion in the end zones of the fluid bed. The model of Miyauchi (1974) accounts for conversion in the region

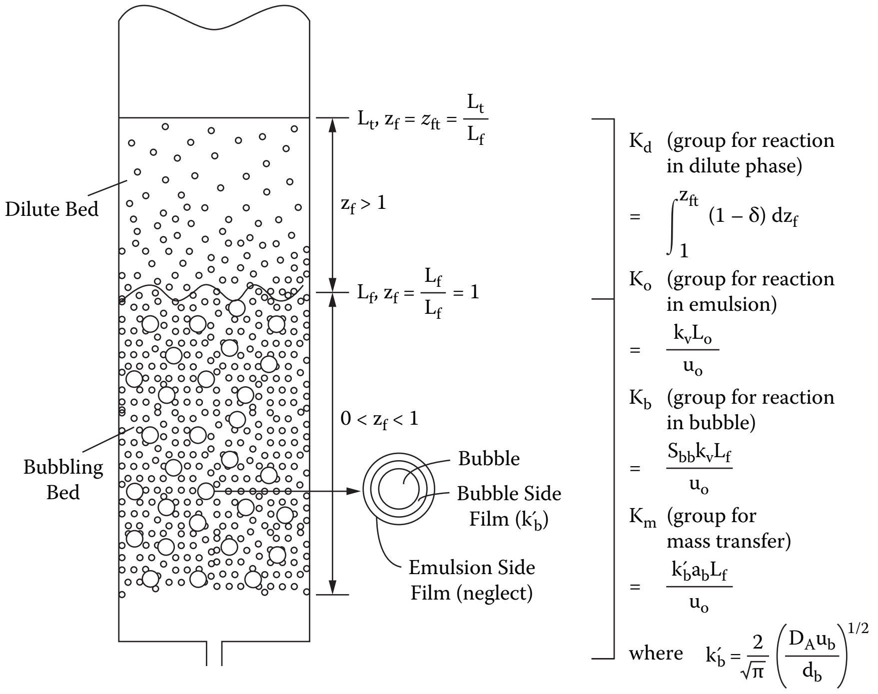

FIGURE CS5.3 Parameters of the Miyauchi model. (From Doraiswarmy, L. K., 1991.)

immediately above the bed. This region is characterized by higher voidage and by an increase of this voidage with height (Lewis et al., 1962; Fan et al., 1962). The final equation is developed in terms of four dimensionless groups: for reaction in the emulsion phase (K_0), for reaction in the bubble phase (K_b), for mass transfer (K_m), and for reaction in the dilute phase above the bubbling bed (K_d) based on experimental voidage distribution data. K_m and K_0 are combined into a single group K'. The various groups and their definitions are given in Figure CS5.3 (Doraiswamy, 2001), and the final equation may be written as

$$(1 - X_A) = \exp[-(K' + K_b + K_d)] \tag{CS5.19}$$

where

$$\frac{1}{K'} = \frac{1}{K_m} + \frac{1}{K_0} \tag{CS5.20}$$

Assigning numerical values,

$$K_m = k_{ob} a_b L_f / u_0 \tag{CS5.21}$$

The value of k_{ob} (the overall coefficient at the bubble-emulsion interface) can be calculated by an elaborate method described by Miyauchi and Marooka (1969) (see also Doraiswamy and Sharma, 1984), giving a value of 0.819 cm/s. Thus,

$$K_m = 4.7502$$

giving

$$K' = 3.0211$$

Now let us calculate K_b and K_d:

$$K_b = s_{bb}\delta k_v L_f / u_0 = 0.165 \tag{CS5.22}$$

$$K_d = \frac{k_v L_f}{u_0}\int_1^{Z_t}(1-\delta)dZ \tag{CS5.23}$$

where

$$Z_t = 3/2.9$$

To evaluate the integral in Equation (CS5.23), δ should be known as a function of height between $z = 1$ and $z = z_t$. Unfortunately, neither are available. However, as an approximate solution, we use the average experimental value of = 0.310 for this region. Thus,

$$K_d = \frac{1.2\times 290}{30}\times(1-0.310)\times\frac{0.1}{2.9} = 0.276$$

thus

$$[1 - X_A] = \exp[-3.0211 + 0.165 + 0.276]$$

or

$$X_A = 0.923$$

Conversion = 92.3%

Fryer–Potter Model

In the models considered so far, no distinction was made between the velocities of the gas in the bubble, cloud/wake, and emulsion phases. In a model of Fryer and Potter (1972a, b), the following features are postulated:

1. The entire bubble phase is provided by part of the incoming gas.
2. The remaining incoming gas combines with the emulsion gas to provide the gas for the cloud/wake phase, part of which constitutes the exit gas along with the bubble-phase gas, and the rest constitutes the downflowing emulsion gas.

These two postulates, captured in Figure CS5.1d, e, provide the basis for the equations for the three velocities as well as for the boundary conditions for the mass balances for the three phases. The calculations are tedious but quite straightforward. The final conversion obtained is 92.35%.

Jayaraman–Kulkarni–Doraiswamy Model

The Fryer–Potter model assumes plug flow in all the phases, including the emulsion phase. Experimental evidence indicates that the emulsion phase gas is more nearly mixed than in plug flow. If

it is fully mixed, the Fryer–Potter model converts from a boundary value problem to an initial value problem (Jayaraman et al., 1981). This leads to considerable simplification in the calculations. All equations other than the emulsion phase equation remain unchanged. All mass balance equations can be readily written and solved (see Jayaraman et al., 1981). The conversion obtained is 88.98%.

Summary of Results

Model	Conversion, %
1. Davidson	88.10
2. Kunii–Levenspiel	77.90
3. Miyauchi	92.35
4. Fryer–Potter	92.35
5. Jayaraman–Kulkarni–Doraiswamy	88.98
Mean	87.93

Other Models: A Brief Discussion

The five models used in the design just presented do not differ greatly in predicting the exit conversion. The average deviation is 2.41% and the maximum is 4.57%. These deviations are not greatly significant, considering the many simplifying assumptions made. The assumption of a single effective bubble size is the most limiting. The values of the wake fraction used and the assumption of complete mixing or plug flow of gas are other serious drawbacks. It is likely that the gas is only partially mixed, which is difficult to accommodate in any design. The assumption of isothermicity is questionable for highly exothermic or endothermic reactions and is inconsistent with the plug-flow assumption, notwithstanding the role of solids mixing in eliminating temperature variations.

Models have been proposed that eliminate the constant bubble size assumption and allow for variation in size. Features of the major models now available have been summarized by Doraiswamy and Sharma, Table 14.3 (1984).

The assumptions discussed above are obvious. Many others are less so and are inherent in almost all fluid-bed models. The most important is with respect to particle size range. Most models do not account for this explicitly, except the K–L model, which gives different equations for fine, intermediate, and coarse particles (Kunii and Levenspiel, 1991). Our calculations for all the five models are for mainly Geldart B class particles and should generally be valid for the so-called fine and intermediate size particles. With the inherent uncertainties of prediction in all the models now available, a finer distinction is not warranted between these two classes of particles.

Except the Miyauchi model, the models considered do not account for conversion in the dilute phase. For really fast reactions with high velocities through the grid plate nozzles, conversion in the jetting region immediately above the grid plate should also be considered (see Figure 11.35). It has to be calculated separately, and it becomes the conversion used as the inlet to the bubbling bed region of any of the models now available. On the other hand, the conversion in the dilute phase is part of the overall calculation in the Miyauchi model considered in our calculations. Kunii and Levenspiel (1991) also suggest a procedure by which this can be included in their model.

An Overall Strategy

Several factors have to be considered in the design of a fluidized-bed reactor. The designs just considered did not include all factors as required for a more rigorous design (see Doraiswamy and Sharma, 1984; Doraiswamy, 2001; and Kunii and Levenspiel, 1999).

Lesson

Fluidized-bed reactor modeling has attracted considerable attention over the years, but there also has been an increasing realization that so many "unpredictables" are involved in the modeling that a realistic design from first principles is difficult. This case study examines five important available models. The chief lesson from this study is that, for a complicated reactor system like the fluidized-

bed reactor, none of the models completely accounts for real-life situations. Thus, a fairly simple one, the Kunii–Levenspiel model, is recommended for preliminary designs a detailed design of a commercial reactor should be based on data from a pilot plant reactor about 10% the size of the proposed commercial unit.

Case Study 11.6 Gas-Solid Noncatalytic Reaction: Development of a Solid Sorbent for Cleaning Coal Gas Followed by Modeling of the Reaction and a Conceptual Reactor Design

Gasification of coal with steam and limited oxygen is a common method of removing the sulfur in coal. The reaction converts sulfur to hydrogen sulfide (H_2S) and some carbonyl sulfide (COS). The concentration of H_2S ranges from 0.1 to 3.0%, depending on the type of coal. To use this gas for electric power generation, preferably by the new *integrated gasification combined cycle (IGCC)* process, the H_2S has to be removed at the high temperatures and pressures existing in the gas turbines (unlike the less-efficient conventional process, in which the gasification is at atmospheric pressure). A solid adsorbent removes both H_2S and COS.

Calcium-based sorbents are highly effective (e.g., Squires et al., 1971; Westmoreland and Harrison, 1976; Heesink and van Swaaij, 1995; Fenouil and Lynn, 1995a, b; Yrjas et al., 1996; Zevenhoeven et al., 1996). The sulfurous gas is removed according to the reaction

$$CaO(s) + H_2S(g) = CaS(s) + H_2O(g) \qquad \text{(CS6.R1)}$$

Other metal oxides have also been used, such as zinc oxide (see, e.g., Uysal et al., 1988; Khare et al., 1995).

The main requirements of a commercially viable sorbent are as follows: it should be inexpensive, be able to operate at the gasifier outlet conditions, be highly reactive with H_2S, be regenerable for at least 100 cycles involving sulfidation (to remove H_2S) and oxidation (to regenerate the original oxide), and possess high enough strength to withstand these repeated cycles. Wheelock and cowokers (Wheelock and Akiti, 2000; Jagtap and Wheelock, 1996; Akiti et al., 2001, 2002a, b) have developed sorbents that meet these requirements, including a cyclic oxidation-reduction scheme for generation. They have also proposed a model for the sulfidation step as described in this case study.

Sorbent Development

The pelletization of the calcium-based sorbent particles is often the cheapest and the most practical approach. However, to produce a strong pellet, it is necessary to mix a binding material with the active solid. The chief drawback is that the solid matrix formed tends to crack with repeated reaction and regeneration cycles, since there is a volume change when CaO is converted to CaS and other intermediates that may form (e.g., $CaSO_4$). Furthermore, the impurities present in the binding material may lead to sintering at temperatures lower than the reaction temperature, thus reducing the effectiveness of the sorbent.

To counter this problem, it is necessary to combine the strength of the binder with the reactive capacity of the sorbent in a configuration that will not diminish either. This requires physical separation of the two materials in the pellet and can be accomplished by coating the sorbent material with a protective layer of the binder that forms a tough shell. We call this configuration the *core-in-shell (CIS)* sorbent. Different variations of this basic configuration have been used by varying the core and shell materials and compositions. It has been found that combinations of the two in both the core and shell give pellets of optimum strength and reactivity. Clearly, these combinations should have different compositions.

Pellet formation essentially involves three steps: nucleation (consolidation of several grains into a nucleus), transition (joining of several nuclei to form larger entities), and ball growth (growth

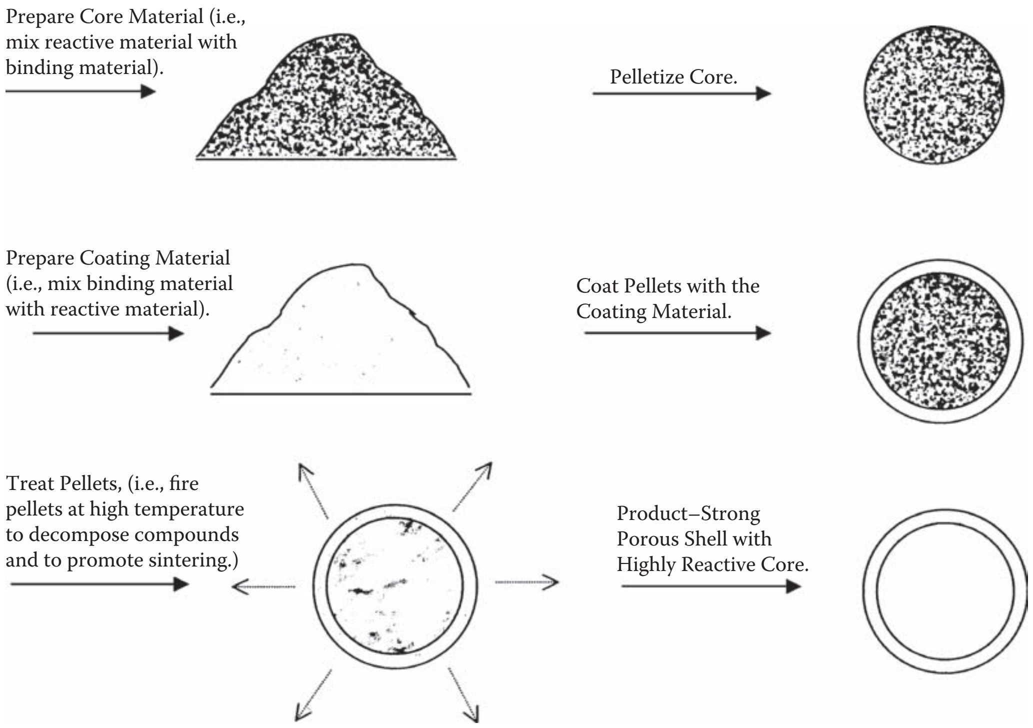

FIGURE CS6.1 A practical protocol for preparing core-in-shell pellets.

of larger entities into the required pellets at the expense of the smaller ones that get crushed). Based on these steps, a protocol for preparing CIS pellets is illustrated in Figure CS6.1.

As mentioned earlier, a viable procedure for pellet regeneration is an integral part of pellet development. Several procedures have been suggested (e.g., Yoo and Steinberg, 1983; Chou and Li, 1984a, b; Illerup et al., 1993; van der Ham et al., 1996; Jagtap and Wheelock, 1996; Wheelock, 1997, 2000). The recommended procedure (Jagtap and Wheelock, 1996; Wheelock, 1997, 2000, 2004) essentially involves a cyclic operation alternating between oxidizing and reducing atmospheres in the reactor. During the oxidation process, CaS is converted to CaO according to the reaction

$$CaS(s) + 3/2O_2(g) = CaO(s) + SO_2(g) \tag{CS6.R2}$$

However, under the conditions of high temperature (650 to 1000 K) and excess oxygen existing in the reactor, the following reaction also occurs:

$$CaS(s) + 2O_2(g) = CaSO_4(s) \tag{CS6.R3}$$

which is unfortunately the favored reaction, both thermodynamically and kinetically. The larger volume of the $CaSO_4$ causes pore plugging, eventually leading to an impenetrable layer around the reactive solid (CaO). However, the $CaSO_4$ can be converted back to CaO by treatment with CO according to the reaction

$$CaSO_4(s) + CO(g) = CaO(s) + CO_2(g) + SO_2(g) \tag{CS6.R4}$$

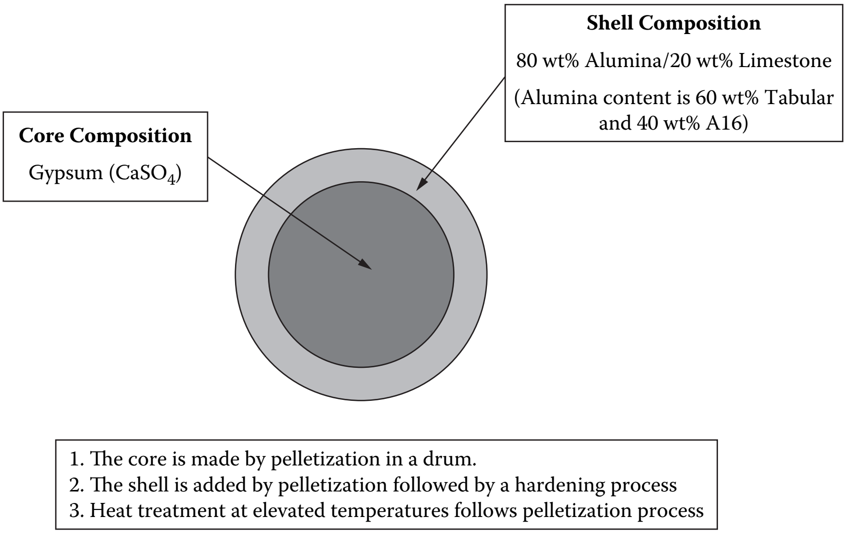

FIGURE CS6.2 Compositions of core and shell in the recommended CIS pellets.

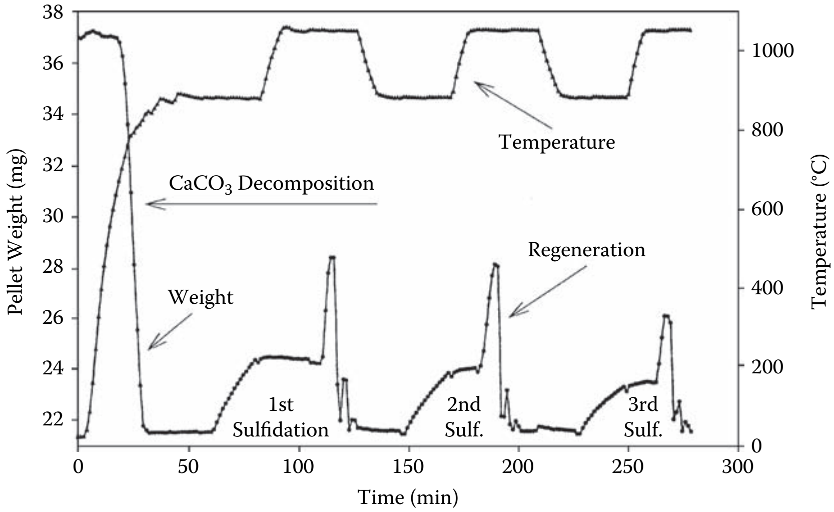

FIGURE CS6.3 Reaction-regeneration cycles involved in the overall reaction scheme.

Thus, regeneration is accomplished by alternating between oxidizing conditions [when reactions (CS6.R2) and (CS6.R3)] occur) and reducing conditions [when reaction (CS6.R4) occurs], leading to complete conversion of CaS to CaO.

Several shell materials and two core materials as well as different compositions of the shell and core were tested by Akiti (2001) and Akiti et al. (2001, 2002a,b). Although more research is still needed, the pellet described in Figure CS6.2 gives acceptable results. Using this pellet, the complete reaction-regeneration cycle involved in the overall reaction scheme is shown in Figure CS6.3.

Modeling of the Sulfidation Step (i.e., the Main Reaction)

The more important basic gas-solid reaction models and their extensions are described in Section 11.3.2. Heesink and van Swaaij (1995) proposed a particle-pellet model for reaction between calcined limestone and H_2S at temperatures ranging from 500 to 700°C using a pellet of conventional

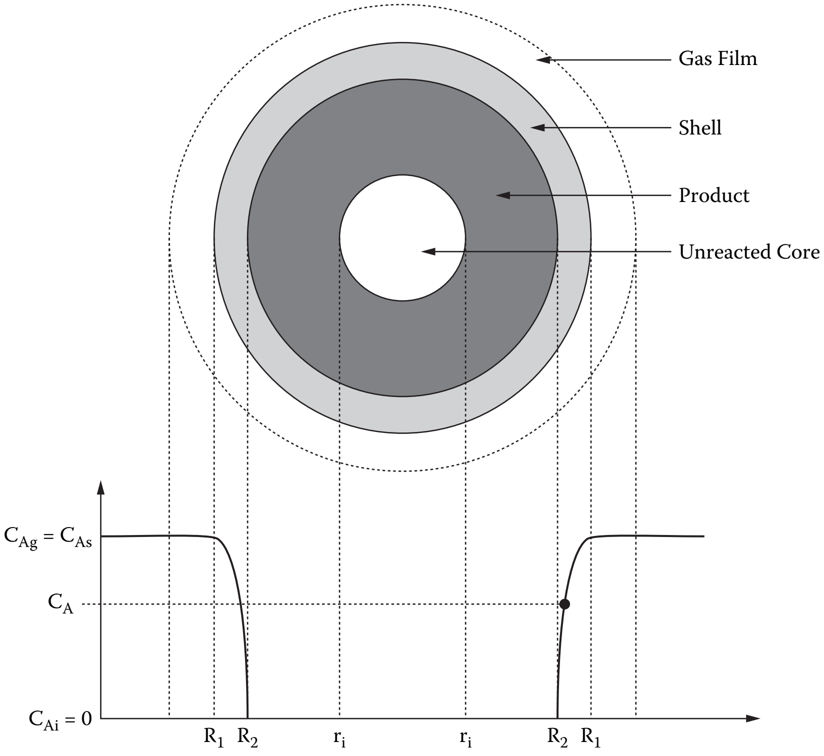

FIGURE CS6.4 A model for reaction in a CIS pellet assuming the shell acts as a separate phase offering pure mass transfer resistance.

design. A model can also be developed for the CIS pellet, but we use the simpler SIM (Akiti, 2001; Hasler et al., 2003).

Two simple extensions of SCM can be used to describe CIS behavior. The external shell is treated as a separate phase surrounding the pellet (Figure CS6.4) that offers one more step of pure mass transfer resistance with no reaction in addition to the fluid film. Akiti. (2001) used such a model to obtain an approximate fit of the data.

More recent studies by Hasler et al. (2003) showed, however, that the lime in the shell (see Figure CS6.2) reacts to the extent of 25% to 40%. The photograph shown in Figure CS6.5 suggests that one of the zone models described in Section 11.3.2.1.3 better describes the observed behavior. Since the zone thickness exhibits rapidly decreasing product density toward the core, one can, as a first approximation, assume SCM behavior with the ash and shell layers treated as separate layers as proposed by Akiti (2001). The outer shell acts as a "solid film." Although this shell contains some lime that undergoes reaction, the amount is so small relative to that in the core that it can be neglected. Diffusion through the two layers (ash and shell) is the controlling resistance, with a small contribution from the fluid film surrounding the pellet. Further studies are needed, however, to verify the zone model (or the particle-pellet model).

Reactor Design

In Section 11.4.2, we discussed the three main categories of reactors that can be used for gas-solid reactions. Since the present system uses pellets of reasonable size, fluid-bed reactors can be ruled out. We shall therefore consider fixed- and moving-bed reactors. Two features of this system should first be noted:

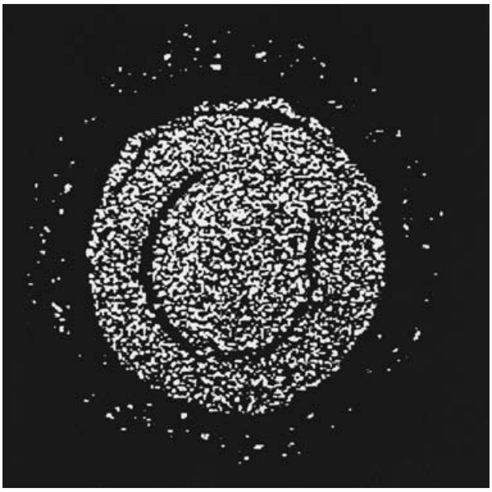

FIGURE CS6.5 Cross-sectional view of a reacted CIS pellet.

1. The reaction involves cyclic operation alternating between sulfidation, in which the absorbent (a metal oxide) removes the sulfur from the feed stream and oxidation, in which the sulfided adsorbent is oxidized to regenerate the original oxide of the adsorbent.
2. The dust present in the flue gas must be removed in the sulfidation unit. Dust can be removed only in fixed or moving beds of pellets by allowing it to accumulate in the interstitial space. This is not possible in a fluidized bed, providing one more reason why this bed is unacceptable.

Strictly, the total reaction scheme consists of three steps, one for sulfidation and two for regeneration. In other words, the total reaction scheme consists of a reaction-regeneration cycle into which a secondary regeneration cycle is embedded, consisting of alternating steps of oxidation and reduction (Figure CS6.5). Any conceptualization of a reactor scheme must take these reactions into account. Two alternatives are possible:

1. Use two reactors in which the main reaction (sulfidation) and regeneration (reduction and oxidation) are performed separately.
2. Use three reactors, one each for sulfidation, oxidation, and reduction.

Scheme 1 might appear to be the cheaper, but it is difficult to design a single reactor for regeneration involving periodic switching between oxidizing and reducing environments. Hence, a three-reactor system commends itself as the better alternative.

Each of the reactors in the three-reactor system can be a fixed- or moving-bed reactor. The fixed-bed reactor scheme for regeneration suffers from the need to subject each reactor to alternating environments, one for oxidation and the other for reduction. While one reactor is accomplishing oxidation, the other would be engaged in reduction. A very close control strategy is required to operate this scheme successfully. Even so, the residual environment of one reaction before the second reaction is allowed to occur in a given reactor can vitiate the results. These are powerful arguments against the fixed bed. Thus, purely from a qualitative discussion of the alternatives, the moving-bed reactor appears best.

A Practical Moving-Bed Design

Because dust removal is one of the main requirements of a good operating system, a special design proposed by Westinghouse (Yang et al., 1992), the *standleg moving granular bed filter,* appears to

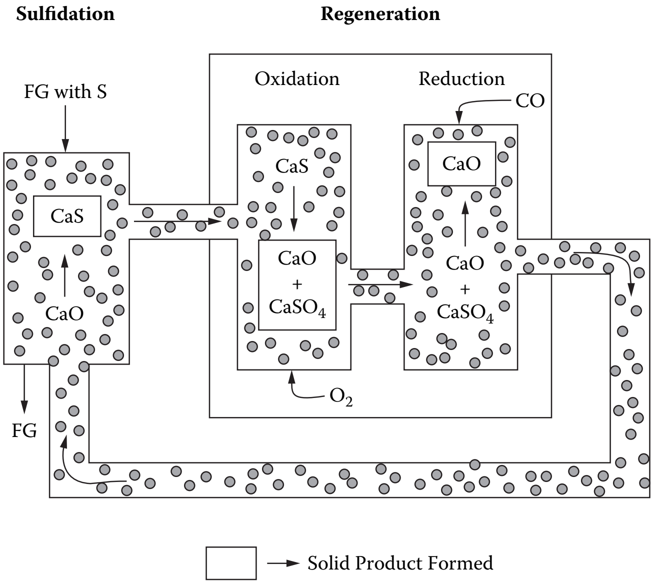

FIGURE CS6.6 A reaction-regeneration cycle into which a secondary regeneration cycle is embedded consisting of alternate cycles of oxidation and reduction.

be the best basis for designing the sulfidation reactor. A modification of the Westinghouse design was proposed by Colver et al. (2002), in which the gas and solids move countercurrently (as against the cocurrent flow in the original Westinghouse design); this modification is recommended here. This reactor differs from the conventional moving-bed reactor mainly with respect to the details of design, as brought out in Figures CS6.7a and b. The design equations given in Section 11.4.2.5.2

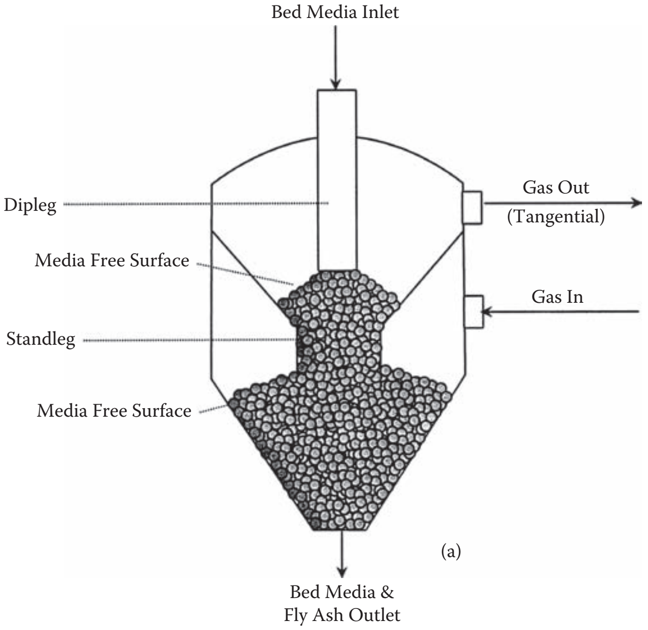

FIGURE CS6.7 Moving-bed reactor designs for the system at hand: (a) conventional design; and (b) a special design proposed by Colver et al. (2002). *Continued.*

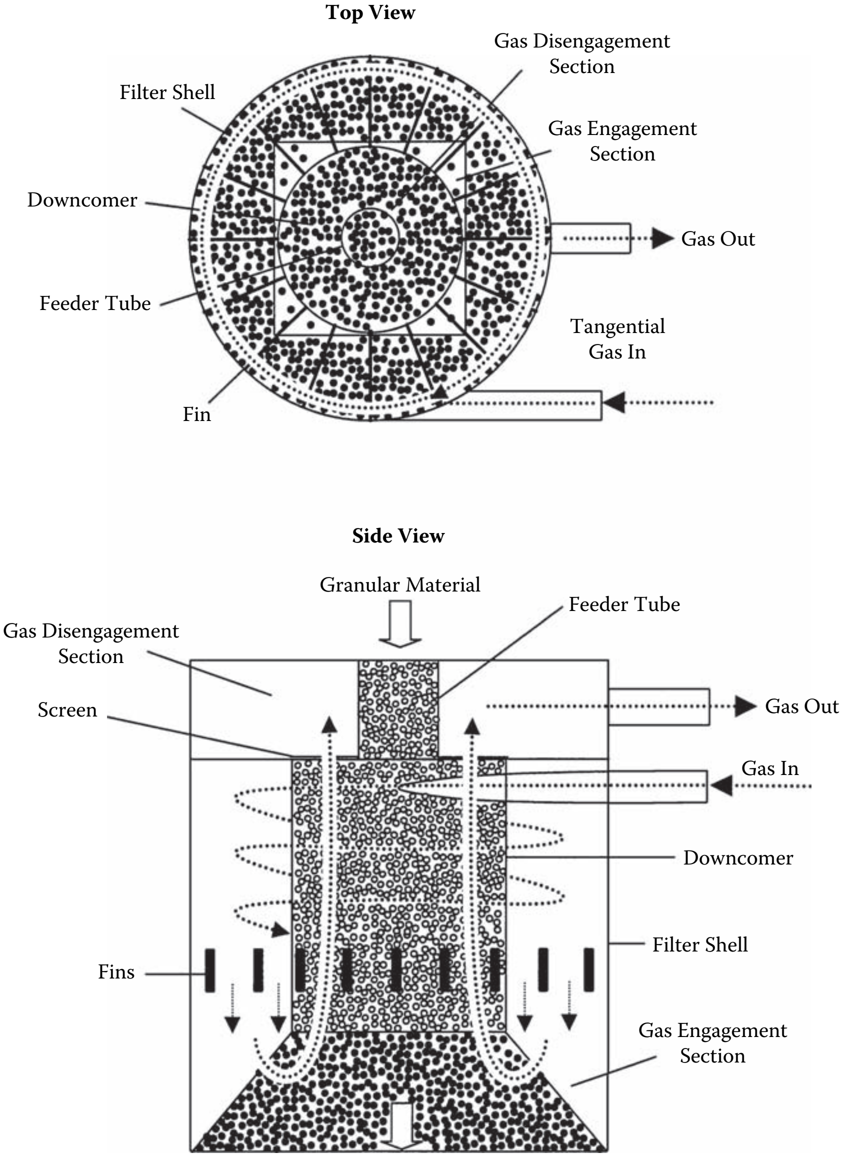

FIGURE CS6.7 *Continued.*

are equally applicable to this reactor, for both the cocurrent and countercurrent configurations. The reactors for the regeneration step can be of the conventional moving-bed type.

With insufficient data to design the reactor, we suggest this design be used only for the sulfidation step in the overall operating scheme shown in Figure CS6.6. It is necessary that a dust collector (not shown in the figure) be used to ensure dust-free feed to the regeneration system.

Lesson

The use of coal for producing electric energy has always been of importance. Since sulfur can be removed, there has been increased attention recently to developing solid sorbents to remove the sulfur as hydrogen sulfide and some sulfur carbonyls. Among the many solids tried, lime has been one of the most widely used. Because of its poor crushing strength, it has a tendency to crumble. The present case study describes the development of a pellet in which the softer calcium salt is

encased in a hard outer shell (the so-called core-in-shell pellet). As in all kinetic analyses involving solid catalysts, the kinetic parameters determined experimentally hold only for that catalyst and for the feed of specified purity used; these parameters hold only for the sorbent developed for a particular coal. However, it must be noted that, in the preparation of the sorbent, any chloride compound should be avoided, since the released HCI would be harmful to the sorbent's life. CaO-based sorbents stabilize after 16 to 18 regenerations, with the value falling to about 60% of the original. Even so, it is quite economical to use this sorbent. The type of coal, including the maceral impurities, is of minor importance. The composition of the sorbent is the determining factor and works for many coals, provided compounds like chlorides are avoided. Hence, preliminary testing is always recommended.

The kind of pellet developed in this study has implications outside the limits of its present use in coal gas cleaning. The core-in-shell concept a priori can be extended to reversible reactions where one of the products of reaction can be "adsorbed out" by the inner core while the reaction continues in the catalytic shell, thus increasing the conversion. The lesson is that novel solutions can be found for challenging problems and, equally important, they can often find applications in a variety of other situations, if only one keeps looking for possibilities.

Case Study 11.7 Gas-Liquid Reaction: Air Oxidation of Sodium Sulfide (a Simple Reaction with Typical Problems of Gas-Liquid Reactions)

Nomenclature for Case Study 11.7

$[A]$	bulk concentration of solute gas (kmol/m^3)
$[A^*]$	saturation concentration of solute gas (kmol/m^3)
$[B]$	concentration of liquid phase reactant (kmol/m^3)
C_1	constant in Equation (CS7.38) (1/kmol)
C_P, C_V	heat capacities (kJ/kg °C)
$\mathbf{D}_A$	diffusivity of component A (m^2/s)
D	column diameter (m)
D_D	diameter of downcomer (m)
D_R	diameter of riser (m)
d_N	nozzle diameter (m)
f_G	friction factor for gas flow in a pipe (–)
G	molar flow rate of gas (kmol/s)
g	acceleration due to gravity (m/s^2)
H	column height (m)
H_C	location of the downcomer sparger from the bottom (m)
H_D	height of dispersion (m)
H_W	Henry's coefficient for aqueous Na_2S solution (kmol/m^3 Pa)
h	height coordinate (m)
k_i	rate constant, I = 1,2. . . . . (conc^{1-n}/time)
k_L	true liquid-side mass transfer coefficient (m/s)
k_La	volumetric liquid-side mass transfer coefficient (1/s)
L	volumetric liquid flow rate (m^3/s)
Lc	length of the contactor (m)
N_N	number of nozzles
$\mathbf{P}$	power consumption (W)
p_{O_2}	oxygen partial pressure (Pa)
P	pressure (Pa)
$\bar{P}_T$	average pressure in the column (Pa)
R_A	specific rate of absorption of A (kmol/m^2 s)
$(\mathrm{Re})_G$	gas-phase Reynolds number (–)
$(\mathrm{Re})_L$	liquid-phase Reynolds number (–)
r_A	volumetric rate of absorption of A (kmol/m^3 s)

S	cross sectional area (m^2)
T	temperature (°C)
u_G	gas velocity (m/s)
u_L	liquid velocity (m/s)
u_N	nozzle velocity (m/s)
u_S	slip velocity (m/s)
V_D	volume of dispersion (m^3)
y	mole fraction of solute gas in gas phase (–)
Z	stoichiometric coefficient for the reaction between oxygen and sodium sulfide
z	length coordinate (m)
z_t	length of pipeline reactor (m)

Greek

α'	term defined in Equation (CS7.48) (m^3/kmol)
β	term defined in Equation (CS7.9) (1/m)

The Problem

Air oxidation of aqueous sodium sulfide solution is encountered in the pulp and paper industry where the black liquor, which contains sodium sulfide (Na_2S), is oxidized. In a typical process, 200 tons/day of an aqueous solution of sodium sulfide are oxidized with air at 75°C. The concentration of Na_2S is to be reduced from 12 to 0.5 kg/m^3. The following contactors operated contin-

uously are to be considered: (1) bubble column, (2) sectionalized bubble column, (3) external loop air-lift reactor, (4) horizontal sparged contactor, (5) pipeline contactor, and (6) packed column. The operating conditions for each contactor are given at the appropriate places. The black liquor contains additional dissolved solids, which consume O_2. Its properties are significantly different from those of an aqueous sodium sulfide solution. However, for illustration, we shall consider the oxidation of an aqueous sodium sulfide solution according to the following stoichiometric equation:

$$2O_2 + 2Na_2S + H_2O \rightarrow Na_2SO_3 + 2NaOH + S \quad \text{(CS7.R1)}$$

Data

The reaction is first order in both oxygen and sodium sulfide, rate constant k_2 at 75°C = 4.64 m^3/kmol s (there is some doubt about this constant, as it is dependent on several metal impurities; however, for the sake of illustration, this value is reasonably reliable), Henry's constant for O_2 in water at 75°C = 7.2×10^{-9} kmol/m^{3}Pa, Henry's constant for O_2 in Na_2S solution $H_W = 6.42 \times 10^{-9}$ kmol/m^3 Pa (at the average concentration), density of the solution $\rho_L = 1000$ kg/m^3, vapor pressure of water at 75°C = 3.87×10^4 Pa (290 mm Hg), diffusivity of O_2 in Na_2S solution at 75°C = 6.8×10^{-9} m^2/s.

1. Bubble Column (BC) (Countercurrent Operation)

Assumptions

The liquid phase is completely backmixed, and the gas phase moves in plug flow. The superficial velocity of the gas at the top of the column will be fixed at 5×10^{-2} m/s. It may be further assumed that the value of k_La in the column is 0.04 s^{-1} and that of k_L is 2×10^{-4} m/s. Fractional liquid holdup in the bubble column = 0.8. The values of ε_L, k_L, and a actually depend on superficial gas velocity (u_G), column diameter (D), column height (H), sparger design, the nature of the gas-liquid system, and operating pressure and temperature. At relatively low pressures (<0.5 MPa), it is known (Deckwer, 1992; Joshi et al., 1998) that the values of ε_L, k_L, and a are independent of column diameter when D exceeds 0.15 (refer to Section 11.4.2.1.1). Furthermore, these are independent of column height and sparger design when H/D exceeds a certain critical value (3 for highly coalescing to 10 for highly noncoalescing systems). However, quantification of the nature of the gas-liquid system (and its variation with temperature and pressure) is not currently possible. Therefore, it is desirable to measure k_L and a in a small-scale bubble column (D > 150 mm, 10 > H/D > 3) using the same system and operating conditions (T and P). Such measurements are preferably made at least at four levels of u_G and three of T and P in the vicinity of the proposed operating conditions. In the present case study, it is assumed that the experiments were performed as indicated above and that, at the operating condition of u_G, T, and P under consideration, the values of ε_L, k_L, and a are 0.8, 2×10^{-4} m/s, and 200 m^2/m^3, respectively.

Solution

The rate of oxygen absorption in aqueous Na_2S is assumed to be

$$R_A a = k_L a([A]^* - [A]_b) \quad \text{(CS7.1)}$$

The conditions to be satisfied are

$$k_L a \approx \varepsilon_L k_2 [B]_b \quad \text{(CS7.2)}$$

$$\sqrt{\frac{\mathbf{D}_A \; k_2 [B]_b}{k_L}} << 1 \quad \text{(CS7.3)}$$

The material balance for A over a differential height dH_D of the column gives

$$G\,dy = R_A a\,S\,dH_D \tag{CS7.4}$$

Substitution of $r_A a$ from Equation (CS7.1) in Equation (CS7.4) gives

$$G\,dy = k_L a([A]^* - [A]_b)SdH_D \tag{CS7.5}$$

$[A^*]$ is given by the following equation:

$$[A]^* = H_W P_T (1 + \psi H_D)y \tag{CS7.6}$$

where

$$\psi = \frac{1}{P_T}\frac{dP}{dH_D} \tag{CS7.7}$$

Substitution of $[A^*]$ from Equation (CS7.6) in Equation (CS7.5) and subsequent rearrangement gives

$$\frac{dy}{d\,H_D} = \beta(1 + \psi H_D)y - \left[\frac{k_L a[A]_b S}{G}\right] \tag{CS7.8}$$

where

$$\beta = \frac{k_L a H_W P_T S}{G} \tag{CS7.9}$$

$[A]_b$ can be obtained from the overall material balance

$$G\,(y_0 - y_e) = \varepsilon_L k_2 [A]_b [B]_e V_D \tag{CS7.10}$$

where V_D is the total volume of dispersion (reactor). Elimination of $[A]_b$ in Equations (CS7.5) and (CS7.10) gives

$$\frac{dy}{dH_D} = \beta(1 + \psi\,H_D)y - \frac{\nu}{H_D} \tag{CS7.11}$$

where

$$\nu = \frac{k_L a(y_0 - y_e)}{\varepsilon_L k_2 [B]_e} \tag{CS7.12}$$

Equation (CS7.11) on integration gives

$$y_0 \exp\left[-\frac{\beta}{2\psi}(1+\psi H_D)^2\right] - y_e \exp\left[-\frac{\beta}{2\psi}\right]$$
$$+\frac{v}{H_D}\sqrt{\frac{\pi}{2\beta\psi}}\left[erf\left(\sqrt{\frac{\beta}{2\psi}}\,(1+\psi H_D)\right) - erf\left(\sqrt{\frac{\beta}{2\psi}}\right)\right] = 0 \tag{CS7.13}$$

Here we have $L = 2.32 \times 10^{-3}$ m^3/sec, $[B]_0 = 0.154$ kmol/m^3, and $[B]_e = 6.4 \times 10^{-3}$ kmol/m^3.

The amount of oxygen provided is 200% in excess of the stoichiometric requirement. We also assume that G remains constant. Therefore, $y_e = 2/3 \times 0.21 = 0.14$.

The overall material balance can be written as

$$G(y_0 - y_e) = \frac{L}{Z}\left([B]_0 - [B]_e\right) \tag{CS7.14}$$

Substituting the relevant values, we determine $G = 4.89 \times 10^{-3}$ kmol/s. From the values

$$\varepsilon_L k_2 [B]_e = 0.0238 \text{ s}^{-1},\ k_L a = 0.04 \text{ s}^{-1}, \text{ and } \sqrt{\frac{\mathbf{D}_A k_2 [B]_e}{k_L}} = 0.071$$

we note that the condition given by Equations (CS7.2) and (CS7.3) is satisfied. The superficial gas velocity at the top of the column = 5×10^{-2} m/s.

The gas phase also contains water vapor. It is assumed that relatively small amounts of Na_2S do not alter the vapor pressure characteristics of water. Furthermore, the increase in the concentration of Na_2S due to the evaporation of water may be neglected, as the rate of evaporation of water is about 1.75% of the liquid flow rate.

Therefore, the overall volumetric gas flow rate at the outlet is given by

$$4.89 \times (760/470) \times (348/273) \times 22400 = 22.59 \times 10^4 \text{ cm}^3/\text{s} = 0.2259 \text{ m}^3/\text{s}$$

Hence, the cross-sectional area of the bubble column, $S = (0.2259/5 \times 10^{-2}) = 4.52$ m^2. Therefore, $D = 2.4$ m.

We thus have

$$P_T = \frac{760-290}{760} = 0.618 \text{ atm} = 6.26\times 10^4 \text{ Pa},\ \beta = \frac{k_L a\ H_W P_T S}{G} = 1.49\times 10^{-2}$$

$$\psi = \frac{\varepsilon_L \rho_L g}{P_T} = 0.125,\ v = \frac{k_L a\ (y_0 - y_e)}{\varepsilon_L k_2 [B]_e} = 0.118$$

After substituting the relevant values, Equation (CS7.13) was solved by trial and error to give H_D = 29.1 m.

Due to the foaming nature of the black liquor, the value of $k_L a$ is likely to be higher than 0.04 s^{-1} at a u_G of 5×10^{-2} m/s. The problem is reworked for a value of $k_L a$ equal to 0.12 s^{-1} at $u_G = 5 \times 10^2$ m/s and the value of H_D found to be 30.0 m. The height of the column changes little with such a large correction of $k_L a$. When $H_D = 29.1$ m, $\varepsilon_L = 0.8$, and $\rho_L = 1000$ kg/m^3, the total pressure at the bottom (P_B) is 2.28×10^5 Pa. As a result, the oxygen partial pressure at the bottom $(p_{O_2})_B =$

TABLE CS7.1
Effect of k_La on the Height of Bubble Column (Under Conditions Such That No Desorption Occurs in Any Part of the Column)

k_La (at u_G = 5 cm/s) s^{-1}	Cross-Sectional Area cm^2	Diameter m	Height m
0.04	1.64×10^4	4.43	16.0
0.0616	2.08×10^5	5.15	12.35
0.127	3.28×10^5	6.46	7.24

TABLE CS7.2
Effect of Pressure on the Height of Bubble Column

Total Pressure at the Top atm	Height cm	Pressure at the Bottom atm
1	2860	3.2
2	1530	3.18
3	1100	3.85
4	872	4.68

0.21 (P_B – 3.87 × 10^4) = 3.98 × 10^4 Pa, whereas $(p_{O_2})_T$ = 8.76 × 10^3 Pa. It can be seen that the partial pressure of oxygen (and hence the saturation concentration [A*]) varies by a large factor from bottom to top. In contrast, the concentration of dissolved oxygen $[A]_b$ is uniform throughout the reactor because of the complete backmixed behavior of the liquid phase. As a consequence, the driving force ([A*] – $[A]_b$), which is positive at the bottom, may reverse its sign in the top region. Because of the large variation in p_{O_2}, absorption may occur in the bottom region and desorption in the top, as discussed by Parulekar et al. (1988).

Effect of Suspended Impurities

In practice, depending on the quality of wood, the black liquor contains dissolved and suspended impurities. These impurities in turn have a marked influence on the mass transfer coefficient. This problem was discussed earlier, and the methodology for the estimation of k_La has been given. To understand the parametric sensitivity of k_La, the example has been reworked for two higher values of k_La, and the results are given in Table CS7.1.

Operation of Bubble Column under Pressure

Because of desorption in the upper part of the column, it may be desirable to operate the column under pressure. For different total pressures (at the top), the problem has been reworked, and the results are reported in Table CS7.2.

Based on pressures at the bottom, it can be seen that an increase in the pressure at the top of the column from 1.0133 × 10^5 to 3.04 × 10^5 Pa gives nominal variation in the pressure at the bottom. Therefore, the operating cost would remain practically the same. However, there is a substantial reduction in the height of the column. An increase in pressure at the top from 1.0133 × 10^5 to 2.03 × 10^5 Pa increases the partial pressure of O_2 at the top from 1.32 × 10^4 to 3.44 × 10^4 Pa.

2. Sectionalized Bubble Column (SBC)

Since the extent of backmixing in the liquid phase is substantial, it is desirable to consider the sectionalization of the column (a packed bubble column has not been considered, since the black

liquor usually contains considerable suspended impurities). The sectionalized bubble column is shown schematically in Figure 11.21c.

For the nth section of the sectionalized bubble column, the relationship between y_n and y_{n+1} can be obtained from Equation (CS7.13) as

$$y_{n+1}\exp\left[-\frac{\beta}{2\psi}\left(1+\psi H_D\right)^2\right]-y_n\exp\left(-\frac{\beta}{2\psi}\right)+\Gamma\left(\frac{y_{n+1}-y_n}{[B]_{b_n}}\right)=0 \qquad \text{(CS7.15)}$$

where

$$\Gamma=\frac{k_L a}{\varepsilon_L k_2 H_D}\sqrt{\frac{\pi}{2\beta\psi}}\left[erf\left(\sqrt{\frac{\beta}{2\psi}}\left(1+\psi H_D\right)\right)-erf\left(\sqrt{\frac{\beta}{2\psi}}\right)\right] \qquad \text{(CS7.16)}$$

Material balance for the nth section gives

$$y_{n+1}-y_n=\frac{L}{zG}\left([B]_{b_{n-1}}-[B]_{b_n}\right) \qquad \text{(CS7.17)}$$

Substitution of y_{n+1} from Equation (CS7.17) into Equation (CS7.15) and subsequent rearrangement gives

$$\lambda_1[B]_{b_n}^2-[B]_{b_n}\left(\lambda_1[B]_{b_{n-1}}+\lambda_2 y_n-1\right)-[B]_{b_{n-1}}=0 \qquad \text{(CS7.18)}$$

where

$$\lambda_1=\frac{1}{\Gamma}\exp\left(-\frac{\beta}{2\psi}\left(1+\psi H_D\right)^2\right) \qquad \text{(CS7.19)}$$

$$\lambda_2=\frac{ZG}{L\Gamma}\left(\exp\left[-\frac{\beta}{2\psi}\left(1+\psi H_D\right)^2\right]-\exp\left(-\frac{\beta}{2\psi}\right)\right) \qquad \text{(CS7.20)}$$

Equation (CS7.18) can be solved for $[B]_{b_n}$ to give

$$[B]_{b_n}=\frac{\left(\lambda_1[B]_{b_{n-1}}+\lambda_2 y_n-1\right)+\sqrt{(\lambda_1[B]_{b_{n-1}}+\lambda_2 y_n-1)^2+4\lambda_1[B]_{b_{n-1}}}}{2\lambda_1} \qquad \text{(CS7.21)}$$

Procedure for the Design of a Sectionalized Bubble Column

1. Calculate the area of cross section of the column from a consideration of superficial gas velocity.
2. Choose a suitable height for the section.

TABLE CS7.3
Comparison of Different Reactors

No.	Reactor	Diameter m	Height M	Volume m^3	Pressure at Entrance MP	Power Consumption kW
1	Bubble column	2.31	30.35	127	3.35	20.5
2	Sectionalized bubble column	2.31	19.5	81.7	2.51	14.9
3	External-loop airlift reactor	$D_R = D_D$ = 1.88	15.3	84.9	1.96	10.5
4	Horizontal sparged reactor	5.0	24.2 (length)	475	1.33	3.84
5	Pipeline reactor (pure O_2, 20% excess, operating pressure 3 atm.)	0.194	168	5.0	3.04	7.42
6	Packed column	1.69	407	913	Essentially atmospheric	—

3. Start from the top of the column. For section (1), $y_n = y_e$, $[B]_{b_{n-1}} = [B]_{b_o}$, $n = 1$, for $[B]_{b0}$ from Equation (CS7.21).
4. Calculate y_2 from Equation (CS7.17).
5. Repeat the calculation for the next section.
6. Continue the calculation until $[B]_{b_n} = [B]_{b_e}$. If $[B]_{b_n} < [B]_{b_e}$, the height of last section can be calculated from Equation (CS7.13). If the superficial gas velocity at the top is maintained at 5×10^{-2} m/s, then, as shown earlier, D = 2.4 m.

Let the height of each section be 0.5 m. The above procedure gives the total number of sections as 34.64. We may provide 35 complete sections so that the total height is 17.5 m. The sectionalized bubble column is more attractive than a bubble column, because both the volume and the power consumption are approximately 64% of those in the bubble column.

3. External-Loop Air-Lift Reactor (EL-ALR)

As indicated in Section 11.4.2.1.4, the energy requirement of a bubble column can be reduced with an external-loop air-lift reactor (Figure 11.23a). As an illustration, consider case 2 in Table CS7.2. This case was shown to be optimum on the basis of bottom pressure or the pressure at which the gas phase enters the column. Furthermore, there is no complication of desorption.

Let us assume the following: height of reactor = 15.3 m, slip velocity = 0.15 m/s, and average superficial gas velocity at the column middle = 0.05 m/s.

The expressions for the slip velocity in the riser and downcomer region of the column are

$$\frac{u_G}{\varepsilon_{GR}} - \frac{u_L}{\varepsilon_{LR}} = u_S \tag{CS7.22}$$

$$-\frac{u_G}{\varepsilon_{GD}} - \frac{u_L}{\varepsilon_{LD}} = u_S \tag{CS7.23}$$

where ε_{LR}, ε_{LD}, ε_{GD}, and ε_{GR} are the fractional holdups of liquid (L) and gas (G) phases in the riser (R) and downcomer (D) of the loop reactor. The energy balance over the column can be used to obtain the average liquid circulation velocity (refer to Section 11.4.2.1.4):

$$u_L = [2(\varepsilon_{GR}H_D - \varepsilon_{GD}H_C)g]^{0.5} \tag{CS7.24}$$

Solving the above equations simultaneously yields the values of fractional gas holdup for the riser as well as the downcomer, the liquid velocity, and the height of critical location of the sparger from the bottom. The downcomer sparger is located 5.4 m from the bottom. Since H_D = 15.3 m, the diameter of the downcomer and riser ($D_D = D_R$ assumed) was found in such a way that the total gas volume in EL-ALR equals that in the bubble column of case 2 in Table CS7.3. As a result, we get $D_R = D_D$ = 1.88 m. It may be noted that the procedure has been considerably simplified. For rigorous calculations, see Lele and Joshi (1993).

4. Horizontal Sparged Contactor (HSC)

For all other contactors considered previously, we have used 200% excess oxygen. Hence, the gas utilization efficiency in these contactors is low. Let us consider a horizontal sparged contactor, which has the advantage of low pressure drops. The following assumptions are made: the liquid phase is completely backmixed, and the average pressures can be used (since the pressure drop is small).

The following dimensions may be considered: diameter of the contactor = 5 m, liquid submergence = 4 m, nozzle spacing = 0.5 m, distance of the nozzle tips from the bottom of the contactor = 0.2 m.

The material balance for oxygen can be written as

$$Gdy = k_L a([A]^* - [A]_b)dV_D \tag{CS7.25}$$

$$= k_L a\left(H_W \bar{P}_T y - [A]_b\right)dV_D \tag{CS7.26}$$

The direction of V_D has been taken as the direction of increasing y. Integration of Equation (CS7.26) gives

$$V_D = \frac{G}{k_L a\, H_W \bar{P}_T} \ln\left[\frac{H_W \bar{P}_T y_0 - [A]_b}{H_W \bar{P}_T y_e - [A]_b}\right] \tag{CS7.27}$$

$[A]_b$ can be obtained from an overall material balance as

$$G(y_0 - y_e) = \frac{L}{Z}\left([B]_0 - [B]_e\right) = V_D \varepsilon_L k_2 [A]_b [B]_e \tag{CS7.28}$$

Eliminating $[A]_b$ between Equations (CS7.27) and (CS7.28) gives

$$V_D = \frac{G}{k_L a\, H_W \bar{P}_T} \ln\left[\frac{y_o - \dfrac{\delta}{V_D}\left([B]_0 - [B]_e\right)}{y_e - \dfrac{\delta}{V_D}\left([B]\right)_0 - [B]_e}\right] \tag{CS7.29}$$

where

$$\delta = L/\left(\varepsilon_L Z k_2 H_W \bar{P}_T [B]_e\right)$$

In this example, we have selected the following parameter values:

$P_B = 1.0133 \times 10^5$ Pa (excluding vapor pressure of water)
$P_T = 6.27 \times 10^4$ Pa (excluding vapor pressure of water)
$\bar{P}_T = (P_B + P_T)/2 = 8.20 \times 10^4$ Pa
$k_L a = 0.02\ s^{-1}$
$\varepsilon_L = 0.9$
$\delta = 165$

Substituting these values in the above equation for V_D and solving by trial and error gives $V_D = 333\ m^3$. This liquid volume corresponds to a submergence of 4 m. The cross-sectional area of the contactor corresponding to the liquid submergence of 4 m is equal to 16.83 m^2. Therefore, the length of the contactor

$$L_C = \frac{333}{16.83} = 19.8\ \text{m}$$

Number of nozzles, $N_N = 47$; nozzle gas velocity, $u_N = 70.0$ m/s
Nozzle diameter, $d_N = 0.00735$ m

(For a foaming system, the value of $k_L a$ of 0.02 s^{-1} appears to be reasonable for a horizontal sparged contactor.) The total volume of dispersion for the horizontal sparged contactor = 333 m^3. Furthermore, from the earlier section of this case study under "Operation of Bubble Column under Pressure," it can be seen that the total volume of dispersion for the bubble column = 132 m^3. A comparison between the horizontal sparged contactor and the bubble column can now be made on the basis of the total power consumption.

The power consumption for the horizontal sparged contactor can be calculated using the following equation:

$$\mathbf{P}_H = \frac{\pi}{4} d_N^2 u_N N_N \left[\rho_L \varepsilon_L g \frac{(H_D - 20)}{100} + \frac{\rho_G u_N^2}{2} \right] \quad \text{(CS7.30)}$$

ε_L = fractional liquid holdup = 0.9. Substitution of the relevant values in Equation (CS7.30) gives $\mathbf{P}_H = 5.12$ kW. For the bubble column, the power consumption can be calculated using the following equation:

$$\mathbf{P}_V = \frac{v^*}{v^* - 1} G R_g T \left[\left(\frac{P_B}{P_T} \right)^{\frac{v^*-1}{v^*}} - 1 \right] \quad \text{(CS7.31)}$$

where $v^* = C_p/C_v$, G is the molar flow rate of gas, P_T = pressure at the top of the bubble column, 62.66 kN/m^2, and P_B = pressure at the bottom of the bubble column, 228.38 kN/m^2. Substituting these values in Equation (CS7.31) gives $\mathbf{P}_V = 22.13$ kW. Hence, the horizontal sparged contactor can be advantageously used, as compared to the bubble column, when such an excess of air is used.

5. Pipeline Contactor (PC)

Data

Pure oxygen, 20% in excess over the theoretical requirement; operating pressure = 3.04×10^5 Pa, absolute; liquid-side Reynolds number = 40,000 (to keep the two-phase flow patterns as froth); liquid-side mass transfer coefficient at the entrance (u_G = 0.127 m/s, u_L = 0.077 m/s); $k_L a$ = 0.12 s^{-1}.

Assumptions

The two-phase flow pattern (in this case, froth) does not change along the length of the pipeline. The liquid-side mass transfer coefficient varies linearly with the superficial gas velocity at a constant liquid flow rate. As indicated later, the pressure drop can be neglected.

The fractional liquid holdup can be calculated by the procedure proposed by Lockhart and Martinelli (1949). The values of fractional liquid holdup are calculated to be 0.5 at the inlet (u_G = 0.127 m/s, u_L = 0.077 m/s) and 0.7 at the outlet (u_G = 0.0212 m/s, u_L = 0.077 m/s). The following correlation is assumed to hold for ε_L:

$$\varepsilon_L = -585G + 0.74 \tag{CS7.32}$$

Overall material balance between the inlet and the location where oxygen flow rate is G gives

$$G_0 - G = \frac{L}{Z}\left([B]_0 - [B]\right) \tag{CS7.33}$$

or

$$[B] = [B]_0 - \frac{Z}{L}(G_0 - G) \tag{CS7.34}$$

The material balance for a differential length dz, z cm away from the entrance, gives

$$-dG = R_A aSdz \tag{CS7.35}$$

The values of $k_L a$ and $\varepsilon_L k_2[B]$ are comparable at the entrance and at the exit, as shown below.

	$k_L a$ (s^{-1})	$\varepsilon_L k_2[B]$(s^{-1})
Entrance	0.12	0.357
Exit	0.02	0.0208

Under these conditions, the rate of absorption of oxygen is calculated by the following equation:

$$R_A a = [A]^* \left[\frac{1}{\dfrac{1}{k_L a} + \dfrac{1}{\varepsilon_L k_2 [B]}}\right] \tag{CS7.36}$$

Substitution of Equation (CS7.36) in Equation (CS7.35) gives

$$[A]^* S dz = -dG\left[\frac{1}{k_L a} + \frac{1}{\varepsilon_L k_2 [B]}\right] \quad \text{(CS7.37)}$$

In the pipeline contactor, $k_L a$ is assumed to be proportional to G, i.e.,

$$k_L a = C_1 G \quad \text{(CS7.38)}$$

Substitution of $k_L a$ from Equation (CS7.38) and ε_L from Equation (CS7.32) into Equation (CS7.37) gives

$$dz = \frac{-dG}{S[A]^*}\left(\frac{1}{C_1 G} + \frac{1}{k_2(-585G + 0.74)\left[[B]_o - \frac{ZG_o}{L} + \frac{ZG}{L}\right]}\right) \quad \text{(CS7.39)}$$

Let

$$\delta' = L[B]_0 - ZG_0 \, (Z = 1) \quad \text{(CS7.40)}$$

Therefore,

$$dz = \frac{-dG}{S[A]^*}\left[\frac{1}{C_1 G} + \frac{L}{k_2(-585G + 0.74)(\delta' + G)}\right] \quad \text{(CS7.41)}$$

Integration of Equation (CS7.41) with the boundary conditions

$$\text{at} \quad z = 0 \quad G = G_0$$

$$z = z_T \quad G = G_e \quad \text{(CS7.42)}$$

$$z_T = \frac{1}{S[A]^*}\ln\left(\left(\frac{G_0}{G_e}\right)^{\frac{1}{C_1}}\left[\left(\frac{\delta' + G_0}{\delta' + G_e}\right)\left(\frac{-585G_e + 0.74}{-585G_0 + 0.74}\right)\right]^{v'}\right) \quad \text{(CS7.43)}$$

where

$$v' = \frac{L}{k_2(0.74 + 585\delta')} \quad \text{(CS7.44)}$$

In this problem, the theoretical oxygen requirement is

$$= \frac{L}{Z}\left([B]_0 - [B]_e\right)$$

$$= 2.32 \times 10^{-3}(0.154 - 0.0064) = 0.342 \times 10^{-3} \text{ kmol/s}$$

The oxygen supplied is 20% in excess of the theoretical requirement. Therefore,

$$G_o = 0.41 \times 10^{-3} \text{ kmol/s and } G_e = (0.41 - 0.342) \times 10^{-3} = 0.068 \times 10^{-3} \text{ kmol/s}$$

It is given that the Reynolds number of the liquid = 40,000 and the viscosity of the solution at 75°C = 0.38×10^{-3} Pa·s.

Therefore, diameter of pipeline = 0.197 m; cross-sectional area, S = 0.031 m^2. At the entrance, $k_La = C_1G_o = 0.12$ s^{-1}, $G_o = 0.41 \times 10^{-3}$; therefore $C_1 = 293.68$, and

$$\delta' = L\left([B]_0 - \frac{ZG_0}{L}\right)$$

$$= -5.27 \times 10^{-5}$$

$$[A]^* = (P - P_{H_2O})H_W$$

$$= 1.703 \times 10^{-3} \text{ kmol/m}^3$$

$$v' = L/[k_2(0.74 + 585\delta')]$$

$$= 0.705 \times 10^{-3}$$

Substitution of the relevant values in Equation (CS7.43) gives

$$z_t = 170 \text{ m}$$

In the above case of a pipeline contactor, pure oxygen is used instead of air. The excess of unreacted oxygen, which comes out of the pipeline contactor, can be compressed and reused with the fresh oxygen feed.

Let us consider the use of a large excess of oxygen to reduce the length of the contactor. The above problem is reworked for the case of 250% excess oxygen over the theoretical requirement:

$$G_0 = 1.197 \times 10^{-3} \text{ kmol/s}, \quad G_e = 0.855 \times 10^{-3} \text{ kmol/s}$$

The values of fractional liquid holdup, ε_L, at the inlet and exit are found to be 0.37 and 0.43, respectively. For this case, ε_L can be assumed to be constant and equal to the average value of 0.4.

Following the same procedure as per Equations (CS7.35) through (CS7.44), the length of the contactor can be obtained from the following equation:

$$z_t = \frac{1}{S[A]^*}\ln\left[\left(\frac{G_0}{G_e}\right)^{\frac{1}{C_1}}\left(\frac{\delta' + G_0}{\delta' + G_e}\right)^{v''}\right] \tag{CS7.45}$$

where

$$v'' = L/(\varepsilon_L k_2) = 1.25 \times 10^{-3}, \; C_1 = 292.68$$

$$\delta' = L\{[B]_0 - (ZG_0/L)\} = -0.84 \times 10^{-3}$$

Substitution of these values in Equation (CS7.45) gives

$$z_t = 101 \text{ m}$$

Hence, the increase of oxygen from 20 to 250% excess gives a relatively small decrease in the contactor length from 170.0 m to 101.0 m.

Pressure drop in the pipeline contactor can be calculated from the procedure given by Lockhart and Martinelli (1949):

$$D = 0.194 \text{ m},\ u_L = 0.0773 \text{m/s},\ u_G = 0.074 \text{ cm/s},\ \rho_L = 1000 \text{ kg/m}^3,\ \rho_G = 3.4 \text{ kg/m}^3$$

$$(\text{Re})_L = 40{,}000,\ (\text{Re})_G = 2030,\ f_G = 0.00788$$

$$(\Delta P / \Delta L)_L = 3.384 \times 10^{-4} \left(\text{kN/m}^2\right)/\text{m}$$

$$X_L = \left[\left(\frac{\Delta P}{\Delta L}\right)_L \Big/ \left(\frac{\Delta P}{(\Delta L)}\right)_G\right]^{1/2} = 15.21$$

$$(\Delta P/\Delta L)_G = 1.462 \times 10^{-6} \left(\text{kN/m}^2\right)/\text{m}$$

X_L is the X-parameter in the Lockhart–Martinelli correlation. For both the gas and the liquid phases under turbulent conditions, the ordinate values can be obtained from the Lockhart–Martinelli chart. Thus, $y_L = 2.5$, where y_L is the Y-parameter in the Lockhart–Martinelli correlation.

Therefore, the total two-phase pressure drop

$$= y_L \times (\Delta P/\Delta L)_L \times \text{total length}$$

$$= 143.82 \text{ N/m}^2$$

6. Packed Column (PC)

Data

Superficial gas velocity = 0.1 m/s, liquid-side mass transfer coefficient, $k_La = 5 \times 10^{-3}\ \text{s}^{-1}$, effective gas-liquid interfacial area, $a = 100\ \text{m}^2/\text{m}^3$. The material balance between any section of the column and the outlet gives

$$G(y - y_e) = \frac{L}{Z}([B]_0 - [B]) \quad \text{(CS7.46)}$$

Equation (CS7.46) on rearrangement gives

$$y = \gamma - \alpha'[B] \quad \text{(CS7.47)}$$

where

$$\alpha' = L/(ZG) \quad \text{(CS7.48)}$$

$$\gamma = y_e + \alpha'[B]_0 \tag{CS7.49}$$

Material balance across a differential height dh of the column gives:

$$\frac{L}{Z} d[B] = R_A aSdH \tag{CS7.50}$$

At the top of the column,

$$\varepsilon_L k_2[B]_o = 0.0715\ s^{-1};\quad k_L a = 0.005\ s^{-1}\quad \text{and}\quad \sqrt{M} = 1.39;\quad \varepsilon_L = 0.1$$

where

$$\sqrt{M} \text{ is } \sqrt{\mathbf{D}_A k_2 [B]_0} / k_L$$

From the above values, it can be seen that

$$k_L a << \varepsilon_L k_2 [B]_b \tag{CS7.51}$$

and

$$\sqrt{M} = 1 \tag{CS7.52}$$

At the bottom of the column,

$$\varepsilon_L k_2 [B]_e = 2.98 \times 10^{-3} s^{-1},\quad k_L a = 0.005\ s^{-1},\quad \sqrt{M} = 0.284$$

Therefore,

$$k_L a = \varepsilon_L k_2 [B]_0,\quad \sqrt{M} << 1 \tag{CS7.53}$$

Based on Equations (CS7.51) and (CS7.52) at the top of the column, the reaction falls in between regimes 1, 2, and 3. From Equation (CS7.53), at the bottom of the column, the reaction falls in between regimes 1 and 2. Thus, the following equation holds for $R_A a$ in the entire column:

$$R_A a = a[A]^* \left[\frac{1}{\frac{1}{\sqrt{\mathbf{D}_A k_2 [B] + k_L^2}} + \frac{a}{\varepsilon_L k_2 [B]}} \right] \tag{CS7.54}$$

Substituting $R_A a$ from Equation (CS7.54) into Equation (CS7.50) and using Henry's law ($[A^*] = H_W P_T y$), we get

$$\frac{L}{Z}d[B]=\left[\frac{ayP_TH_W}{\dfrac{1}{\sqrt{\mathbf{D}_Ak_2[B]+k_L^2}}+\dfrac{a}{\varepsilon_Lk_2[B]}}\right]Sdh \tag{CS7.55}$$

Substituting y from Equation (CS7.47) into Equation (CS7.55) and simplifying gives

$$d[B]=dH\left[\frac{\beta^*(\gamma-\alpha'[B])}{\dfrac{1}{\sqrt{[B]+\delta_1^2}}+\dfrac{\eta}{[B]}}\right] \tag{CS7.56}$$

where

$$\beta^*=\frac{ZaSH_WP_T\sqrt{\mathbf{D}_Ak_2}}{L} \tag{CS7.57}$$

$$\delta_1=\frac{k_L}{\sqrt{\mathbf{D}_Ak_2}},\quad \eta=\frac{a\sqrt{\mathbf{D}_Ak_2}}{\varepsilon_Lk_2} \tag{CS7.58}$$

Integration of Equation (CS7.56) between $h = 0$, $[B]_b = [B]_e$, and $h = H([B]_b = [B]_o)$ gives

$$H=\frac{1}{\beta^*\alpha'\sqrt{(\delta_1^2)+(\gamma/\alpha')}}\ln\left[\frac{\sqrt{\delta_1^2+[B]_0}+\sqrt{\delta_1^2+(\gamma/\alpha')}}{\sqrt{\delta_1^2+[B]_0}-\sqrt{\delta_1^2+(\gamma/\alpha')}}\times\frac{\sqrt{\delta_1^2+[B]_e}-\sqrt{\delta_1^2+(\gamma/\alpha')}}{\sqrt{\delta_1^2+[B]_e}+\sqrt{\delta_1^2+(\gamma/\alpha')}}\right]$$
$$+\frac{\eta}{\gamma\beta^*}\ln\left[\frac{[B]_0(\gamma/\alpha')-[B]_e}{[B]_e(\gamma/\alpha')-[B]_0}\right] \tag{CS7.59}$$

$L = 2.32 \times 10^{-3}$ m^3/s, $[B]_0 = 0.154$ kmol/m^3, $[B]_e = 6.4 \times 10^{-3}$ kmol/m^3

$$y_0=\frac{0.21(760-290)}{760}=0.13$$

The oxygen supplied is 200% in excess over that theoretically required. We also assume that G remains constant. Therefore, $y_e = (2/3) \times 0.13 = 0.0867$.

From overall material balance,

$$G(y_0-y_e)=\frac{L}{Z}([B]_0-[B]_e) \tag{CS7.60}$$

Substitution of the relevant values in Equation (CS7.60) gives $G = 7.91 \times 10^{-3}$ kmole/s.

The superficial gas velocity, u_G, is equal to 0.1 m/s (assumed).

Hence, S = 3.652 m^2, and D = 2.16 m.

$$\alpha' = L/(ZG) = 0.293, \quad \gamma = y_e + \alpha'[B]_0 = 0.1319$$

$$\beta^* = \left[ZaSH_W P_T \sqrt{\mathbf{D}_A k_2}\right]/L = 9.85 \times 10^{-3}$$

$$\delta_1 = k_L / \left(\sqrt{\mathbf{D}_A k_2}\right) = 0.281$$

$$\delta = \left(a\sqrt{\mathbf{D}_A k_2}\right)/\left(\varepsilon_L k_2\right) = 0.038$$

Substituting the relevant values in Equation (CS7.59), H can be calculated and is found to be 469 m, i.e., an abnormally large packed column. Such a column provides very low liquid holdup (0.03 to 0.1), and the present oxidation reaction occurs in the liquid phase. Therefore, a packed column should be rejected.

A comparison of all the equipment is presented in Table CS7.3. For all the cases, the reactor volume and power consumption are given. The former indicates the capital cost, whereas the latter indicates the operating cost. A preliminary comparison reveals that SBC and EL-ALR are comparable but superior to the conventional BC. The volume of HSR is approximately 5.4 to 5.8 times higher than SBC or EL-ALR. However, the power consumption is low (0.25 and 0.362 times lower, respectively). Although the power consumption of the PC is very low, the capital cost of the packed volume would be prohibitive.

Lesson

This case study on oxidation of sodium sulfide illustrates the design of a variety of gas-liquid reactors and compares their performances. Bubble column reactors are particularly attractive, as they offer advantages such as simplicity of construction and operation, but they suffer from such drawbacks as high pressure drop and backmixing in the liquid phase. To reduce the pressure drop, two modifications have been considered: an external-loop air-lift reactor and a horizontal sparger reactor. Both result in substantial energy savings (because of low ΔP) under similar conditions of capacity and conversions in the gas and liquid phases.

The other limitation of liquid-phase backmixing has been addressed through the modification of sectionalization. In this manner, near plug-flow behavior is achieved, and the column height is reduced to as much as 60%. The reduction in height reduces the equivalent pressure drop and hence the energy consumption for air compression.

The case study demonstrates yet another peculiar behavior of bubble columns: steep reduction in oxygen partial pressure from bottom to top, mainly a result of the change in total pressure due to hydrostatic head. Such a situation results in column underutilization. To overcome this problem, guidelines have been given, with detailed calculations indicating substantial savings.

The effects of a few other important parameters have also been considered, but the study should be extended to include investigation of all of them. Cost considerations in selecting parameters such as temperature, pressure, excess oxygen, height-to-diameter ratio, and so forth play an important role in final selection. Cost implications in the design and selection of downstream equipment also constitute a major factor. The philosophy and details of design outlined above for bubble columns should be extended to include other gas-liquid reactors. For instance, for packed columns, the type, size, and cost of different packings (offered by different vendors) should be examined by careful selection of liquid distributors, redistributors, and packing supports.

A practically useful table, presented in Section 11.4 (Table 11.26), provides valuable guidelines for the selection of gas-liquid reactors. Other reactor configurations should be considered and a table similar to Table 11.26 prepared.

Case Study 11.8 Gas-Liquid Reaction: Absorption of NO_x Gases for the Manufacture of Nitric Acid (a System with Multiple Complexities)

Nomenclature for Case Study 11.8

D	diffusivity (m^2/s)
H_W	Henry's constant ($kmol/m^2(kN/m^2)$)
$H_W \sqrt{k\mathbf{D}}$	absorption factor for fast pseudo-first-order reaction ($kmol/m^2(kN/m^2)s$)

The Problem

Absorption of NO_x gases is an important step in the manufacture of nitric acid. It is one of the most complex of all absorption operations, because of the following. (1) The NO_x gas contains NO, NO_2, N_2O_3, N_2O_4, and so on, and the absorption of NO_x gases in water results in both nitric acid and nitrous acids. (2) Several reversible and irreversible reactions occur in both the gas and liquid phases. (3) Simultaneous absorption and desorption of several gases occurs, followed by chemical reaction; the absorption of NO_2, N_2O_3, and N_2O_4 is accompanied by chemical reactions, whereas the desorption of NO, NO_2, and HNO_2 is preceded by chemical reactions. (4) Equilibria prevail between various components in each phase. (5) Heterogeneous equilibria also prevail between the gas phase and liquid phase components. Sherwood et al. (1975) and Joshi et al. (1985) have reviewed NO_x absorption.

For the design of NO_x absorption towers, it is necessary to understand the several equilibria and the rates of mass transfer and chemical reaction. The mechanism of NO_x absorption in water has been given by Pradhan et al. (1997). Furthermore, substantial heat effects are associated with NO_x absorption resulting in temperature variations. These aspects of the reaction, along with a mathematical model, method of solution, and an optimum design strategy, have been described by Pradhan et al. (1997). *Note: the tables and figures referred to in this section are from the original reference.* Some results are given below.

Effect of Various Parameters

To get the number of stages needed for the desired absorption, operating variables such as pressure, temperature, and heights of submergence and empty sections were varied over a wide range. The capacity of the absorber was 750 tons/day (100% basis), and 30% excess oxygen was used. Values of the parameters are listed in Table 5 in the original reference.

The effects of total pressure, height of submergence, and height of empty section on the number of plates have been studied as a function of the outgoing NO_x concentration (up to 20 ppm level). Figures 3-A, 3-B, and 3-C show the effect of height of empty section at weir heights of 0.025, 0.05, and 0.1 m, respectively, and at 1.3 MPa pressure. At higher empty section heights, fewer plates are required. Although the number of plates decreases, this does not necessarily mean that the total height decreases. In many cases, the total height increases with an increase in the height of empty section. Tables 6, 7A, and 7B of the original reference indicate that the total height increases with an increase in the height of the empty section. The increase is nominal when the empty height is increased from 0.4 to 0.7 m. This result is useful because the cost associated with many stages can be reduced. However, a similar result is not obtained when the empty height is increased to 4 m and then to 10 m. The total height substantially increases in such a case.

The effect of liquid submergence has also been investigated. The results are summarized in Tables 6, 7A, and 7B for outlet NO_x concentrations of 700 and 20 ppm. Four levels of liquid submergence (weir height) were considered: 25, 50, 100, and 200 mm. It can be seen that the number of plates decreases with an increase in the height of liquid submergence. The decrease is small when the submergence is increased from 100 to 200 mm. Furthermore, from Tables 6, 7A, and 7B of the original reference, the effect of the empty section is more dominant than that of weir height.

The effect of temperature is shown in Table 7B of the reference. The number of plates increases with increased temperature. However, it is not advantageous to operate the absorption column at

temperatures requiring significant refrigeration. The rate of heat removal due to vaporization of a liquid refrigerant (often ammonia) can be used advantageously in the top section, where the rate of oxidation is very low. Most heat is usually removed in the bottom section of the column by the ambient water. Hence, the operating temperature is decided by the ambient temperature, and the optimum heights for empty section and submergence section can be selected rather directly. However, the optimum temperature and pressure depend on the geographical location of the nitric acid plant and the cost of power. The costs will be considered in the optimum design strategy.

Optimum Design

The total cost ($/day) was estimated at two levels of outlet NO_x concentration, 700 and 150 ppm. The sensitivity of fixed cost was studied by assuming stainless steel prices at two levels: $3.52/kg and $7.04/kg. The results are in Tables 9A and 9B for different combinations of weir and empty section heights at five levels of total pressure, 0.4, 0.71, 1.01, 1.31, and 2.02 MPa. As indicated, pressure is a major parameter governing the fixed cost. To understand the overall effect of fixed and operating costs, the daily contribution was estimated on the basis of 25 and 45% of the fixed cost as the yearly (300 days) expenditure. For this case, 95% of the compressor energy was assumed to be recoverable, i.e., 5% of the cost of compression was included in the operating cost. The analysis was performed at a height of 0.025 m, with empty section height as parameter. The results are shown in Figures 6A and 6B for 700-ppm, and in Figures 6C and 6D for 150-ppm, outlet concentration. The following observations can be noted: (1) For empty heights of 0.4 and 0.7 m, the total cost decreases monotonically with increase in pressure. The reduction is sharp up to 1 MPa and thereafter minimal. (2) For empty heights of 1.5, 4, and 10 m, the total cost curves show minima. The curve for 1.5 m is shallow, whereas it is deep for 10 m and in between for 4 m. The optimum pressure decreases with an increase in empty height. However, it must be emphasized that the optimum costs (at minima) for 4- and 10-m empty heights are higher than those for 0.4-, 0.7-, and 1.5-m empty heights. (3) The total costs for three empty heights (0.4, 0.7, and 1.5 m) are comparable-being in the range 0.7 to 1.0 MPa. (4) The optimum plate spacing depends on the fixed cost components. For instance (from Figures 6E and 6F of the original reference), at 0.4 MPa pressure, the total cost is minimum for 4-m empty height. With an increase in pressure, the optimum height decreases. Thus, the optimum heights are 1.5, 0.7, and 0.4 m at pressures of 0.7, 1.0, and 1.3 MPa, respectively. Suchak and Joshi (1994) and Pradhan et al. (1997) have examined the effects of mass transfer characteristic and residence time on the designs of packed and plate column.

Lesson

Examples of simple reactions (such as considered in Case Study 11.7) are not hard to find in industry, but those of complex reactions are more widespread. One can envisage systems with increasing complexities such as the manufacture of nitric acid. The complexities include the following: (1) multiple (parallel) reactions by the same reactant, (2) reactions in series, (3) multiple reactions among multiple reactants, (4) reversible reactions, (5) reactions in multiple phases, and (6) simultaneous mass transfer with chemical reactions. These complex problems can be tackled if sufficient details of the following are provided: (1) reaction chemistry, (2) rate expressions, (3) rate constants, and (4) diffusivities and solubilities in the case of multiphase systems. The kinetics of each reaction can be determined in the laboratory by (1) ensuring conditions that make the desired step rate controlling and (2) minimizing/suppressing the other reactions. In some cases, lumped parameters such as $H\sqrt{k\mathbf{D}}$ can be obtained and used directly.

Although one can progressively account for one additional complexity at a time, it is also possible to take a direct leap to a problem with a combination of complexities, as illustrated in this case study on NO_X absorption in the manufacture of nitric acid. The NO_X absorption system may contribute about 40% of the total equipment cost. Hence, optimal design of the NO_X absorption tower is important; major cost-determining factors should be identified and selectively addressed with greater rigor.

Case Study 11.9 Gas-Liquid-Solid (Noncatalytic) Reaction: Oxydesulfurization of Coal in a Slurry Reactor

Nomenclature for Case Study 11.9

$[A]s$	concentration of dissolved solute gas at the solid surface (kmol/m^3)
$[A]_e$	concentration at the exit (kmol/m^3)
b	stoichiometric coefficient
b_r	eigenvalues of Equation (CS9.10)
C	concentration of tracer (kmol/m^3)
c	dimensionless concentration of tracer
c_0	dimensionless concentration of tracer at the inlet
D	reactor diameter (m)
H	reactor height (m)
$\mathbf{D}_e$	effective diffusivity through ash layer (m^2/s)
$\mathbf{D}s$	dispersion coefficient (m^2/s)
$E(\theta)$	exit age distribution function
k_r	rate constant for surface reaction
L	length (m)
N_C	critical stirrer speed (rps)
P	pressure (MPa)
Pe	Peclet number
Q	amount of the pulse tracer
R	particle radius (m)
r	radius of shrinking core (m)
S_{wb}	ratio of wake to bubble volumes (–)
T	temperature (K)
T_r	eigenvalue Equation (CS9.10)
$\bar{t}$	average residence time (s)
t	time (s)
u_G	superficial gas velocity (m/s)
u_L	superficial gas velocity (m/s)
u_S	settling velocity (m/s)
u_{SL}	slurry velocity (m/s)
u_c	circulation velocity (m/S)
X	conversion (–)
$\bar{X}$	overall conversion (–)
z	distance
Z	dimensionless distance (z/L)

Greek

ε_S	solid holdup
ε_G	gas holdup (–)
δ	film thickness at the interface (m)
ρ_B	density of component B (kg/m^3)
τ	time required for complete conversion (s)
θ	dimensionless time (t/τ)

The Problem

Precombustion of sulfur from coal by selective oxidation is an important step in coal cleaning, without the need for a postcombustion cleanup step to remove sulfur oxides. This process, known as *oxydesulfurization of coal*, is a three-phase gas-liquid-solid system. As an example, a sparged reactor will be designed to oxydesulfurize 100 tons/day of coal in an aqueous slurry of coal with air.

Data

The reaction temperature and the water vapor pressure are 466 K and 1.36 MPa, respectively. The coal particle size is 100μm. At the operating temperature of 460 K and in the range of H_2SO_4 concentrations encountered in oxydesulfurization, the vapor pressure of sulfuric acid is below 1×10^{-2} Pa. The operating pressure is in the range of 2 to 7 MPa, and thus most of the sulfuric acid will remain in the liquid phase. For simplicity, all the sulfur is assumed to be in the form of FeS_2 (content = 2.7 wt% of coal). The bulk density of coal is 889 kg/m³ and of water for making the slurry is 1000kg/m³. The slurry concentration is 26 wt%.

Determination of the Rate-Controlling Step

The steps during the process of oxydesulfurization are as follows:

1. Transfer of oxygen through the gas-liquid film
2. Transfer of oxygen through the liquid-solid film
3. Diffusion of oxygen through the ash layer
4. Chemical reaction between the dissolved oxygen and FeS_2 at the solid surface

The mechanism of oxydesulfurization of coal has been extensively investigated by Vracar et al. (1970), Friedman and Warzinski (1977), Vetter (1967), and Joshi et al. (1982). The dissolution of sulfide minerals can be interpreted as an electrochemical surface reaction similar to the corrosion of metals. Oxygen is reduced at cathodic areas, and sulfides are dissolved liberating electrons to complete the couple.

$$FeS_2 + \frac{7}{2}O_2 + H_2O \rightarrow Fe^{2+} + 2SO_4^{2-} + 2H^+$$

$$2FeS_2 + \frac{15}{4}O_2 + H_2O \rightarrow 2Fe^{3+} + 4SO_4^{2-} + 2H^+ \tag{CS9.R1}$$

$$FeS_2 + 3.75O_2 + 2H_2O \rightarrow 0.5Fe_2O_3 + 2H_2SO_4$$

To determine the rate-controlling step, it is necessary to study all of the four possibilities by experiments over a wide range of particle sizes, temperatures, pressures, and impeller speeds.

The overall reaction may be represented by the shrinking core model (SCM). Laboratory-scale experiments were carried out in a 1-L vessel in the temperature range of 428 to 488 K and total air pressure range of 3.44 to 7.88 MPa. Coal particles of practically uniform size were used for the experiments, and coal loading was varied over a range of 0.025 to 0.22 kg/L of water. The experiments were carried out by changing the stirrer speed, and it was observed that, above a certain critical speed (N_c), the rate was independent of the speed. Therefore, the gas-liquid and liquid-solid mass transfer resistances can be considered to be negligible when the stirrer speed is higher than N_c. Thus, the process becomes either ash diffusion controlled or chemical reaction controlled. The experiments over the temperature range mentioned enabled the estimation of the energy of activation, which was found to be 46.5×10^{06} J/kmol. The value of activation energy indicates that the overall operation is reaction controlled. The reaction order with respect to oxygen was found to be 0.7 (for reasons reported by Joshi et al., 1981).

To get supporting evidence for the earlier conclusion of the reaction-controlled operation, the fractional conversion of FeS_2 (in coal) with time was studied, and the time required for complete conversion was also obtained. The following SCM relationships were used (see Section 11.3.2.1.1) to determine the controlling mechanism. For ash diffusion control,

$$\frac{t}{\tau} = 1 - 3(1 - X)^{2/3} + 2(1 - X) \tag{CS11.9.1}$$

where

$$\tau = \frac{\rho_B R^2}{6Z\mathbf{D}_e[A]_s} \tag{CS9.2}$$

is the time for complete conversion. For chemical reaction control,

$$\frac{t}{\tau} = 1 - (1 - X)^{1/3} \tag{CS9.3}$$

where

$$\tau = \frac{\rho_B R}{Zk_r\left[A\right]_S^{0.7}} \tag{CS9.4}$$

The experimental conversion-time relationship was found to agree with Equation (CS9.3). Furthermore, the experimental value of t was found to be proportional to R. From these two observations, and also from the value of activation energy, it was concluded that the oxydesulfurization process of coal is chemical reaction controlled. For coal of 100 μm size, the time required for complete conversion was found to be 1160 s.

Design of Three-Phase Sparged Reactor

The following assumptions have been made:

1. The variation in total pressure due to static head of liquid is small as compared to the total pressure.
2. Conversion of solute in the gas phase is small. Thus, the extent of backmixing in the gas phase is unimportant. The interfacial concentration of the solute gas will be calculated at the log mean partial pressure of the inlet and the outlet.
3. As a consequence of assumptions 1 and 2, the superficial gas velocity, gas holdup, and liquid-solid mass transfer coefficient remain practically constant along the length of the reactor.
4. Solid loading is uniform in the reactor. This assumption is reasonable, since the particle size is small, and/or the density difference between the solid and liquid is small.
5. As discussed before, the rate-controlling step is the surface reaction between dissolved oxygen and FeS_2. It is assumed that, under the hydrodynamic and other operating conditions, the assumption of the rate-controlling step holds.
6. Since the particles retain their identity in the reactor and the rate equations are nonlinear, a residence time distribution model will be used. The particle slip velocity was found to be negligible as compared with the liquid-phase circulation velocities, which govern the dispersion coefficient. It will be assumed that the axial dispersion coefficients for the solid and liquid phases are practically the same. Thus, the exit age distribution for the solid particles can be found by following the procedure for the liquid phase.
7. The particles are spherical and of uniform size.
8. The reactor is operated under isothermal conditions at 460 K.

The residence time distribution is obtained by solving the following material balance equation for a tracer:

$$\frac{\partial c}{\partial \theta} = \frac{1}{Pe}\frac{\partial^2 c}{\partial Z^2} - \frac{\partial c}{\partial Z} \tag{CS9.5}$$

where c is the dimensionless concentration, and other dimensionless parameters are

$$Z = z/L, \quad e = \frac{L\,u_{SL}}{(1-\varepsilon_G)\mathbf{D}s}, \quad \theta = \frac{tu_{SL}}{L(1-\varepsilon_G)} \tag{CS9.6}$$

The boundary conditions are

$$c_0 = c\,|_{0^-} = c\,|_{0^+} - \frac{1}{Pe}\frac{\partial c}{\partial Z}\,|_{0^+} \text{ at Z = 0} \quad \text{for all } \theta$$

$$\frac{\partial c}{\partial Z} = 0 \text{ at } Z = 1, \quad \text{for all } \theta \tag{CS9.7}$$

$$c = 0 \text{ at } \theta = 0, \quad \text{for all } Z$$

The parameters are

$$\int_0^\infty c dt = \int_0^\infty (C/Q)\,dt = 1 \tag{CS9.8}$$

and

$$Q = \int_0^\infty C dt \tag{CS9.9}$$

where C is the actual concentration at the exit, and Q is the amount of pulse tracer. When solved in dimensionless form, the exit age distribution is given as

$$E(\theta) = 2\exp(Pe/2)\sum(-1)^{r+1}\exp(T_r,\theta)\frac{b_r^2}{\frac{4}{Pe}+1+b_r^2} \tag{CS9.10}$$

where b_r is the root of

$$b_r = \tan\left(r\frac{\pi}{2} - \frac{Peb_r}{4}\right) \quad \text{and} \quad T_r = \left(-\frac{Pe}{4}\right)\left(1+b_r^2\right)$$

For the case of continuous feed of particles to a bubble column slurry reactor, with an exit age distribution of particles E(θ), a mass balance gives

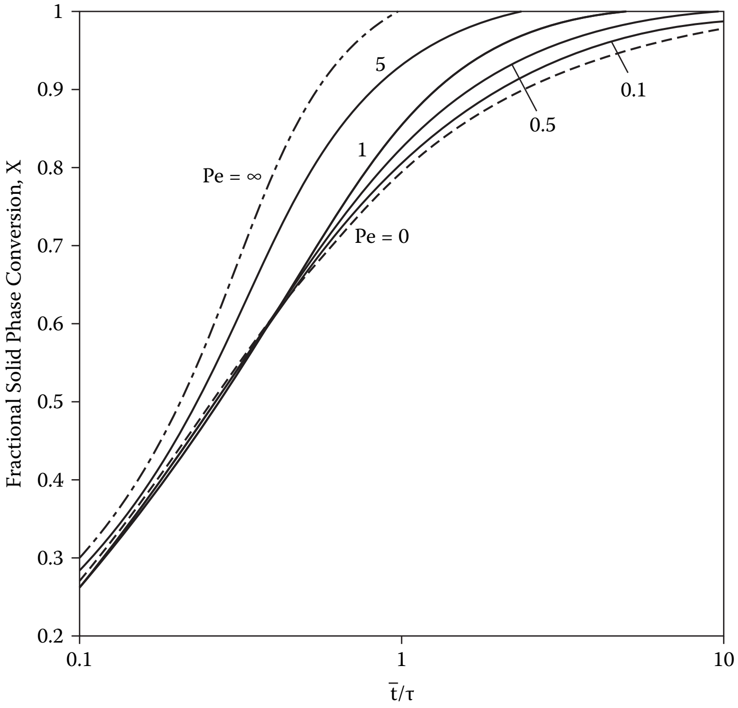

FIGURE CS9.1 Performance diagram of a three-phase reactor where the solid phase undergoes reaction: overall solid phase conversion with respect to dimensionless residence time, with Peclet number as parameter.

$$1-\bar{X}=\int_{0}^{\tau/\bar{t}}(1-X)E(\theta)d\theta \tag{CS9.11}$$

where $E(\theta)$ is given by Equation (CS9.10), X is the conversion of particles with ages between θ and $(\theta + d\theta)$, and $\bar{X}$ is the overall average conversion. For the present reaction-controlled mechanism, $\bar{X}$ is given by Equation (CS9.3). The solution of Equation (CS9.11) is shown graphically in Figure CS9.1. The figure also includes the two extreme cases of plug-flow and backmixed conditions.

Design

Data

Coal to be treated = 100 tons/day, FeS_2 content in coal is 22.5 kmol/day. By stoichiometric balance given in reaction scheme CS9.R1, oxygen required = 84.37 kmol/day.

As a first case, let us consider 200% excess oxygen, which corresponds to 1205.35 kmoles of air per day. Let us assume an average total pressure of 7.6 MPa, which includes water vapor pressure of 1.36 MPa and air partial pressure of 6.24 MPa. At the operating pressure and temperature, the volumetric flow rate of gas = 31.86 m^3/h or 8.66×10^{-3} m^3/s.

Mass flow rate of slurry = 384.6 tons/day.

Total water required for slurry = 284.615 tons/day, and the volume of slurry = 395.93 m^3/day.

Volumetric flow rate of slurry is 0.0046 m^3/s, and the time required for complete conversion is 1160 s.

Typical Procedure

1. Assume a value for the Peclet number, say 0.3.

2. For obtaining the time required for the desired fractional conversion (99%), Figure CS9.1 can be used over a range of Pe numbers. For example, for $Pe = 0.3$, the ratio of residence time to the time required for complete conversion can be seen to be 6.75.
3. Since $\tau = 1160$ s, the average residence time ($\bar{t}$) becomes 7830 s. The reactor volume is obtained by taking the product of the average residence time and the average flow rate (0.00458 m^3/s) and is 35.88 m^3. This is a slurry volume. If the fractional gas holdup is 5%, and the gas space (over the dispersion) is 20%, the reactor volume is 45.2 m^3.
4. The volumetric gas flow rate is 8.66×10^{-3} m^3/s. If we select a superficial gas velocity of 5 mm/s, the cross-sectional area is 1.766 m^2, and $D = 1.5$ m. For the reactor volume of 45.33 m^3, total height (H) = 25.6 m, and the height of dispersion (H_D) = 21.33 m, which leaves 20% for the gas space. The superficial slurry velocity is obtained from

$$u_{SL} = H\left(1-\varepsilon_G\right)/\,\bar{t} = 0.00259 \text{ m/s} \tag{CS9.12}$$

5. For given superficial gas and liquid velocities as well as temperature and pressure, the fractional gas holdup (and also other design parameters) depends on the nature of the gas-liquid systems. Fortunately, the value of ε_G is independent of column diameter if the operating regime remains unchanged. For the ranges of u_G, u_L, P, and T under consideration, the regime of operation is homogeneous (for further details, refer to Deckwer, 1992; Joshi et al., 1998). Therefore, it is usually recommended that a few experiments be performed in a small-scale column (at least 150 mm I.D.) in the ranges of interest of u_G, u_L, P, and T as used for large-scale columns. For the present values of these variables, let ε_G be 0.05 and the slip velocity 0.1 m/s.
6. Similar to ε_G, the dispersion coefficient also depends on the nature of the gas-liquid system. Therefore, it is recommended that the dispersion coefficient be estimated in a small-diameter column. Furthermore, the literature correlation is accepted except for the proportionality constant, which is estimated using the results from 150-mm I.D. column and for the system under consideration.

   Let the resulting correlation be

$$\mathbf{D}_S = 326\left[\frac{DS_{wb}\varepsilon_G u_S}{1-\varepsilon_G - S_{wb}\varepsilon_G}\right]^{1.7} \tag{CS9.13}$$

   where S_{wb} is the ratio of wake to bubble volumes. Kumar and Kuloor (1970) have recommended $S_{wb} = 11/16$. For $\varepsilon_G = 0.05$ and $u_s = 0.1$ m/s, $\mathbf{D}_s$ works out to be 0.0489 m^2/s.
7. The estimated values of the dispersion coefficient can be used to calculate the Peclet number as

$$Pe = \frac{H_D u_{SL}}{\left(1-\varepsilon_G\right)\mathbf{D}_S} = \frac{21.39\times 0.00259}{0.95\times 0.0489} = 1.19 \tag{CS9.14}$$

8. From Figure CS9.1, it can be seen that, for an overall average conversion of 99% at $Pe = 1.19$, $\bar{t}/\tau$ is 3.18. Therefore, $\bar{t}$ = 3683 s and slurry volume = 16.87 m^3 and the reactor volume is 45.29 m^3. Let us select, D = 1.5 m, H = 25.63 m, H_D = 21.36 m. Substitution of these values in Equation (CS9.14) gives $Pe = 1.19$ which is different from the starting

assumed value of 0.3. By following the steps 1 through 8 by trail and error, the dimensions work out to be D = 1.48 m, H = 16.77 m, H_D = 13.9 m, u_{SL} = mm/s and the value of *Pe* was found to be 0.801.

Lesson

Three-phase noncatalytic reactions are of great industrial importance. The present case study is concerned with such a reaction where the reactant goes through a number of steps in series, i.e., oxygen transfer through gas-liquid and liquid-solid films, diffusion through solid ash layer, and finally reaction with the solid. An important requirement in such cases is the use of laboratory information for discerning the rate-controlling mechanism from many plausible candidates prior to scaleup. Moreover, in cases where the solid particles take part in the reaction, the rate equations are nonlinear, adding mathematical complexity to the simulation. Simple dispersion models or even the tanks-in-series model, amply described in the literature, are not applicable in such cases. The present case study shows that models based on exit age distributions and extent of backmixing in the solid phase are useful. A new methodology is suggested for including the extent of backmixing of the solid phase in reactor design. The chief lesson of this study is that, while existing models and procedures may often be useful, the search for new, more directly relevant procedures can often be a rewarding exercise. In this case also, the possibility of optimization should be considered as in Case Study 11.7, and efforts should be made to produce a cost-effective column design.

Case Study 11.10 Gas-Liquid-Solid (Noncatalytic) Reaction: Carbonation of Lime

Nomenclature for Case Study 11.10

$[A]$	concentration of component CO_2 in the liquid phase ($kmol/m^3$)
$[A^*]$	saturation concentration of component *A* at the gas-liquid interface ($kmol/m^3$)
a	interfacial area as defined by Equation (CS10.6) (m^2/m^3)
a_P	interfacial area of the particle (m^2/m^3)
a_{P0}	initial interfacial area of particles per unit volume of dispersion (m^2/m^3)
$[B]$	concentration of OH^- in the liquid phase ($kmol/m^3$)
$[B]_b$	bulk concentration of component *B* ($kmol/m^3$)
$[B]_S$	saturation solubility of component *B* ($kmol/m^3$)
C_D	drag coefficient (–)
D	impeller diameter (m)
$\mathbf{D}_A$	diffusivity of component CO_2 (m^2/s)
$\mathbf{D}_B$	diffusivity of component OH^- (m^2/s)
d	characteristic length (m)
d_b	bubble diameter (m)
d_P	particle diameter (m)
d_{Po}	initial diameter of particle (m)
F_I	inert flow rate (kmol/s)
G_S	mass velocity ($kg/m^2/s$)
g	gravitational constant (m/s^2)
H	height of reactor (m)
H_x	Henry's constant for component *x* ($kmol/m^3$)/(N/m^2)
k_{CO2}	reaction rate constant for CO_2 hydrolysis ($m^3/kmol/s$)
k_La	gas-liquid mass transfer coefficient (1/s)
k_{SL}	solid-liquid mass transfer coefficient (m/s)
$\sqrt{M}$	term defined by Equation (CS10.13) (–)
M_{Wi}	molecular weight of component i (kg/kmol)
N	speed of rotation of impeller (rps)
N_{CD}	critical speed for complete dispersion (rps)

N_{JSG}	critical speed for solid suspension in presence of gas (rps)
N_{max}	maximum operating speed (rps)
n	moles of CO_2 required (kmoles)
P	total pressure (N/m^2)
p_x	partial pressure of component x (N/m^2)
PDN	production (kg)
$\mathbf{P}_O$	power number (–)
$\mathbf{P}_G$	power consumption in presence of gas (W)
$\mathbf{P}_L$	power consumption in absence of gas (W)
Q	volumetric flow rate of gas (m^3/s)
R_A	specific rate of absorption of A ($kmol/m^2$ s)
Re_p	particle Reynolds number (–)
R_g	universal gas constant (J/(kgmol K))
r_A	rate of reaction ($kmol/m^3$ s)
S	cross-section of reactor (m^2)
Sc	Schmidt number, $\mu_L/\rho_L \mathbf{D}_B$ (–)
Sh	Sherwood number, $k_{SL}d_p/D_{AB}$ (–)
T	temperature (K)
$\mathbf{T}$	reactor diameter (m)
u	superficial velocity (m/s)
u_c	circulation velocity (m/s)
u_G	superficial gas velocity (cm/s)
u_{G0}	superficial gas velocity at the inlet (m/s)
$u_{S\infty}$	terminal settling velocity of particle (m/s)
V_D	volume of dispersion (m^3)
V_S	volume of solids (m^3)
W	blade width (m)
X_S	percentage solid loading (%)
x	mol CO_2/ mol inerts (–)
x_1	mole of CO_2/mole of inerts at the inlet (–)
Z	stoichiometric coefficient (–)

Greek

α	constant defined in Equation (CS10.4) (–)
α_1	constant defined in Equation (CS10.3) (–)
β	term defined in Equation (CS10.12) (–)
β_1	constant defined in Equation (CS10.3) (–)
ε_G	gas holdup (–)
ε_L	liquid holdup (–)
ε_S	solid holdup (–)
ε_{S0}	initial solids holdup (–)
γ_P	number of particles per unit volume ($1/m^3$)
η	enhancement factor defined by Equation (CS10.11) (–)
μ_L	viscosity of liquid (kg/m s)
$\bar{\rho}$	average density of the medium (kg/m^3)
ρ_S	density of solid (kg/m^3)
ρ_L	density of liquid (kg/m^3)

Subscripts

D	dispersion
f	final
G	gas

L	liquid
P	particle
S	solid
S-L	solid-liquid
0	initial
1, 2	conditions 1, 2

The Problem

A company has a multipurpose batch plant to produce various chemicals on demand. The plant has a 10 m^3 mechanically agitated sparged reactor (diameter = 2.19 m, height = 2.64 m) for pressures up to 2×10^5 N/m^2. Pure calcium carbonate ($CaCO_3$) is to be produced for toothpaste, cosmetics, and paints. Based on the logistics of the manufacture of $CaCO_3$ by the carbonation of lime, each batch run requires approximately 4 h to complete. Calculate the maximum production of $CaCO_3$ that can be achieved in the existing setup and find the corresponding process conditions using reasonable assumptions.

Data

Gas with 20 mol% CO_2 (rest 80% inerts, N_2) is available from a nearby plant; the reactor has a six-blade pitched (45°) downflow turbine agitator; maximum power delivered to the shaft by the motor = 60,000 W; density of solid $CaCO_3$ = 2700 kg/m^3; density of solid $Ca(OH)_2(\rho_s)$ = 2080 kg/m^3; impeller details: 45° pitch six-bladed downflow turbine, impeller diameter D = 0.9 m, impeller width W = 0.2 m, clearance = 0.7 m, power number P_o = 1.6; $Ca(OH)_2$ initial particle diameter = 0.1 mm; viscosity of water, $\mu_L = 10^{-3}$ Pa·s; diffusivity of CO_2 in water, $\mathbf{D}_A = 2.17 \times 10^{-9}$ m^2/s; diffusivity of OH in water, $\mathbf{D}_B = 3.472 \times 10^{-9}$ m^2/s; Henry's constant for CO_2 solubility in water, $H_{CO_2} = 2.849 \times 10^{-7}$ kmol/m^3/(N/m^2) at 30°C.

Reaction Mechanism

The production of $CaCO_3$ can be represented by the overall reaction

$$Ca(OH)_2(1) + CO_2\,(g) \rightarrow CaCO_3\,(s) + H_2O\,(1) \qquad \text{(CS10.R1)}$$

The steps involved are

1. *Absorption of CO_2,* $CO_2\,(g) \rightarrow CO_2(1)$ (CS10.R2)
2. *Dissolution of* $Ca(OH)_2$, $Ca(OH)_2\,(s) \rightarrow Ca(OH)_2\,(1)$ (CS10.R3)
3. *Ionization of* $Ca(OH)_2$, $Ca(OH)_2\,(1) \rightarrow Ca^{2+}\,(1) + 2\,OH^-\,(1)$ (CS10.R4)
4. *Formation of bicarbonate ion,* $CO_2\,(1) + OH^-\,(1) \rightarrow HCO_3^-\,(1)$ (CS10.R5)
5. *Formation of carbonate ion*, $HCO_3^-\,(1) + OH^-\,(1) \rightarrow H_2O\,(1) + CO_3^{2-}\,(1)$ (CS10.R6)
6. *Formation of $CaCO_3$,* $Ca^{2+}\,(1) + CO_3^{2-}\,(1) \rightarrow CaCO_3\,(1)$ (CS10.R7)
7. *Precipitation of $CaCO_3$*, $CaCO_3\,(1) \rightarrow CaCO_3(s)$ (CS10.R8)

Juvekar (1976) has performed exhaustive experimental and modeling work on this system. According to this study, steps 3, 5, 6, and 7 are very fast. As a result, steps 1, 2, and 4 control the overall rate of reaction.

To calculate the maximum capacity of the reactor for the production of $CaCO_3$, we simulate the reaction for different levels of production per shift and check if the operation is feasible.

Solution

Initially assume a production of 5 tons $CaCO_3$ per batch. Assuming a handling loss of 2%, reaction product = (102/100) × 5 = 5.10 tons = 5100 kg. Molecular weight of $CaCO_3$ = 100, $CaCO_3$ in reaction

product = 5100/100 = 51 kmoles. Stoichiometric $Ca(OH)_2$ required = 51 kmoles, stoichiometric CO_2 required = 51 kmoles. An estimation of the operating parameters is given below.

Gas Flow Rate

CO_2 is available from another plant as a 20 mol% stream (remaining 80% inerts, N_2). Assuming 5% excess CO_2, the gas stream required = (51/0.2) × (105/100) = 267.75 kmoles. Since the reactor can handle up to 2×10^5 N/m² maximum process pressure, choose a lower operating pressure of 1.8×10^5 N/m². Choose room-temperature operation, T = 30°C = 303.16 K. Initial gas volume = $nR_gT/P = (267.75 \times 8314 \times 303.16)/1.8 \times 10^5 = 3749$ m³. Since this volume is very high compared to the reactor volume of 10 m³, choose semibatch mode of operation with continuous supply of feed gas and removal of residual gas to maintain the reactor pressure. In view of this, a slurry of $Ca(OH)_2$ in water is prepared and CO_2 is bubbled through it for 4 h. The mother liquid phase will be initially saturated with $Ca(OH)_2$. As the reaction proceeds, $CaCO_3$ precipitates out. The mother liquor can be separated from the solid $CaCO_3$ precipitate by filtration. For ease of operation and control, assume constant gas flow rate.

Inlet gas flow rate = Q = 3749 m³/(4 h × 3600) = 0.26 m³/s
Reactor inner diameter $\mathbf{T}$ = 2.19 m, height H = 2.64 m
Area of cross section of the reactor $S = (\pi/4)\mathbf{T}^2 = 3.767$ m²
Superficial gas velocity at the inlet, $u_{G0} = Q/S = 0.069$ m/s
F_1, kmol/s of inert = 267.75/(4 × 3600) × mol fraction of inerts
= {267.75/(4 × 3600)} × (1 – 0.2) = 0.0149 kmol/s
x at the outlet = 0.012

Initial solids holdup ε_{S0}:
Of the reactor volume of 10 m³, assume 20% head space.
Volume of the dispersion = 10 × [1 – (20/100)] = 8 m³.
Stoichiometric quantity of CO_2 required for the reaction = 51 kmol/s
Initial weight of $Ca(OH)_2$ = 51 × 74 = 3774 kg.
Density of solid $Ca(OH)_2$, ρ_S = 2080 kg/m³.
Volume of solids V_S = 3774/2080 = 1.814 m³.
Initial holdup of solids, ε_{S0}
$\varepsilon_{S0} = V_S/V_D = 0.2268$.

Gas holdup ε_G:
Assume an impeller speed (N) of 3.82 rps. The gas holdup is calculated using the following correlation (Rewatkar et al. 1993):

$$\varepsilon_G = 3.54\left(\frac{D}{\mathbf{T}}\right)^{2.08}\left(\frac{N^2D}{g}\right)^{0.51}\left(\frac{Q}{(\mathrm{N})D^3}\right)^{0.43} = 0.233 \tag{CS10.1}$$

Liquid holdup ε_L:

$$\varepsilon_L = 1 - \varepsilon_G - \varepsilon_{S0} = 0.54$$

Power consumption:
To calculate the power consumption in the absence of gas (P_L),

$$\text{Average density, } \bar{\rho} = \rho_L\,(1 - \varepsilon_{S0}) + \rho_S\varepsilon_{S0}$$

$$\mathbf{P}_L = \mathbf{P}_O \rho N^3 \mathbf{D}^5 = 65565 \text{ W} \tag{CS10.2}$$

In the presence of gas, the power consumption ($\mathbf{P}_G$) is lower at the same speed. It is estimated using the following correlation of Rewatkar and Joshi (1991b, d):

$$\left(\frac{\mathbf{P}_G}{\mathbf{P}_L}\right) = 0.434\left(\frac{Q}{ND^3}\right)^{-\alpha_1}\left(\frac{N^2D}{g}\right)^{-\beta_1}\left(\frac{W}{D}\right)^{0.174}\left(\frac{D}{\mathbf{T}}\right)^{-0.64} \tag{CS10.3}$$

where $\alpha_1 = 0.064\ \mathbf{T}^{-0.94}$, $\beta_1 = 0.148\ \mathbf{T}^{-1.42}$.

$\mathbf{P}_G$ = 27,941 W. This is less than the maximum available power of 60,000 W that the motor can supply to the impeller. Hence, 3.82 rps is permissible. It will be shown later that the available extra power can be used for extra production capacity.

Critical speeds of agitator: Critical impeller speed for solid suspension
The speed should be adequate to keep the particles suspended. The critical speed for suspension in the presence of gas, N_{JSG}, is calculated from the following correlation (Rewatkar and Joshi 1991d):

$$\frac{\left(u_{S\infty}^{0.5} - \alpha u_c\right)}{N_{JSG}D}\left(\frac{\mathbf{T}}{D}\right)X_S^{0.1}u_G^{0.14} = 0.18 \tag{CS10.4}$$

where

$$\alpha = 0.9u_{S\infty}^{1.27}$$

In this equation for N_{JSG}, $u_{S\infty}^{1.27}$ is the terminal settling velocity of the particle in an infinite medium and is calculated by the standard procedure (McCabe et al., 1993), giving $u_{S\infty}^{1.27}$ = 0.006 m/s. X_S, the percent solids loading = 100 $\rho_S\varepsilon_S/(\rho_S\varepsilon_S + \rho_L\varepsilon_L + \rho_G\varepsilon_G)$ = 46.62.

$$N_{JSG} = 1.15 \text{ rps}$$

Critical speed for complete dispersion N_{CD}:
The speed should be adequate for the gas to be completely dispersed. It is calculated from the following correlation (Harnby et al., 1992):

$$\left(\frac{Q}{N_{CD}D^3}\right) = 0.2\left(\frac{\mathbf{T}}{D}\right)^{0.5}\left(\frac{N_{CD}^2D}{g}\right)^{0.5} \tag{CS10.5}$$

N_{CD} = 1.94 rps. The maximum operating speed N = 3.82 rps. This speed is much higher than N_{JSG} and N_{CD}; hence, the solids are suspended and the gas is completely dispersed.

Interfacial area for gas-liquid mass transfer (a):
The value of a was calculated from the following correlation (Lopes de Figueiredo and Calderbank, 1979):

$$a = 593\left(\frac{P_G}{V_D\varepsilon_L}\right)^{0.25}u_G^{0.75} \tag{CS10.6}$$

$$= 716.9 \text{ m}^2/\text{m}^3$$

Bubble diameter d_b:

$$d_b = 6\varepsilon_G/a = 2 \times 10^{-3} \text{ m}$$

Interfacial area for solid liquid mass-transfer a_{P0}:
Initial particle surface area $a_{P0} = 6\varepsilon_{S0}/d_{P0} = 6 \times 0.2268/0.0001 = 13608.2 \text{ m}^2/\text{m}^3$. As the particle dissolves and reacts, the particle size diminishes until it vanishes.

Schmidt number Sc:

$$Sc = \left(\frac{\mu_L}{\rho_L \mathbf{D}_B}\right) = 288.02, \text{ where } B \text{ denotes OH}^- \text{ ion}$$

As soon as $Ca(OH)_2$ dissolves into the aqueous phase, it ionizes almost completely, being a strong base.

Gas-liquid mass transfer coefficient $k_L a$:
The value of $k_L a$ is estimated using the following correlation (Chandrasekharan and Calderbank, 1981):

$$k_L a = \frac{0.0248}{D^4}\left(\frac{\mathbf{P}_G}{V_D \varepsilon_L}\right)^{0.55} Q^{0.551/\sqrt{D}} = 2.28 \quad \text{(CS10.7)}$$

In the presense of fine particles $k_L a$ decreases and has been assumed to be 0.49 sec^{-1}.

$$k_L = (k_L a)/a = 6.86 \times 10^{-4} \text{ m/s}$$

Solid-liquid mass transfer coefficient k_{SL}:
The value of k_{SL} is estimated using the following correlation (Rowe et al., 1965):

$$Sh = 2.0 + 0.72(\text{Re}_P)^{0.5} Sc^{0.333} \quad \text{(CS10.8)}$$

where

$$\text{Re}_P = \frac{d_P u_{s\infty} \rho_L}{\mu_L} = 0.59, \quad Sh = \frac{k_{SL} d_P}{\mathbf{D}_B} = 5.6$$

$$k_{SL} = 1.96 \times 10^{-4} \text{ m/s}$$

Estimation of batch time for the reaction:
It is assumed that the gas is completely backmixed. Gas-side resistance for mass transfer is neglected. The reaction is performed under isothermal conditions. Initially, a slurry of $Ca(OH)_2$ in water is prepared and the liquid is saturated with $Ca(OH)_2$. Then CO_2 gas is sparged to the reactor. It is assumed that the number of reacting $Ca(OH)_2$ particles per unit volume of the reactor is constant (no breakage or agglomeration) until the particles are completely consumed. The instantaneous rate of reaction is integrated with respect to time until all the $Ca(OH)_2$ is consumed. Thus, the batch time is obtained:

$$CO_2 + 2\,OH^- \rightarrow CO_3^{-2} + H_2O \tag{CS10.R9}$$

For this reaction, $Z = 2$ (stoichiometric coefficient, moles of OH^- required per mole of CO_2). At any instance t, the rate of reaction of the dissolved carbon dioxide with the OH^- is given by

$$R_A = -k_{CO_2}[A][B] \tag{CS10.9}$$

where $[A]$ and $[B]$ denote the concentrations of CO_2 and OH^- in kmol/m^3 and k-ion/m^3 in the liquid phase, respectively. In the presence of mass transfer with fast chemical reaction in the liquid film, the rate of mass transfer of CO_2 is given by

$$R_A a = k_L a[A]^*\eta \tag{CS10.10}$$

where the enhancement factor

$$\eta = \frac{\sqrt{M}}{\tanh\sqrt{M}}\sqrt{\frac{\beta-\eta}{\beta-1.0}} \tag{CS10.11}$$

with

$$\beta = 1 + \frac{[B]}{Z[A]^*}\sqrt{\left(\frac{\mathbf{D}_B}{\mathbf{D}_A}\right)} = 3.46 \tag{CS10.12}$$

$$\sqrt{M} = \frac{\sqrt{\mathbf{D}_A k_{CO_2}[B]_b}}{k_L} = 1.51 \tag{CS10.13}$$

$$[A]^* = H_{CO_2} p_{CO_2}$$

where H_{CO_2} = Henry's law constant for CO_2

Partial pressure of CO_2 is calculated from

$$p_{CO_2} = P\frac{x}{(1+x)}$$

x being the mol CO_2 per mol inert in the gas.

The rate of formation of OH^- by dissolution of $Ca(OH)_2$ is given by $k_{SL}a_P([B]_s - [B]_0)$, where $[B]_S$ is the concentration of OH^- at the solid-liquid interface and is the saturation solubility of $Ca(OH)_2$, and $[B]_0$ = bulk concentration of OH^-.

In the initial stages of the reaction, when the particle size is large, the rate of solid dissolution is high as compared to the rate of CO_2 absorption with reaction. The bulk concentration of OH^- is equal to the saturation concentration $[B]_S$, i.e., $[B]_0 = [B]_S$:

$$\frac{k_{SL}a_P[B]_S}{Z} >> k_L a[A]^*\eta \tag{CS10.14}$$

Therefore

$$R_A a = k_L a \mathrm{H}_{\mathrm{CO}_2} P\left(\frac{x}{1+x}\right)\eta \tag{CS10.15}$$

where x = kmol CO_2/kmol inerts at the outlet and has the same value throughout the backmixed vessel. The above equation is solved for x at any time t and the rate of $CaCO_3$ production (kg/s) is calculated from

$$\frac{d}{dt}(PDN)_{\mathrm{CaCO}_3} = R_A a V_D M_{W\mathrm{CaCO}_3} \tag{CS10.16}$$

As the $Ca(OH)_2$ is consumed, its particle size decreases:

$$-\frac{d}{dt}\left[\gamma_P\left(\frac{\pi}{6}d_P^3\right)\rho_S V_D\right] = R_A a V_D M_{W\,\mathrm{Ca(OH)}_2} \tag{CS10.17}$$

$$-\frac{d}{dt}(d_P) = \frac{2R_A a V_D M_{W\,\mathrm{Ca(OH)}_2}}{\pi\gamma_P\rho_S V_D d_P^2} \tag{CS10.18}$$

where γ_P = number of $Ca(OH)_2$ particles per unit volume of dispersion.

In the final stages of the reaction, when the particle size is very small, the rate of solid dissolution is very low as compared to the rate of CO_2 absorption with reaction. The bulk concentration of OH^-,

$$\frac{k_{SL}a_p[B]_S}{Z} << k_L a[A]^*\eta \qquad [B]_0 = 0 \tag{CS10.19}$$

Thus, the overall rate is governed by the supply of OH^- ions. In this phase, the production rate of $CaCO_3$ is given by

$$\frac{d}{dt}(PDN)_{\mathrm{CaCO}_3} = \frac{1}{2}k_{SL}\left(\gamma_P\pi d_P^2\right)[B]_S V_D(M_{W\,\mathrm{CaCO}_3}) \tag{CS10.20}$$

As the $Ca(OH)_2$ is consumed, there is a corresponding decrease in the particle size:

$$-\frac{d}{dt}\left[\gamma_P\left(\frac{\pi}{6}d_P^3\right)\rho_S V_D\right] = \frac{1}{2}k_{SL}\left(\gamma_P\pi d_P^2\right)[B]_S V_D M_{W\,\mathrm{Ca(OH)}_2} \tag{CS10.21}$$

$$-\frac{d}{dt}(d_P) = \frac{k_{SL}[B]_S M_{W\,\mathrm{Ca(OH)}_2}}{\rho_S} \tag{CS10.22}$$

The rates of production and decrease in particle diameter are integrated with time until the particle vanishes. In this way, the batch time is calculated and is 4.09 h, which is close to the desired batch time for the reaction.

TABLE CS10.1
Production Capacity of a Given Stirred Tank Reactor

Case	Batch Production (Tons)	ε_S	k_La (sec^{-1})	N (sec^{-1})	ε_G	N_{JSG} (sec^{-1})	N_{CD} (sec^{-1})	P_L (W)	P_G (W)
1	4	0.181	0.44	3.23	0.181	1.05	1.94	44151	19094
2	5	0.227	0.49	3.82	0.233	1.11	1.94	65565	27941
3	6	0.272	0.54	4.07	0.277	1.16	1.94	90229	38000
4	7	0.318	0.58	4.36	0.317	1.20	1.94	113945	47554
5	8	0.363	0.60	4.58	0.351	1.24	1.94	134737	55838
6	8.5	0.386	0.61	4.75	0.366	1.30	1.94	143716	59387

Note: In the above table it has been confirmed in all the cases that operating speed is more than critical impeller speed for solid suspension and gas dispersion.

To calculate the maximum attainable production, the above procedure is repeated for different assumed levels of production. The results are shown in Table CS10.1. However, for levels above 8.5 tons per batch, it can be seen that, even after utilizing the maximum motor power of 60 kW, the maximum feasible operating speed is ~30% higher than that required for suspension of the solids in the presence of gas, $N_{max} < N_{JSG}$. This maintains a safe margin to ensure complete suspension. If we increase the production further, then solid and gas holdups are very high, and N_{max} is marginally higher than N_{JSG}, which may not be a safe design.

Hence, the maximum production is 8.5 tons per batch, with a batch reaction time of ~4 h. Extra time of perhaps 0.75 to 1.5 h is of course required to unload, clean, and reload the reactor for the next batch run. The profile of particle diameter as percentage of initial diameter is plotted against time in Figure CS 10.1.

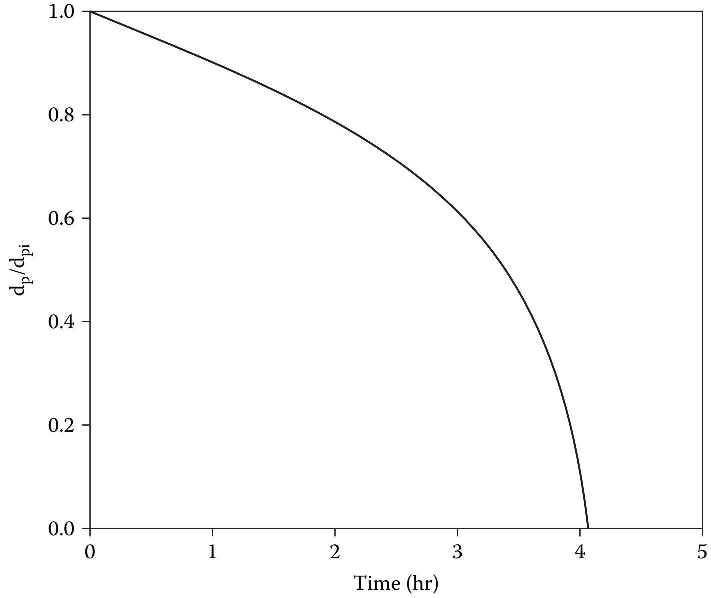

FIGURE CS10.1 The fate of a calcium hydroxide particle in the reactor.

Lesson

This case study is an example of how a common reaction can provide the basis for modeling a novel reaction system: a gas-liquid-solid reaction performed in the batch mode; the solid in this case is first dissolved followed by chemical reaction with a product of the reactive absorption of the solute gas. Unlike Case Study 11.9, where all steps were in series, here some steps occur in parallel. Moreover, the rate-controlling mechanisms often change with time and process conditions. These facets of the problem are dealt with to determine the maximum production capacity of a reactor, which can often be a cost-determining issue. The lesson here is that maximizing the use of an existing reactor is sometimes preferable to designing a new one.

Case Study 11.11 Gas-Liquid-Solid (Catalytic) Reaction: Hydrogenation of an Organic Compound

Nomenclature for Case Study 11.11

A	constant in Equation (CS11.7) (–)
$[A]_b$	bulk concentration of solute gas A (kmol/cm^3)
$[A^*]$	saturation concentration of gas A (kmol/cm^3)
$[A]_S$	surface concentration of gas A (kmol/cm^3)
a_1, b_1, c_1	constants in Equation (CS11.9) (–)
A	effective gas-liquid interfacial area per unit volume (m^2/m^3)
a_P	area of the catalyst particle per unit volume (m^2/m^3)
$[B]_b$	concentration of the liquid phase reactant (gmol/cm^3)
$[B]_S$	surface concentration of B (kmol/cm^3)
C_3	constant in Equation (CS11.6) (–)
D	impeller diameter (m)
$\mathbf{D}_0$	diffusivity (m^2/s)
d_b	bubble diameter (m)
d_P	diameter of catalyst particle (m)
d_P^*	critical particle size of diffusion control operation (m)
Fl	flow number, Q_G/ND^3 (–)
Fr	Froude number, u^2/gd_p (–)
g	gravitational constant (m/s^2)
k_i	rate constant, $i = 1,2,\ldots$ (conc^{1-n}/time)
k_{SL}	solid-liquid mass transfer coefficient (m/s)
k_L	mass transfer coefficient (m/s)
L	characteristic length of the catalyst particle (–)
$\sqrt{M}$	enhancement factor (–)
N	impeller speed (rps)
N_{CG}	critical impeller speed for gas induction (rps)
N_M	impeller speed at which mass transfer resistance is eliminated (rps)
$\mathbf{P}o$	power consumption in absence of gas (W)
$\mathbf{P}_G$	power consumption in presence of gas (W)
Q_G	gas induction rate (m^3/s)
Q_{GS}	rate of gas induction in presence of sparging (m^3/s)
Q_{UG}	net rate of escape of the unreacted gas into the head space (m^3/s)
R	impeller radius (m)
R_A	rate of reaction of A (kmol/m^2 s)
Re	Reynolds number, $d_p u_{G0}\rho/\mu$ (–)
r_A	overall rate of reaction of component A (kmol/(m^3 s))
S	impeller submergence (m)
$\mathbf{T}$	tank diameter (m)
u_{G0}	superficial gas velocity at the inlet (m/s)
u_I	impeller tip speed in Equation (CS11.7) (m/s)
V_L	liquid volume (m^3)
W	solid loading (kg/m^3)

Greek

α^*	constant in Equation (CS11.7) (–)
α_1, α_2, α_3, α_4	constants in Equation (CS11.6) (–)
β_1, β_2, β_3	constants in Equation (CS11.8) (–)
ε	effectiveness factor of the catalyst particles (–)
ε_S	solid holdup (–)
ε_G	gas holdup (–)
λ^*	constant in Equation (CS11.7) (m)
σ	surface tension (N/m)
ρ_L	density of liquid (kg/m^3)

ψ	slip factor (–)

Subscript

G	gas
p	particle
S	catalyst surface
L	liquid

The procedure to determine the rate-controlling step is described below for a gas-liquid-solid reaction. The specific case of a gas-liquid reaction is only a part of this entire process. A reaction sequence between a gas and a liquid (catalyzed by solid particles) involves many steps. These are shown schematically in Figure CS11.1a. As a first step, the gas-phase reactant has to diffuse through a gas film to the gas-liquid interface. If the reaction involves a pure gas such as hydrogen, oxygen, and so on, then the diffusional resistance in the gas phase is generally absent. The gaseous reactant then dissolves in the liquid phase at the gas-liquid interface and is subsequently transported to the bulk liquid through the liquid film. The gaseous reactant and the reactant from the liquid phase then diffuse through the liquid film near the solid catalyst particles. Once they reach the solid surface, both reactants diffuse through the porous catalyst particles. These reactants are then adsorbed on the catalytically active sites. The reaction occurs on these active sites, and products are formed. The products of reaction then have to desorb from such active sites and diffuse through the pores of the catalyst and the liquid film into the bulk liquid.

Obviously, many steps are involved, and any step can be the rate-determining one. In addition, if the reaction is highly endothermic or exothermic (typical of oxidation, hydrogenation reactions), then heat has to be supplied or removed from the reactor. Sometimes the rate of heat transfer may control the overall rate of the reaction. In gas-liquid reactions catalyzed by solid particles, the suspension of catalyst particles can sometimes control the overall rate of reaction. As a first step in the process design portfolio, the rate-controlling step has to be determined, as described below.

The various resistances for mass transfer and the concentration driving force for the transport of the reactants can be seen in Figure CS11.1a. Based on these concentrations and the volumetric transport coefficients, the overall rate of reaction can be written as

$$\begin{aligned} R_A a &= k_L a\left([A]^* - [A]_0\right) \\ &= k_{SL} a_P\left([A]_0 - [A]_S\right) \\ &= \varepsilon k_2 [A]_S [B]_S \end{aligned} \tag{CS11.1}$$

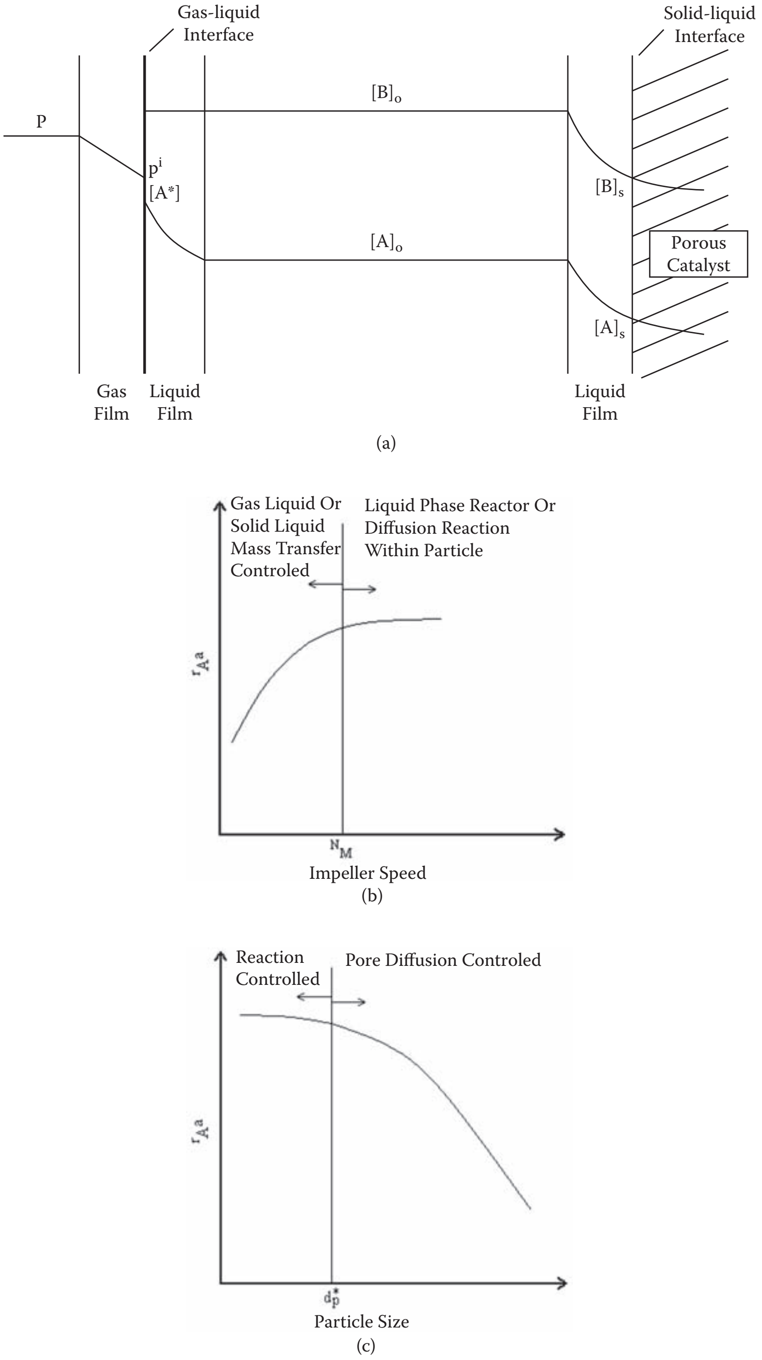

FIGURE CS11.1 The three-phase catalytic reactor: (a) concentration profiles of gas and liquid phase components; (b) effect of impeller speed on overall rate of reaction; and (c) effect of particle size on overall rate of reaction at stirrer speeds higher than N_M. (From Patwardham, A. W. and Joshi, J. B., 1998.)

Here, ε is the effectiveness factor of the catalyst particle (see Section 11.3). Eliminating $[A]_0$ and $[A]_s$ and rearranging,

$$\frac{[A]^*}{R_A a} = \frac{1}{k_L a} + \frac{1}{k_{SL} a_P} + \frac{1}{\varepsilon k_2 [B]_S} \tag{CS11.2}$$

The gas-liquid and the solid-liquid interfacial areas per unit volume can be written in terms of the holdup of the respective phases and the mean bubble/particle diameter. Assuming the bubbles and particles to be spherical, Equation (CS11.2) takes the following form:

$$\frac{[A]^*}{R_A a} = \frac{d_b}{6 k_L \varepsilon_G} + \frac{d_P}{6 k_{SL} \varepsilon_S} + \frac{1}{\varepsilon k_2 [B]_S} \tag{CS11.3}$$

This equation is very useful in determining the rate-controlling step.

The gas-liquid-solid reaction under investigation is performed in a laboratory-scale stirred contactor (500 mL to 2 L). The catalyst type, solid loading, particle size, and reaction conditions (temperature and pressure) are chosen. Under these conditions, the impeller speed is varied, and the overall rate of reaction is monitored. At low impeller speeds, the gas-liquid and solid-liquid mass transfer coefficients ($k_L a$ and $k_{SL} a_P$) are low. The overall reaction is therefore mass transfer controlled. As the impeller speed increases, the values of these mass transfer coefficients increase, and as a result the overall rate of reaction increases. This is shown in Figure CS11.1b. At high impeller speeds, the rates of gas-liquid and solid-liquid mass transfer are high, and the overall rate of reaction is limited by the reaction kinetics or diffusion through the porous catalyst particles. The speed above which the overall reaction is controlled by internal diffusion or chemical reaction is denoted as N_M.

At impeller speeds above N_M, the second or third term on the right-hand side of Equation (CS11.3) becomes controlling; i.e., the overall rate is controlled by intrinsic chemical reaction or pore diffusion. Under such conditions, if experiments are performed at different particle sizes, then the effects of internal diffusion and chemical reaction can be elucidated.

For a first-order chemical reaction occurring within the catalyst particle, the effectiveness factor of the catalyst particle is given as

$$\varepsilon = \frac{\tanh(\phi)}{\phi} \tag{CS11.4}$$

Here, ϕ is given by $\phi = s\sqrt{k_1 / \mathbf{D}}$. where s is the generalized length defined by Equation (11.49). At speeds higher than N_M, the reaction occurs with different particle sizes, and a graph of the overall rate of reaction vs. particle size is plotted. Such a graph is shown in Figure CS11.1c. For small particle sizes, the pore diffusional limitations are essentially absent (ε = 1), and the overall rate of reaction is controlled by the chemical reaction. As the particle size is increased, the diffusional limitations become increasingly important, and above a certain particle size d_P*, the overall rate of reaction is determined by the diffusion of the reactants into the catalyst pores. The evaluation of the kinetic parameters for the reaction should be performed at impeller speeds higher than N_M and particle sizes lower than d_P*. The reaction taking place on the catalyst surface itself is composed of various steps, such as (1) adsorption of the reactants on the active sites, (2) chemical reaction at the active sites, and (3) desorption of the products from the active sites. The rate of reaction can be written in terms of these various steps (see Section 11.3).

At impeller speeds well below N_M, the reaction may be gas-liquid and/or solid-liquid mass transfer controlled. If the solid loading (ε_S) is varied under these conditions ($N << N_M$), then only

TABLE CS 11.1
Effect of Variable Parameters on the Rate of Reaction

	Effect of Increase in Values of Variables on the Overall Rate of Reaction							
Rate controlling step	$[A^*]$	$[A]_b$	$[A]_s$	$[B]_0$	$[B]_s$	ε_s	d_p	N
Gas-liquid mass transfer	$\propto [A^*]$	$\propto [A^*] - [A]_b$	$[A]_s = [A_b]$	No effect	No effect	No effect	No effect	increases
Solid-liquid mass transfer	$[A^*] = [A]_0$	$\propto [A]_b$	$\propto [A]_b - [A]_s$	No effect	No effect	$\propto \varepsilon_s$	$\propto (1/d_p)$	increases
Pore diffusion	$[A^*] = [A]_s$	$[A]_b = [A]_s$	$\propto [A]_s$	No effect	No effect	No effect	$\propto (1/d_p)$	No effect
Chemical reaction	$[A^*] = [A]_S$	$[A]_b = [A]_s$	$\propto [A]_s^m$	$[B]_b = [B]_S$	$\propto [B]_s^n$	$\propto \varepsilon_s$	No effect	No effect

the second term on the right-hand side of Equation (CS11.3) is affected. If the rate of reaction varies linearly with the solid loading, then it can be concluded that the overall reaction is solid-liquid mass transfer controlled. However, if the rate of reaction is unaffected by the solid loading, then gas-liquid mass transfer is the rate-controlling step.

Whenever heat effects are important, a proper energy balance has to be established. The rate at which heat is generated inside the reactor and the rate at which heat is transferred to and from the heat transfer media need to be quantified to determine whether the rate of heat transfer is the controlling step. Table CS11.1 summarizes the effect of various parameters such as $[A^*]$, $[A]_S$, $[B]_b$, d_P, ε_S, impeller speed, and so forth on the overall rate of reaction for different rate-controlling steps. For the geometry under consideration, the values of k_La and $k_{SL}a_p$ can be estimated from available correlations. Using these values and the estimated kinetic parameters, it is possible to determine the rate-controlling step. During the course of the reaction, one or more operating conditions often change. For example, reactant concentration, operating temperature, pressure, and other conditions may change. Then the rate-controlling step itself may change with time or location in the vessel. In such cases, the rate-controlling step has to be determined as a function of time/location in the reactor. Once the rate-controlling step is known, the overall rate of reaction can be written. This overall rate of reaction can then be integrated with respect to space or time to determine the throughput of the reactor.

Solved Example

Hydrogenation of an organic compound is a typical example of such reactions. The gas and liquid phase reactants are denoted by A and B, respectively. For the purpose of illustration, it will be assumed that the overall reaction is mass transfer controlled. It is desirable to perform such a reaction in a gas-including contractor along with a sparger. The lower impeller is a pitched blade up-flow turbine (PBTU), and a large ring sparger will be assumed. Let u_{G0} be the superficial velocity of the sparged gas. A part of this sparged gas reacts in the vessel, and the remainder escapes into the head space. Simultaneously, the gas is recycled into the liquid using a gas-inducing impeller. Part of the entrained/induced gas also reacts, and the remainder escapes into the head space. For an overall material balance, the maximum permissible superficial gas velocity (u_{Go}) should be such that the rate of gas sparging equals the rate of reaction of the gas. This ensures that the head space pressure remains unchanged with time. Alternatively, if an overall material balance is written for the head space, then it is clear that the net rate of escape of the unreacted gas into the head space (Q_{UG}) must be equal to the rate of gas induction.

Figure CS11.2a shows a comparison of fractional gas holdup under sparging conditions, with and without the use of a gas-inducing impeller. In the absence of a gas-inducing impeller, such a system behaves like a conventional mechanically agitated contactor (MAC). The comparison is made in terms of gas holdup as a function of power consumption per unit volume for different superficial velocities of sparged gas (u_{Go} = 0, 6, 18, and 29 mm/s). It can be seen that the fractional

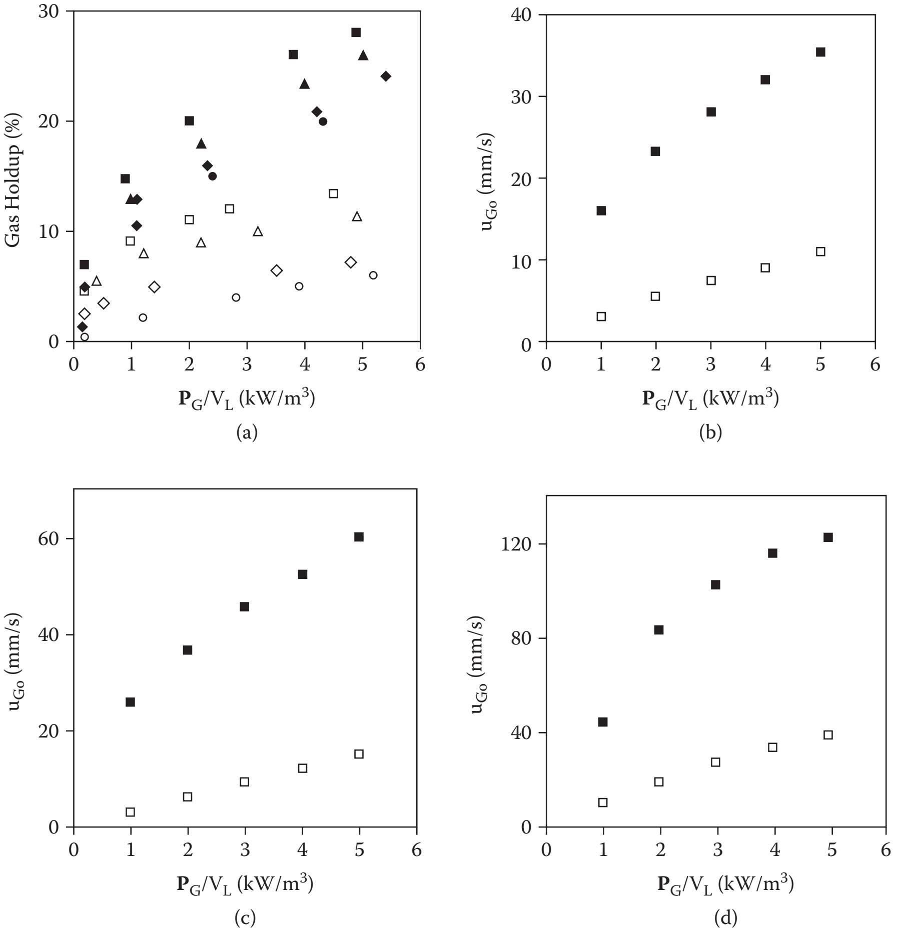

FIGURE CS11.2 Comparison of stirred tank reactor with and without a gas inducing impeller. (a) Comparison of fractional gas holdup under sparging conditions with and without a gas-inducing impeller. Keys: open symbols: without gas-inducing impeller, filled symbols: in presence of gas inducing impeller ○: 0 mm/s, ◊: 6 mm/s, △: 18 mm/s, o: 29 mm/s. (b) Permissible values of superficial gas velocity with respect to power consumption: Mass transfer controlled operations. Keys: open symbols: without gas-inducing impeller, filled symbols: in presence of gas-inducing impeller. (d) Permissible values of superficial gas velocity with respect to power consumption: Fast reaction controlled operations for $\sqrt{M}$ = 5. (d) Permissible values of superficial gas velocity with respect to power consumption: Fast reaction controlled operations for $\sqrt{M}$ = 50. (From Patwardnam, A. W. and Joshi, J. B., 1998.)

gas holdup in the presence of a gas-inducing impeller is substantially higher than for MAC. Similarly, $u_{Go} = 0$ corresponds to the case of gas induction alone (no sparging). It can also be seen that, as the rate of sparging increases, the gas holdup increases. The following stepwise procedure is recommended for design.

Stepwise Procedure

1. The stoichiometry of the reaction under consideration is known. Furthermore, the solubility of gas and the physicochemical properties of the gas and the liquid phases are known.
2. The geometry of the system is first chosen, e.g., tank diameter, impeller design, D/T ratio, clearance, submergence, sparger size, impeller speed, and others.

3. A particular superficial gas velocity, u_{Gi}, is chosen.
4. For this value of superficial gas velocity, the gas induction rate (Q_G), fractional gas holdup (ε_G), and power consumption ($\mathbf{P}_G$) are calculated, both in the presence of a gas-inducing impeller and in its absence. Hydrodynamic characteristics and the mass transfer coefficient are estimated using the correlations of Patwardhan and Joshi (1998).
5. Based on these hydrodynamic characteristics, the volumetric mass transfer coefficient (k_La) is calculated. Alternatively, the value of k_La could also be measured in a small-scale experimental reactor (at least 0.5 m dia.) under the actual conditions prevailing (temperature, pressure, physicochemical properties, and so forth).
6. From the value of k_La, the rate at which the sparged and the induced gas react is estimated.
7. The net rate at which the sparged gas accumulates (Q_{UG}) into the head space is calculated as the difference between the rate of sparging and the rate of reaction of the sparged gas.
8. If Q_G is lower than Q_{UG}, pressure builds up in the head space, and the u_{Gi} is unacceptable, or if Q_G is higher than Q_{UG}, head space pressure decreases and, again, the u_{Gi} is unacceptable. Thus, a new value of u_{Go} is chosen, and the procedure is repeated from step 3 onward until $Q_{UG} = Q_G$. Thus, this procedure yields a value of u_{Gi} that is acceptable for a given geometry of the system (step 2).
9. The procedure is repeated by choosing different operating conditions (e.g., impeller speed) so that different values of $u_{Go} - \mathbf{P}_G$ are generated.
10. The entire procedure can be repeated if there is an enhancement in the rate of mass transfer due to chemical reaction. The results of the above procedure are given in Figures CS11.2b through d. The following correlations were used for the calculations:

$$N_{CG} \text{ in absence of sparging, } N_{CG} = \frac{1}{2\pi R}\sqrt{\frac{2gS}{\psi}} \quad \text{(CS11.5)}$$

$$\text{Change in } N_{CG} \text{ due to sparging, } \frac{(\Delta N_{CG})^2 \pi^2 D^2 \psi}{2gS} = \alpha_1 (C_3/D)^{\alpha_2} u_G^{\alpha_3} (S/\mathbf{T})^{\alpha_4} \quad \text{(CS11.6)}$$

Gas induction rate in absence of sparging,

$$Q_G = \lambda^* N R^2 \left(1 - \frac{2gS}{\psi u_I^2}\right) + \alpha^* N R^3 \left(1 - A\left(\frac{2gS}{\psi u_I^2}\right)^{3/2}\right) \quad \text{(CS11.7)}$$

$$\text{Change in gas induction rate due to sparging, } 1 - \frac{Q_{GS}}{Q_G} = \beta_1 F1^{\beta_2} \left(C_3/D\right)^{\beta_3} \quad \text{(CS11.8)}$$

$$\text{Fractional gas holdup, } \varepsilon_G = a_1 (D/\mathbf{T})^{b_1} \quad (\mathrm{Re}\, Fr Fl)^{c_1} \quad \text{(CS11.9)}$$

Power consumption,

$$\frac{\mathbf{P}_G}{\mathbf{P}_O} = 0.1\left(\frac{NV_L}{Q_G}\right)^{1/4}\left(\frac{N^2 D^4}{W V_L^{2/3} g}\right)^{-1/5} \quad \text{(CS11.10)}$$

$$\mathbf{P}_O = N_P \rho_L N^3 D^5$$

The enhancement in the rate of mass transfer due to chemical reaction in Figure CS11.2c is $\sqrt{M}$ = 5, and in Figure CS11.2d is $\sqrt{M}$ = 50.

For Figures CS11.2b, c, and d, it was assumed that the production rate was 50 tons/day of compound R by the following reaction:

$$3A(g) + B(l) \rightarrow R(l)$$

The solubility of A in the liquid [A] was assumed to be 0.1 kmol/m^3. It was also assumed that the reaction takes place at 150°C and 10 atm pressure. The performance was estimated using the correlations given above. In addition, the following correlations were used:

$$\text{Mean bubble diameter } d_b = 4.15\left(\frac{(\mathbf{P}_G/V_L)^{0.4}\rho_L^{0.2}}{\sigma^{0.6}}\right)^{-1}\varepsilon_G^{0.5} + 0.09 \qquad \text{(CS11.11)}$$

$$\text{Interfacial area per unit volume, } a = \frac{6\varepsilon_G}{d_b} \qquad \text{(CS11.12)}$$

Volumetric mass transfer coefficient k_La = 0.0002 a.

Figure CS11.2b shows that, for a particular value of power consumption per unit volume, a higher value of u_{Gi} is permissible when a gas-inducing impeller is used along with a sparger. For example, for a power consumption of 2 kW/m^3, the permissible u_{Gi} is about 23 mm/s when a gas-inducing impeller is used as compared to about 6 mm/s when the gas-inducing impeller is not present. A higher permissible u_{Gi} in existing equipment implies that higher productivity can be realized when a gas-inducing impeller is used along with a sparger. If the productivity is to remain the same, then a higher permissible u_{Gi} implies that a smaller size of reactor can be used. If the reaction involves highly corrosive chemicals (e.g., hydrogenation of chloro compounds), then an exotic material of construction is needed (Hastelloy, titanium, tantalum, and so on). A reduction in size of such a reactor implies a considerable saving in equipment cost. Alternatively, if the same permissible u_{Gi} is to be maintained (corresponding to the desired rate of production), then much lower power consumption is required when the gas-inducing impeller is employed. That is, for a u_{Gi} of 10 mm/s, 5 kW/m^3 are required when a gas-inducing impeller is not used as compared to about 0.5 kW/m^3 when one is used. Reduced power consumption results in a significant reduction in operating costs and is particularly important when the cost of electricity is high. A comparison of Figures CS11.2b and d reveals that the difference in u_{Gi} or power consumption increases as the enhancement factor increases.

From the above discussion, it is clear that a given rate of production can be achieved by different combinations of reactor size and power consumption. The selection of the optimum reactor size is based on the annualized cost of the reactor. The annualized cost consists of the cost of capital (depreciation and interest on fixed cost) and the operating cost. The fixed cost consists mainly of equipment cost (that is, the material cost plus fabrication cost), and the operating cost consists mainly of electricity (power) cost. For the purpose of this illustration, five different materials of construction were selected having costs 0.3, 1.0, 3.0, 10.0, and 30.0 $/kg. This range of costs covers practically all of the materials commonly used in industry, such as mild steel, stainless steel, glass-lined vessels, Hastelloy, titanium-lined vessels, and so forth. Two levels of (depreciation + interest) were examined: 20% and 50% per annum. Three costs of electricity were used: 0.035, 0.10, and 0.30 $/kWh.

For a particular reactor volume and operating pressure, the thicknesses of shell and dished ends were calculated. Knowing the density of the material, the weight of the shell was estimated. An extra 50% was added for the nozzles, supports, shaft, impellers, agitator drive, and so on. In addition,

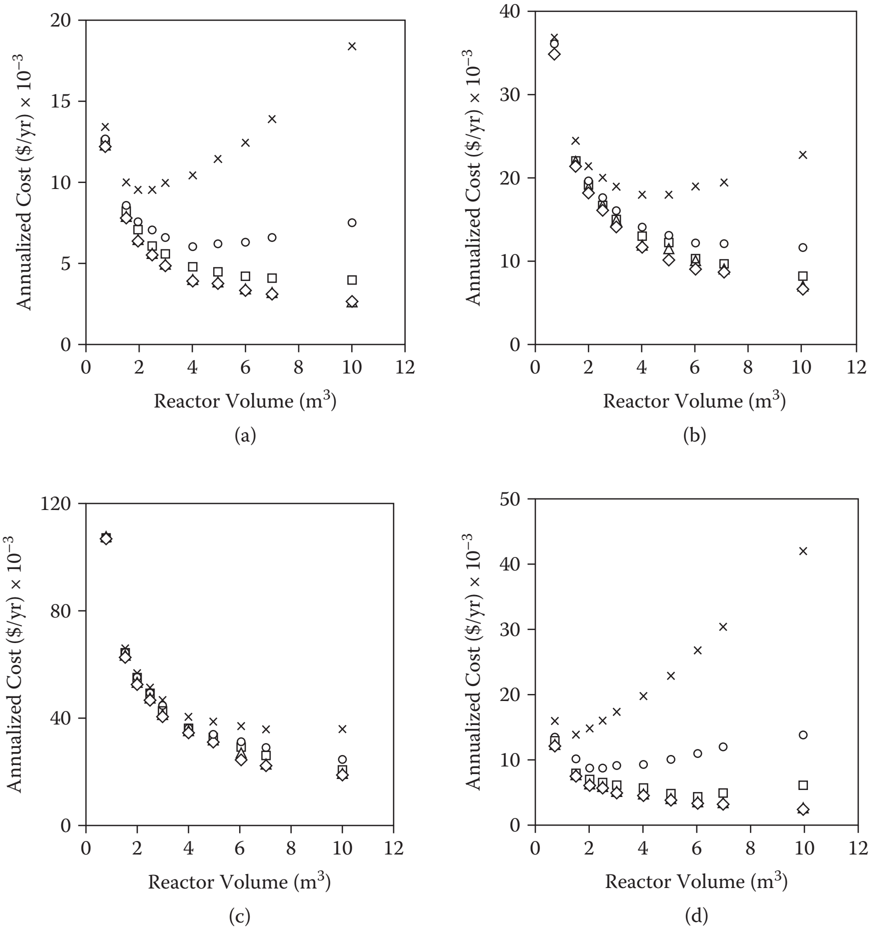

Figure	Electricity Cost $/(kW.hr)	Annualized Capital Cost $/(kg yr)				
		◊	△	□	○	x
(a)	0.035					
(b)	0.01	0.144	0.48	1.44	0.48	14.4
(c)	0.3					
(d)	0.035	0.36	1.2	3.6	12.0	36.0

FIGURE CS11.3 Optimization of hydrogenation reactor on the basis of annualized cost. (From Patwardnam, A. W. and Joshi, J. B., 1998.)

the fabrication cost was considered as 60% of the material cost. The operating cost was calculated as the product of power consumption and the electricity cost. The optimum reactor size was determined based on the annualized cost (capital + operating).

Figure CS11.3 shows the annualized cost for various combinations of fixed and operating cost. The principal operating cost includes electricity, and this has been considered at four levels: 0.035, 0.01, 0.3, and 0.035 $/kWh in Figures CS11.3a through d. For every figure, the annualized capital cost consists of two parts:

1. Cost of material of construction
2. Level of depreciation, interest, maintenance, etc.

For these two factors, five levels of annualized capital costs are considered in all four figures, and the values are shown by symbols. Several conclusions can be drawn. For low-cost materials like mild steel, the annualized cost decreases as the reactor volume is increased. This is because the fixed cost is low, and the operating cost contributes significantly to the annualized cost. Thus, choosing a larger reactor volume and consequently keeping a lower level of power consumption reduces the annualized cost. For medium-cost materials (10 \$/kg), there is a certain reactor size at which the annualized cost is minimum. If the reactor size is larger than this value, the fixed cost increases more than the decrease in power consumption. On the other hand, if the reactor volume is lower than the optimum value, the operating cost increases more than the decrease in the fixed cost. This optimum reactor size shifts to lower volumes as the cost of the material increases. For example, if the material cost is 10 \$/kg, the optimum reactor size is about 4 m^3, and if the material cost is 30 \$/kg, the optimum reactor size is about 2 m^3. Thus, for any values of the material and electricity costs, the annualized cost can be calculated, and the optimum size of the reactor can be found.

Comparing Figures CS11.3a through c (electricity cost 0.035, 0.10, and 0.30 \$/kWh), it can be seen that the optimum reactor size shifts toward higher volumes. Thus, as the cost of electricity rises, larger reactors and decreased power consumption reduce the operating costs. A comparison of Figures CS11.3a and d shows that, as the capital cost increases (from 20 to 50%), the optimum reactor size decreases. This shows the advantage of smaller reactor size to keep the fixed cost low, even though the power consumption (operating cost) increases.

Lesson

This case study is concerned with a three-phase gas-liquid-solid (catalytic) reaction. A systematic stepwise procedure has been described for determining the rate-controlling step, which depends on the catalyst type, particle size, operating pressure and temperature, mass transfer coefficient, and concentrations of reactants and products. As indicated, the rate-controlling step may change with location in a continuous reactor and with time in a batch reactor.

For catalytic hydrogenation, where complete gas utilization is of the utmost importance, the self-inducing type of reactor has been shown to be superior to the conventional gas-liquid stirred reactors. The selection of the reactor volume and level of power consumption per unit volume depends on the material of construction and power cost. By considering a wide range of material and power costs, the selection procedure has been elucidated. Such an optimization exercise should be extended to catalyst (type, particle size, loading, and resulting cost per ton of product), pressure, and temperatures of operation. Often, a significant cost reduction can be obtained by proper optimization of an operating plant. Suitable filtration and recycle of catalyst are crucial components of cost saving.

Case Study 11.12 Solid-Solid Reaction Followed by a Gas-Solid Reaction: Manufacture of Methylchlorosilanes

Nomenclature for Case Study 11.12

A	reactant (CuCl)
$[A]$	concentration of A (kmol/m^3)
$[A]_o$	concentration of A (kmol/m^3)
B	reactant (Ci or FeSi)
$[B]$	concentration of B (kmol/m^3)
$[\hat{B}]$	dimensionless concentration $[B]/[B]_0$
C	constant
$E^*(R)$	elutriation constant (1/s)
$F_{s,0}$	quantity of feed of uniform size R_0 (kg/s)
$F_{s,1}$	quantity of solid leaving the reactor (kg/s)

$F_{s,e}$	quantity of solids elutriated (kg/s)
f_{eff}	fraction defined by Equation (CS12.1)
G	methyl chloride
I	integral defined by Equation (CS12.42)
k	general notation for rate constant (appropriate units)
k_1	constant given by Equation (CS12.9)
k_2	constant given by Equation (CS12.9) (1/s)
k_{ac}	rate constant for the autocatalytic step (m^3/mol s)
k_{hom}	rate constant for homogeneous reaction (m^3/mol s)
$\breve{k}$	rate of change of pore radius (constant) given by Equation (CS12.30) (m/s)
N	total number of particles in the feed (–)
N_B^o	total number of particles of A and B surrounding one central B particle
P	reaction product ($SiCl_4$)
Q	reaction product (Cu*)
$[Q]$	concentration of Q (kmol/m^3)
R	radius of solid or cylindrical coordinate (m)
R_0	initial radius (m)
R_A, R_B	radii of solids A and B (m)
R_M	smallest feed size for a growing particle or largest size for a shrinking particle (m)
$r(R)$	rate of change of particle size (m/s)
r_A	rate of reaction of A (mol/m^3 s)
r_{hom}	rate of homogeneous reaction (mol/m^3 s)
r_t	sum of rates ($r_{hom} + r_{ac}$) (mol/m^3 s)
$r_{t,\max}$	r_t at $X_{A,max}$
s	shape factor (–)
t	time (s)
$\bar{t}$	residence time (s)
t_i	induction period for the reaction (s)
W	weight of solids (kg)
W_A, W_B	weights of solids A and B (kg)
w	weight ratio, W_A/W_B
x_i	conversion of i (–)
$\bar{X}_A$	residence time averaged conversion (–)
$\bar{\bar{X}}_A$	residence time and particle size averaged conversion (–)

Greek

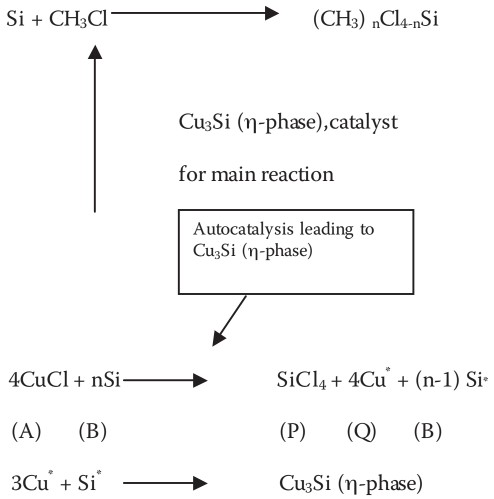
α	group defined by Equation (CS12.2)
δ	bubble fraction in a fluidized bed
$\breve{\phi}$	size distributions function
$\breve{\phi}_0, \breve{\phi}_1, \breve{\phi}_e$	size distributions in the feed, outflow and elutriation streams, respectively
η	η phase (Cu_3Si)
ρ_A, ρ_B	densities of solids A and B (kg/m^3)
τ	time for complete conversion as defined in Table 11.13

Defining the Systems

Methylchlorosilanes are used in the manufacture of a variety of resins, elastomers, and silicone oils. They are produced as a mixture of chlorosilanes, mainly dimethyldichlorosilane, by the reaction between silicon and methyl chloride by a direct route discovered independently by Rochow (1945) and Muller (1950). In this route, metallic copper, with or without promoters, is used to accelerate the reactions. The form of copper is important and depends on its preparation and association with the silicon phase. The whole system of solids comprising silicon metal, copper

catalyst, and other solid materials (present in impure silicon) is collectively called the *contact mass*. Numerous methods have been proposed (see Doraiswamy and Gokarn, 1993), and in this case study, the original method developed by Rochow as modified at the National Chemical Laboratory (NCL) will be used.

A mixture of silicon and cuprous chloride granules is heated in a slow stream of inert gas. Cuprous chloride is thus reduced to metallic copper and $SiCl_4$ gas. The copper produced is in an active state and forms an alloy, the so-called η-phase, with the silicon. This phase is far more active than the alloy prepared by the conventional method of reducing copper oxide by hydrogen and then alloying the copper with silicon. The NCL process uses ferrosilicon instead of pure silicon, because it is much cheaper. Also, the presence of iron in general is reported to add stability to the η-phase (Lobusevich et al., 1976). This phase catalyzes the reaction between silicon and methyl chloride. Thus we have here a solid-solid reaction to give the catalyst followed by a gas-solid reaction to give the final products. The entire scheme may be represented as



(CS12.R1)

The first step (starting at the bottom) is the formation of the η-phase, which then catalyzes the main reaction shown at the top (methylchlorosilane formation). The asterisks denote active states of the element. Then we model the formation of η-phase and develop an equation for predicting the size distribution of products from a given size distribution of the reactant solid.

Kinetics of η-phase Formation (a Solid-Solid Reaction)

As a class, solid-solid reactions are very difficult to analyze. Tamhankar and Doraiswamy (1979) have reviewed the important aspects of these reactions. When the two solids are present as mixed powders, the following situations may arise: product growth controlled by (1) diffusion of reactants through a continuous product layer, (2) nucleation and nuclei growth, and (3) phase-boundary reactions. In addition, kinetic equations based on the concept of an order of reaction can also be used. The last two are possible only when the effect of diffusion is negligible (or is embedded in the rate constant). Where diffusion is important, contact between the solids is of crucial importance. For this purpose, the concept of an *effective contact area* has been used with considerable success (see Doraiswamy and Sharma, 1984, for a brief discussion). In one study (Komatsu, 1965), a theory has been developed based on the number of contact points. For a system consisting of particles of *A* and *B*, the effective contact area of, say, *B* is given by the true surface area multiplied by a fraction f_{eff} defined as

$$f_{eff} = \frac{N(A/B)}{N_B^o} = \left(\frac{\alpha w}{1+\alpha w}\right)^m \quad \text{(CS12.1)}$$

Here, α is given by

$$\alpha = \frac{R_B^3 \rho_B}{R_A^3 \rho_A} \quad \text{(CS12.2)}$$

where R_A and R_B are the radii of A and B, respectively, ρ_A and ρ_B their densities, N_B^o is the total number of particles of A and B surrounding one central B particle, and w is the weight ratio of the components (W_A/W_B). The hypothetical particle with this surface area will be completely in contact with the other component (A). This analysis has the merit of bringing it in line with that for gas-solid reactions, and it is generally very useful.

Where the solids are present as pellets, the analysis becomes far more complicated. Factors such as the formation of a product zone between the two reactant solids, the change in contact area with reaction progress (from a point contact for spheres) to a flat surface, formation of a "neck" between the reacting solids, self-diffusion of reactants as well as their diffusion into the product, and sintering come into play. Models have been proposed to account for these; see, e.g., Arrowsmith and Smith (1966) and Tamhankar and Doraiswamy (1978) for the role of diffusion, and Ristic (1979) for the role of sintering. In the present problem, we shall not be concerned with the analysis of pellet behavior. Furthermore, in view of the general applicability of models based on order of reaction, we use this concept in formulating the kinetics of formation of the η-phase.

Experimental data (Tamhankar et al., 1981) on the formation of the η-phase are plotted in Figure CS12.1 as conversion-time curves. The shape of the curves clearly suggests autocatalytic behavior. In this respect, the η-phase formation reaction is unique, for it is perhaps the only instance

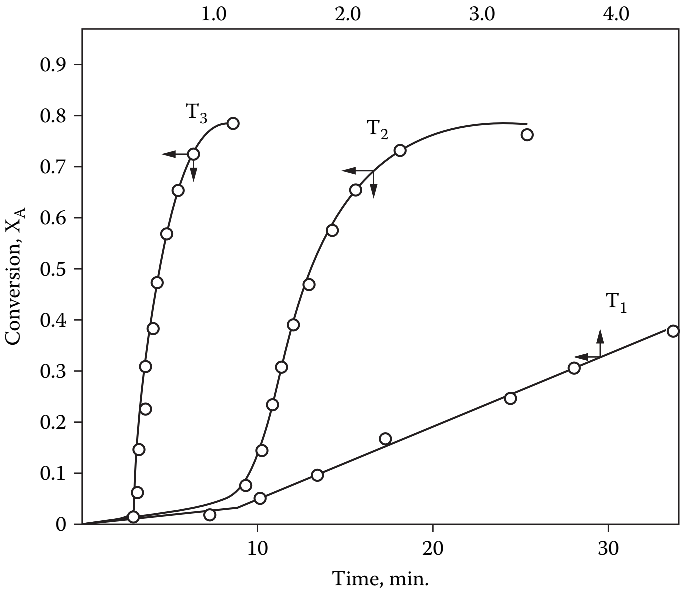


FIGURE CS12.1 Fractional removal of CuCl as a function of time (redrawn from the data of Tamhankar et al., 1981).

of its kind in solid-solid reactions. However, in a complete analysis of this reaction, a simultaneous noncatalytic reaction all but overwhelmed by the autocatalytic step cannot be ignored. Thus, we begin the analysis by considering this noncatalytic step as the staring point. This reaction can be written as

$$A + B \rightarrow P + Q \quad \text{CS12.R2}$$

giving

$$r_{\text{hom}} = -\frac{d[A]}{dt} = k[B][A] = k_{\text{hom}}[A] \quad \text{(CS12.3)}$$

Since experimental curves show autocatalysis, we write

$$A + B + Q \rightarrow P + 2Q \quad \text{CS12.R3}$$

$$r_{ac} = \frac{d[A]}{dt} = k_{ac}[A][Q] \quad \text{(CS12.4)}$$

Total rate is given by

$$r_t = r_{\text{hom}} + r_{ac} = k_{\text{hom}}[A] + k_{ac}[A][Q] \quad \text{(CS12.5)}$$

where $k_{hom} = k[B]$. If X_A is the conversion,

$$r_t = -\frac{d[A]}{dt} = A_0 \frac{dX_A}{dt} \quad \text{(CS12.6)}$$

giving

$$\frac{dX_A}{dt} = \frac{r_t}{[A]_0} = \frac{k_{\text{hom}}[A]_0(1 - X_A) + k_{ac}[A]_0^2 X_A(1 - X_A)}{[A]_0} = R'$$

or

$$\frac{dX_A}{dt} = k_{\text{hom}}(1 - X_A) + k_{ac}[A]_0 X_A(1 - X_A) = \frac{r_t}{[A]_0} \quad \text{(CS12.7)}$$

Thus, a plot of $v_t/(1 - X_A)[A]_0$ vs. X_A should give a straight line of slope $k_{ac}[A]_0$ and intercept k_{hom}.

Another interesting method is to rewrite Equation (CS12.7) and integrate it to give

$$\ln \frac{X_A + k_1}{1 - X_A} = k_2(t - t_i) + \ln k_1 \quad \text{(CS12.8)}$$

where

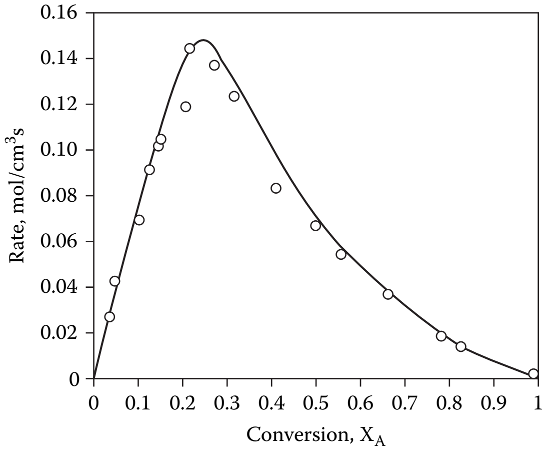

FIGURE CS12.2 Rate as a function of conversion for run T2 of Figure CS12.1 (redrawn from the data of Tamhankar et al., 1981).

$$k_1 = k_{\text{hom}} / [A]_0 k_{ac} \tag{CS12.9}$$

$$k_2 = k_{\text{hom}} + [A]_0 k_{ac} \tag{CS12.10}$$

t_i = induction period for the reaction

A plot of LHS vs. $(t - t_i)$ should give k_2 if k_1 is known (but it is not).

To get k_1, we differentiate the S-shaped X_A vs. t curves (Figure CS12.1). Because of the nature of autocatalysis, the resulting rate curves (see Figure CS12.2) show a maximum. Thus, at

$$X_A = X_{Am}$$

$$\frac{d(dX_A / dt)}{dX_A} = \frac{dr_t}{dt} = [A]_0^2 k_{ac} - k_{\text{hom}}[A]_0 - 2[A]_0^2 k_{ac} X_{Am} = 0 \tag{CS12.11}$$

giving

$$k_{\text{hom}} / [A]_0 k_{ac} = k_1 = (1 - 2X_{Am}) \tag{CS12.12}$$

where $X_{Am} = X_A$ at $r_{t,\max}$.

Using k_1 for getting the LHS in plotting Equation (CS12.8), k_2 can be obtained. Finally,

$$\left.\begin{aligned} k_{\text{hom}} &= \frac{k_1 k_2}{(k_1 + 1)} \\ k_{ac} &= \frac{k_2}{[A]_0 (k_1 + 1)} \end{aligned}\right\} \tag{CS12.13}$$

The actual values obtained are (Tamhankar et al., 1981):

T_1 = 300°C k_{hom} = 2.368 10^{-4} s^{-1} k_{ac} = 0.175 cm^3 mol^{-1} s^{-1}
T_2 = 330°C k_{hom} = 1.333 10^{-3} s^{-1} k_{ac} = 1.778 cm^3 mol^{-1} s^{-1}
T_3 = 360°C k_{hom} = 2.345 10^{-3} s^{-1} k_{ac} = 9.770 cm^3 mol^{-1} s^{-1}

Determining the Size Distribution of Products from a Fluidized-Bed Reactor for Chlorosilanes

The proposed reaction will be performed in a fluidized-bed reactor. This operation consists of two stages. In the first, the solids CuCl (cuprous chloride) and FeS (ferrosilicon) or pure silicon are thoroughly mixed in the bed, which is continuously fluidized by an inert gas at a velocity close to u_{mf}. The following solid-solid reaction takes place (which is equivalent to the last step shown in reaction [CS12.R1]):

$$\begin{array}{l}\mathrm{CuCl(s) + Si(s)\ or\ FeSi(s)} \rightarrow \eta\text{-phase } (\mathrm{Cu_3Si}) \\ \text{(15 parts)} \quad \text{(100 parts)}\end{array} \qquad \text{CS12.R2}$$

In the second step of the operation, the inert gas is replaced by methyl chloride (CH_3Cl), and the fluidizing conditions are maintained so that the gas-phase concentration is uniform. The following gas-solid reaction occurs:

$$\mathrm{CH_3Cl(g){+}Cu_3Si(s) \rightarrow CH_3SiCl_3 + (CH_3)_2SiCl_2, (CH)_3SiCl + \ldots} \qquad \text{CS12.R3}$$

with the kinetics described by SCM. The products are a mixture of methyl chlorosilane, dimethyl dichlorosilane, and trimethyl monochlorosilane. A complete procedure for finding the exit size distribution of solids for an initial distribution $\breve{\phi}_0(R)$ is given by Doraiswamy and Sharma (1984).*

Design of a Continuous Reactor: General Principles

The reaction characteristic of the present system are best performed in a semicontinuous reactor in which the solid is stationary, as described in the previous section. This easily permits the two steps. In general, however, continuous reactors in which both the gas and solid phases move continuously are more important. We therefore briefly consider in this section the mathematical basis for the design of such a reactor. The chief reactor and operating parameters are gas and solids feed rates, product size distribution, bed size, and so on, and procedures for determining them are described. With a size distribution $\breve{\phi}_0(R)$, an elutriation stream $F_{s,e}$, and an arbitrary rate law for the changing particle size, a material balance on solids of size between R and $R + dR$ yields

$$\begin{aligned}&\begin{pmatrix}\text{solids in}\\ \text{feed, kg/s}\end{pmatrix} - \begin{pmatrix}\text{solids in}\\ \text{outflow, kg/s}\end{pmatrix} - \begin{pmatrix}\text{solids leaving}\\ \text{in elutriation}\\ \text{stream, kg/s}\end{pmatrix}\\ &- \begin{pmatrix}\text{growth of solids}\\ \text{into and out of}\\ \text{the interval, kg/s}\end{pmatrix} + \begin{pmatrix}\text{mass increase}\\ \text{of solids within}\\ \text{the interval, kg/s}\end{pmatrix} = 0\end{aligned} \qquad \text{(CS12.14)}$$

* There are some errors in the procedure which can easily be corrected. Also note: Although the chlorosilane gases are the desired products, we use this reaction as a model reaction for illustrating the procedure for predicting the solid product size distribution.

With complete backmixing of the solid, the size distribution of the outflow stream also represents that of the solids within the bed. This equation can be written as

$$F_{s,0}\breve{\phi}_0(R) - F_{s,1}\breve{\phi}_1(R) - WE^*(R)\breve{\phi}_1(R)$$
$$-W\frac{d}{dR}\left[r(R)\breve{\phi}_1(R)\right] \tag{CS12.15}$$
$$+\frac{sW}{R}r(R)\breve{\phi}_1(R) = 0$$

The term $E^*(R)$ represents the elutriation constant defined by the equation

$$\begin{pmatrix}\text{rate of removal}\\ \text{of solids of size } R_j\end{pmatrix} = E^*\begin{pmatrix}\text{weight of that}\\ \text{size of solids}\\ \text{in the bed}\end{pmatrix} \tag{CS12.16}$$

and s and $r(R)$ represent, respectively, the shape factor of the particle (3 for a sphere, 2 for a cylinder and 1 for a flat plate) and the rate of change of particle size. Equation (CS12.15), valid for a particular size range, can be supplemented by an overall balance equation over all sizes to give

$$F_{s,e} + F_{s,1} - F_{s,0} = sW\int_{\text{all } R}\frac{\breve{\phi}_1(R)r(R)}{R}dR \tag{CS12.17}$$

This equation assumes positive or negative values depending on whether the particle grows or shrinks. For shrinking particles, Equations (CS12.15) and (CS12.17) can be rearranged to give the following expression for $W/F_{s,0}$:

$$\frac{W}{F_{s,0}} = \int_{R_t\to\infty}^{R_M}\frac{R^3}{r(R)}I\left[\int_{R_0=R}^{R_0=R_M}\frac{\breve{\phi}_0(R)dR_0}{R_0^3 I}\right]dR \tag{CS12.18}$$

The corresponding outflow size distribution is given by

$$\breve{\phi}_1(R) = \frac{F_{s,0}R^3}{Wr(R)}I\left[\int_{R_0=R}^{R_0=R_M}\frac{\breve{\phi}_0(R)dR_0}{R_0^3 I}\right] \tag{CS12.19}$$

For growing particles, the integration limits are reversed. In these equations, R_M represents the smallest feed size for a growing particle or the largest size for a shrinking particle, and I is an integral defined as

$$I = \exp\left[\int_R^{R_0}\frac{(F_s,1/W) + E^*(R)}{r(R)}dR\right] \tag{CS12.20}$$

The set of Equations (CS12.18) through (CS12.20) generally cannot be solved analytically. However, they represent a total generalization with respect to feed size distribution, reaction kinetics, and presence of an elutriation stream. The use of these equations for calculating the various reactor and operating parameters such as solids feed rate, exit bed size rate, product size distribution, and so on is outlined below (see Kunii and Levenspiel, 1969, for details) for the simpler case of single-size feed.

1. Assuming that the solids weight W or the outflow rate of solids $F_{s,1}$ is known, guess a value of the other and calculate I from Equation (CS12.20) for a number of values of R.
2. Determine $F_{s,0}$ and $F_{s,1}$ or W from Equation (CS12.18). Calculation of $F_{s,0}$ is straightforward. But to calculate $F_{s,1}$ or W, guess values of the unknown quantity and solve Equation (CS12.18) until it is satisfied.
3. Using Equation (CS12.19), calculate the outlet solids size distribution $\phi_1(R)$.
4. Estimate the elutriation rate from Equation (CS12.17).

For specific situations, such as constant-size feed, linear kinetics, or no elutriation, these equations can be simplified to obtain analytical solutions.

Adapting the Procedure to the Chloromethane Reactor

This procedure has been adapted to the design of the gas-solid reactor (i.e., step 2) of the present reaction. The solid-solid reaction of step 1 is performed in the semicontinuous reactor mentioned earlier, but enough η-phase is produced and stored for the continuous second step. The outlet particle size distribution from this step becomes the inlet distribution for the second step. The procedure already outlined above is employed to develop the final equation for exit product size distribution.

General Conversion Equations

We have seen how problems of particle size distribution of reactant and solid products can be employed in the design of fluid-bed reactors. The conversion obtained at the reactor exit depends on these distributions plus various other factors. The equations presented so far were based on continuous solids feed. In calculating the conversions, it is easier to divide the solid reactants into discrete ranges (each with an average size) and express the conversion as the sum from all the ranges. Furthermore, size distribution is usually determined by screen analysis, which gives discrete measurements.

Table CS12.1 (which contains many equations from Kunii and Levenspiel 1969) summarizes the conversion equations based on discrete distributions for selected important situations. The residence time $\bar{t}$ and the time for complete conversion τ are both important. τ is defined in Table 11.13 for different shapes and the residence time (which should be specified to calculate conversion, or vice versa) can be readily computed from $\bar{t} = W/F_{s,0}$.

Obviously, the smaller particles would have completely reacted before the larger ones do. Thus, the lower limit of the summation indicates that particles smaller than R ($\bar{t} = \tau$) are completely converted and should not be considered in calculating the unreacted fraction.

Models with Varying Gas-Phase Concentrations

The chief assumption made in the development presented previously was that the gas environment is known and essentially constant throughout the reactor. This assumption simplified the treatment considerably, since an analysis based on the solid phase alone could be used to describe the bed behavior. Many practical systems using large-particle beds fluidized with a large excess of gas conform to this situation. If vigorously fluidized beds of fine particles are involved, however, the composition of the gas seen by the solid would vary. The previous simple analysis would then be inapplicable. In these instances, the conservation equations for the gas-phase species

TABLE CS12.1
Conversion Equations for Gas-Solid Reactions at Specified Reactor Conditions

	State of Solids Feed	Flow Pattern of Solids	Gas Composition	Conversion Equations	Remarks
1	Single size particles	Plug flow	Uniform	Same as those given in Table 11.13 for all the three controlling steps	Equations give X_B directly; no averaging of any kind is involved since all particles spend equal times in the reactor in a PFR
2	Mixture of different sizes	Plug flow	Uniform	$1-\bar{X}_B = \sum_{R(\bar{t}=\tau)}^{R_M} \left[1 - X_B\left(R_j\right)\right] \frac{F_{s,0}\left(R_j\right)}{F_{s,0}}$	Averaging over size range required; for each size in the equation, the expression for the controlling step involved is used (from Table 3.9)
3	Single size particles	Mixed flow	Uniform	Film resistance control: $1-\bar{X}_B = \frac{1}{2}\left(\frac{\tau}{\bar{t}}\right) - \frac{1}{3!}\left(\frac{\tau}{\bar{t}}\right)^2 + \frac{1}{4!}\left(\frac{\tau}{\bar{t}}\right)^3$ Ash diffusion control: $1-\bar{X}_B = \frac{1}{5}\left(\frac{\tau}{\bar{t}}\right) - \frac{19}{4.20}\left(\frac{\tau}{\bar{t}}\right)^2 + \frac{41}{4620}\left(\frac{4620}{\bar{t}}\right)^3 - 0.000149\left(\frac{\tau}{\bar{t}}\right)^5 + \ldots$ Chemical reaction control: $X_B = 3\frac{\bar{t}}{\tau} - 6\left(\frac{\bar{t}}{\tau}\right)^2 + 6\left(\frac{\bar{t}}{\tau}\right)^3\left[1 - \exp\left(\tau/\bar{t}\right)\right]$	Since the particles spend different times in the reactor, characterized by exponential distribution in a perfectly mixed reactor, averaging of conversions in particles of all residence times is involved.

4	Mixture of different sizes	Mixed flow	Uniform	Film resistance control: $1-\bar{\bar{X}}_B=\sum^{R_M}\left\{\frac{1}{2!}\left[\frac{\tau(R_j)}{\bar{t}}\right]-\frac{1}{3!}\left[\frac{\tau(R_j)}{\bar{t}}\right]^2+\ldots\right\}\frac{F_{s,0}(R_j)}{F_{s,0}}$ Ash diffusion control: $1-\bar{\bar{X}}_B=\sum^{R_M}\left\{\frac{1}{5}\left[\frac{\tau(R_j)}{\bar{t}}\right]-\frac{19}{420}\left[\frac{\tau(R_j)}{\bar{t}}\right]+\ldots\right\}\frac{F_{s,0}(R_j)}{F_{s,0}}$ Chemical reaction control: $1-\bar{\bar{X}}_B=\sum^{R_M}\left\{\frac{1}{4}\left[\frac{\tau(R_j)}{\bar{t}}\right]-\frac{1}{20}\left[\frac{\tau(R_j)}{\bar{t}}\right]^2+\ldots\right\}\frac{F_{s,0}(R_j)}{F_{s,0}}$	Here, two averagings are involved: for residence time distribution [as in (3)] and for particle size distribution [as in (2)]; this is denoted by a double bar over X_B
5	Single size or mixture of different sizes	Plug or mixed flow	Axial variation	See references under "Models with varying gas-phase concentrations"	Situation likely for vigorously fluidized beds of fine particles – encountered commonly in industry; no complete procedure yet available
6	Single size or mixture of different sizes	Plug flow with lateral variation of composition	Axial (and lateral) variation	See Chang et al. (1982)	Lateral variation of solids concentration is prominent in shallow beds

have to be incorporated into the model, and separate equations for the bubble and cloud-wake phases are necessary.

During the course of reaction, the solid reactant in the particles is increasingly displaced by the solid product formed. The volume and specific density of the product formed may not be the same as those of the reactant. For a realistic representation of the bed, it is therefore necessary to account for variations in both size and density of the particles.

Thus, the modeling of the gas-solid noncatalytic reactor is far more complex than that of its catalytic counterpart. Even so, simplified models have been used to get a qualitative (and to some extent, quantitative) feel for the performance of the reactor. Thus, the two-phase model of Davidson and Harrison (1963) has been used by Campbell and Davidson (1975) to analyze the data on the combustion of carbon particles for short periods of combustion in a batch reactor. The model has also been used and considerably extended by Amundson (see Bukur et al., 1977). Tigrel and Pyle (1971) have used this model for the not-too-different problem of catalyst deactivation. Kunii and Levenspiel (1969) and Kato and Wen (1969) have extended their models to gas-solid noncatalytic systems. A particularly useful model that takes account of some of the complexities in practical systems has been suggested by Chen and Saxena (1978).

Comments

In this case, no specific problem in quantitative terms has been posed and solved. For the first step, which is a solid-solid reaction, experimental details have been given because it is a unique solid-solid reaction, perhaps the only known autocatalytic one. Having clearly established this fact, general procedures are described for the two reactors involved, since no experimental data are available for attempting a specific design. The thrust here is the description of a procedure for calculating the outlet solid size distribution given the inlet size distribution. This is an important factor in solid-phase reactions.

Lesson

Silicon reacts with copper chloride catalytically to form a solid product known as η-phase, which then catalyzes the reaction between silicon and methyl chloride to form methyl chlorosilanes. The formation of the η-phase is a unique example of an autocatalytic solid-solid reaction (we are not aware of any other example of such a reaction). Procedures for determining the kinetics of this reaction and the size distribution of the final products of the second reaction are described in this case study. The most important feature of the study is the unexpected discovery of autocatalysis in a solid-solid reaction, which leads us to the important lesson that one should vigorously pursue any such observation that falls outside the "comfort zone" of research, for that is where true discoveries lie. This advice is particularly relevant to engineers, since they generally do not accept the unexpected and would prefer to tread on safer ground.

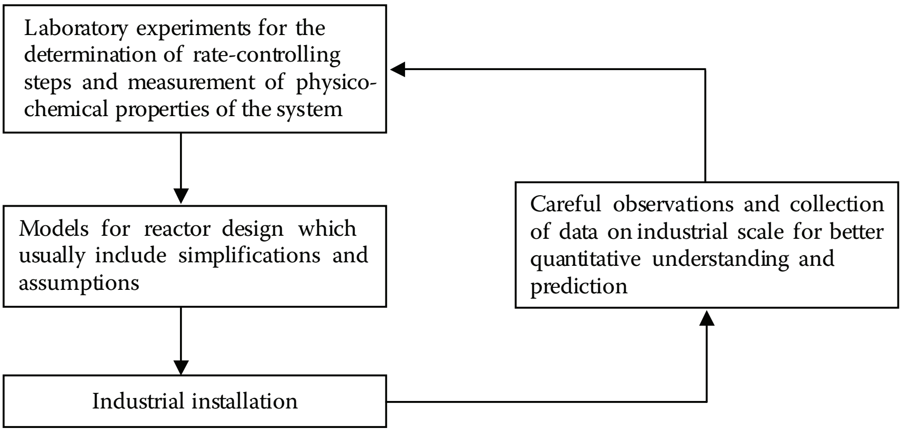
POSTSCRIPT

The case studies presented in this chapter illustrate reactor design procedures for a carefully selected set of reacting systems wherein the physical dimensions of the reactor (diameter, height) and fixed and operating parameters (catalyst loading, superficial velocity, impeller speed, and other) were calculated. As a postscript to these studies, we would like to consolidate and emphasize certain fundamental and practical considerations in reactor selection and design.

- For a given system, the necessary requirements for any proposed reactor design are that the desired capacity, selectivity, and purity be achieved. The exercise should also include pertinent aspects of environmental load and safety.
- Although the engineer may be required to design for a given capacity, it is advisable to provide for additional capacity (in case, this is inexpensive and not the cost-controlling

bottleneck). At the same time, the reactor must be able to perform well at lower loads during slack market periods.

- In the case of small- and medium-scale plants, the reactor may need to have adequate flexibility to produce various similar/different compounds, so a broad-based design is necessary.
- The identification of the rate-controlling step(s) is crucial in the design of multiphase reactors. However, it may be emphasized that the rate-controlling step emerges from a complex combination of series and parallel steps. Often, it is difficult to find the rate-controlling step, since it is compounded by its dependence on location in the reactor. The importance of using a carefully selected laboratory reactor for obtaining precise rate data, uncontaminated by diffusional falsification, cannot be overemphasized. We have emphasized critical points by presenting tables that provide comparative assessments of laboratory reactors for different classes of reactions. The data should be collected over wide parameter ranges, covering possible ranges in industrial practice and extensions on either side. These data are not only useful in design but in subsequent diagnostic analyses, modifications, debottlenecking, replacement, and process identification.
- It is desirable to encourage the production staff to cooperate with the design team to generate plant scale data that can be used to modify/improve the design based on laboratory data. This is particularly true for transport coefficient estimation. The following simplified block diagram is useful for practicing engineers.



- Many reactors are available, and it is advisable not to reject any reactor configuration at the first glance.
- Provision of pressure relief valves, drains, and so on is mandatory.
- Induction of cost considerations at an early stage is strongly recommended.

In addition, an engineer must bear in mind several more specific aspects of design. An attempt to make an exhaustive list would be futile, but some illustrative considerations are mentioned here. The designer must envisage all such aspects that are pertinent to a specific case and incorporate them in the design portfolio.

- For oxidation of hydrocarbons, it is necessary to ensure that, at no time and at no point in the reactor, the flammability limits are approached.
- For catalytic reactions, there must be a provision to trap/recover the catalyst in the event that it is entrained.

- For highly exothermic reactions such as polymerization, it is advisable to include a means for quenching the reaction (e.g., by providing for addition of an inhibitor) in the event of a runaway situation.
- Not only should hazardous conditions be avoided during normal operation, but any such possibility during startup or shutdown should also be foreseen.
- In the case of reactions carried out in mechanically agitated reactors where heat transfer is crucial, provision must be made for adequate heat transfer. During power failure, agitation may stop. Emergency power must be provided to the crucial drives, and provision must be made to drain/flare the contents during an emergency.
- In the case of catalytic packed-bed reactors, provision of extra volume should be considered to accommodate additional catalyst in case of selectivity/activity loss over time.
- In some heat transfer-controlled reactions, it may be possible to partly evaporate the solvent itself, condense it in a reflux condenser, and send the solvent back to the reactor.
- The thermal sensitivities of all the species in the reactor must be known. Some compounds may decompose dangerously at certain conditions, and suitably lower temperatures must be chosen for operation.
- Some reactions may produce solid products that degrade within the reactor and deposit on the cooling coils, and so forth, and drastically affect the heat transfer and product quality. This possibility must be envisaged and accounted for in the design.
- Where handling of solid reactants is involved, the equipment must be designed to present clogging and choking.
- The reactor must be able to perform with different feedstocks (especially of petrochemical origin), and, expectedly, operating conditions for each of them must be specified.

ACKNOWLEDGMENTS

In writing this chapter, particularly the case studies, we have been greatly helped by our students, present and former. We particularly thank Amol Kulkarni, Anand Kulkarni, Ashwin Patwardhan, Dharmesh Ranjan, K. Ekambara, Indraneel Chatterjee, Janaki Patwardhan, T. Kumaresan, Mahesh Dhotre, Rajesh Ghadge, Sanjay Danao, and Swarnendu Roy of the University Institute of Chemical Technology, Mumbai. Our thanks are also due to K. B. S. Prasad of the Indian Institute of Chemical Technology, Hyderabad, for his valuable help and to several graduate students at the Department of Chemical Engineering, Iowa State University, Ames, Iowa. We (particularly L. K. D.) thank Linda Edson for her exquisite typing and for coordinating the staggering list of exchanges between the two authors, incorporating repeated additions, corrections, and revisions. L. K. D. also thanks C. E. Glatz, chair of the Department of Chemical Engineering, for his continued support, even in the author's "retirement."

Nomenclature

A	chemical species (–)
A_P	area of pellet (m^2)
$[A]_p$	concentration of A within a pellet ($kmol/m^3$)
$[A]_s$	concentration of A at catalyst or any solid surface ($kmol/m^3$)
$[\bar{A}]$	average concentration of A ($kmol/m^3$); external field concentration at some point in a bed ($kmol/m^3$)
$[A]_0$	entrance concentration of A ($kmol/m^3$)
$[A]_e$	exit or effluent concentration of A ($kmol/m^3$)
$[A]_f$	final concentration (in time) of A ($kmol/m^3$)
$[A]_i$	initial concentration of A ($kmol/m^3$)
$[\hat{A}]$	dimensionless concentration of A within a pellet, $[A]_P/[A]_S$ (–)
a	interfacial area (m^2/m^3); any exponent (–)
B	chemical species (–)

B'	group defined by Equation (11.141) (–)
$[\hat{B}]$	normalized concentration of B (–)
Bi_m	Biot number for mass transfer (same as Sh) (–)
B	any exponent (–)
C	chemical species (–)
C_P	heat capacity (kcal/kg °C)
C_{pm}	molar heat capacity (kcal/kmol °C)
C_{ps}	heat capacity of solid, (kcal/kg °X)
c	dimensionless concentration $[A]/[A]_0$ (–)
$\mathbf{c}$	vector ($N \times 1$ matrix) of component concentrations (–)
D	chemical species; impeller (or column) diameter (m)
$\mathbf{D}$	diffusivity in general (m^2/s)
$\mathbf{D}_A$	diffusivity of A (m^2/s)
$\mathbf{D}_b$	bulk diffusivity (m^2/s)
$\mathbf{D}_e$	general notation for effective diffusivity (m^2/s)
$\mathbf{D}_{eA}$	effective diffusivity of A (m^2/s)
$\mathbf{D}_{e,As}$	effective diffusivity of A in solid (m^2/s)
$\mathbf{D}_{ea}$	axial effective diffusivity (m^2/s)
$\mathbf{D}_{eG}$	effective diffusivity in a grain (m^2/s)
$\mathbf{D}_{er}$	radial effective diffusivity (m^2/s)
$\mathbf{D}_K$	Knudsen diffusivity (m^2/s)
Da	Damköhler number, $k_s R[A]_b^{m-1}/\mathbf{D}_{e(-)}$
d_{bp}	primary bubble size (m)
d_{bs}	secondary bubble size (m)
d_c	catalyst decay constant (1/s)
d_p	particle diameter (m)
d_T	tube diameter (m)
E	activation energy (kcal/kmol)
E_i	energy input rate (W)
F	function (–); feed rate (mol/s)
F_i	feed rate of i (kmol/s)
F_s	solids circulation rate (kg/s)
F_T	flow rate in a single tube (kmol/s)
F_t	total feed rate (kmol/s)
Fr	Froude group, $u^2/g\, d_p$ (–)
Fr_{mf}	Froude group at minimum fluidization, u_{mf}^2/gd_p (–)
$F, f'\, f_1, f_2, f_3$	functions (–)
f_p	fraction of pores removed (–)
G_A	specific gas (A) flow rate $u\rho_A/M_A$ ($kmol/m^2/s$)
G_B	specific solids (B) flow rate $u\rho_B/M_B$ ($kmol/m^2/s$)
g	shape constant for the grain: 3 for a sphere, 2 for a cylinder, and 1 for a flat plate (–); gravitation constant (m/s^2); functionality
H	enthalpy (kcal/kmol); height (m)
H_A	Henry's law constant of A ($kmol/m^3$ atm)
H_D	height of dispersion (m)
H_{SD}	sparger location on the downcomer side (m)
ΔH_r	heat of reaction (kcal/kmol)
J	group defined by Equation (11.125) (–)
K	reaction equilibrium constant (appropriate units)
K_i	adsorption equilibrium constant of species i (1/atm or m^3/kmol)
k	general notation for reaction rate constant (appropriate units)
$\breve{k}$	term defined in Table 11.4
k_a	rate constant for catalyst activation (1/s)
k_d	rate constant for catalyst deactivation (1/s)
k_G	mass transfer coefficient (m/s)

K_m	rate constant for an *m*th-order reaction [$(m^3/kmol)^{m-1}(1/s)$]
k_P	rate constant for pore removal (1/s)
k_S	rate constant [$(kmol/m^2\ cat)\ (m^3/kmol)^m\ (1/s)$]
k_V	rate constant [$(m^3\ reactor\ /kmol)^{m-1}\ (1/s)$]
k_v	rate constant [$(m^3\ cat/kmol)^{m-1}\ (1/s)$]
k_{vo}	rate constant for fresh catalyst (1/s)
k_{vs}	rate constant at surface conditions, conforming to any set of units of k_v
k_w	rate constant [$(mol/kg\ cat)\ (m^3/mol)^m\ (1/s)$]
k^o	Arrhenius pre-exponential factor (units of the corresponding rate constant)
L	reactor length (m)
L_{mf}	reactor length at minimum fluidization (m)
L^*	dimensionless reactor length defined by Equation (11.162) (–)
M	number of reactions; the "space factor" (appropriate units)
$\sqrt{M}$	ratio of reaction in film to that in bulk, $\sqrt{\mathbf{D}_A k[B]_b / k_L}$
M_i	molecular weight of species i (kg/kmol)
m	reaction order; any exponent (–)
N	number of components; number of kmoles (–); speed (rps)
N_{cs}, N_{CM}	see text
N_{SG}	see text
N_{C50}	see text
N_{C70}	see text
N_i	number of kmoles of component i (–)
N_P	number of particles
N_{QS}	secondary flow number (–)
N_t	total number of kmoles (–)
Nu	Nusselt number (–)
n	reaction order (–)
P	pressure (atm or Pa)
$\mathbf{P}$	power (W)
Pe_{hr}	radial Peclet number for heat transfer, $d_p u C_p \rho / k_{T,er}$ (–)
Pe_{ma}	axial Peclet number for mass transfer, $d_p u / D_{ea}$ (–)
P_i	partial pressure of i (atm or Pa)
P_{nm}	parameter defined in Table 11.9 (–)
Q	volumetric flow rate (m^3/s)
Q_S	solids circulation rate (m^3/s)
R	chemical species (–); radius (m)
R'	group $\nu u_A / u_B$
R_A	specific rate of absorption (reaction) ($kmol/m^2/s$)
$\mathbf{R}_A$	reaction rate per pellet (kmol/s)
$\mathbf{R}_{GA}$	reaction rate of A in a grain (kmol/s)
R_g	ideal gas law constant (kcal/kmol K)
$\hat{R}$	dimensionless radius, r/R (–)
Re_p	particle Reynolds number ($d_p u_g \rho / \mu$ (–)
Re_{mf}'	Reynolds number at minimum fluidization, $u_{mf} d_p \rho / \mu$ (–)
r	general notation for reaction rate (appropriate units); radial coordinate (m)
$\mathbf{r}$	vector ($M \times 1$ matrix) of reaction rates (–)
r_A, r_{VA}	reaction rate of A ($kmol/m^3$ reactor s)
R_{Go}	initial grain radius (m)
r_{Gi}	interface radius in a grain (m)
r_i	radial position at the core-shell interface in SIM (m)
r_j	reaction rate of the *j*th reaction (appropriate units)
r_{SA}, r_A'	reaction rate of A ($kmol/m^2$ cat s)
r_{vA}	reaction rate of A ($kmol/m^3$ cat s)
r_{WA}	reaction rate of A (kmol/kg cat s)
$\mathbf{S}$	selectivity term defined variously as in Table 11.9

S	chemical species (–)
S_g	surface area of grain (m^2)
S_0	initial surface area per unit volume (1/m)
S_p	surface area of pellet (m^2)
S^*	dimensionless reaction surface area defined by Equations (11.90) and (11.92) (–)
S^*_p	dimensionless pore surface area defined by Equations (11.91) and (11.93) (–)
$S_{v,A}$	space velocity of A (1/s)
Sh	Sherwood number k_gR/D_e (–)
s	selectivity k_{v1}/k_{V2}; generalized distance parameter or shape constant of a pellet, 3 for a sphere, 2 for a cylinder, and 1 for a flat plate (–)
s_a	observed (actual) selectivity $(k_{v1}/k_{V2})_a$ (–)
T	temperature (K)
$\hat{T}$	dimensionless temperature within a pellet. (T/Ts) (–)
$\mathbf{T}$	tank diameter (m)
t	time (s)
t_{mix}	mixing time (s)
t_{p1}	total decay time for a fixed final level of decay (s)
$\bar{t}$	residence time in a flow reactor (s)
$\bar{t}_1, \bar{t}_2$	average residence times in reactor (W_1/F_s) and regenerator (W_2/F_2), respectively (s)
$\hat{t}$	any normalized time, e.g., decay time t_p/t_{p1}; time given by Equations (11.72) and (11.88) (–)
T^*	dimensionless time defined by Equation (11.150) (–)
U	overall heat transfer coefficient (kal/m^2 K s)
u	velocity (m/s)
u_{mf}	minimum fluidization velocity (m)
$u_{s\infty}$	terminal settling velocity of particle (m/s)
V	volume (m^3)
V^*	liquid volume in a variable volume reactor given by Equation (11.23)
V_g	pore volume of grain (m^3)
V_p	volume of pellet (m^3)
V_r	reactor volume where specifically mentioned (m^3)
V_T	volume of a single tube (m^3)
W	weight of catalyst (kg)
W_1, W_2	weights of catalyst in reactor and regenerator, respectively (kg)
X'_B, X_{B1}	dummy variables (–)
X^*	extent of reaction of a pellet defined by Equation (11.152) (–)
X_i	conversion of i (–)
Y_i	yield of species i (–)
Y_{ia}	Y_i under actual (observed) conditions (–)
y_i	mole fraction of i (–)
Y_{ra}, Y_{rb}	yields of R defined as $[R]/[A]_0$, $[R]/[B]_0$ (–)
Z	dimensionless reactor length, ℓ/d_p (–)
Z^*	dimensionless distance defined by Equation (11.151) (–)
Z_v	ratio of solid product to solid reactant kmolar volumes (–)

Greek

α	Arrhenius parameter, E/R_gT; diffusivity ratio, $\mathbf{D}_{eAs}/\mathbf{D}_{e,Aso}$ (–)
α_s	Arrhenius parameter at surface conditions, E/R_gT_s (–)
β	shape factor: 2 for sphere, 1 for cylinder, 0 for flat plate
β'	diffusional parameter given by Equation (11.89) (–)
β_m	heat generation term given by Equation (11.54) (–)
χ	dummy variable (–)
$\delta(t)$	residence time distribution function
δ_i	change in volume per unit volume of i upon reaction (see Table 11.1) (kmol)
ε	porosity (voidage) (–); holdup; catalyst effectiveness factor (–)

ε_b	bulk or bed porosity (voidage) (–)
$\bar{\varepsilon}_G$	average gas holdup (–)
ε_{gr}	riser gas holdup (–)
ε_{LD}	downcomer liquid holdup (–)
ε_{lr}	riser liquid holdup (–)
ε_i	change in total volume upon reaction per kmole of *i* reacting (m^3/ kmol)
ϕ	generalized Thiele modulus independent of pellet shape and reaction order defined by Equation (11.50); also general notation for Thiele modulus; modulus defined by Equations (11.71) and (11.87) (–)
ϕ_a	actual or Weisz modulus defined by Equation (11.51) (–)
ϕ_c	a critical value of the Thiele modulus given by Equation (11.78) (–)
ϕ_n	shape generalized Thiele modulus for an n order reaction (–)
ϕ_{pn}	Thiele modulus for an *n*th-order reaction in a flat plate
ϕ_{sn}	Thiele modulus for an *n*th-order reaction in a spherical pellet (–)
η	dimensionless position in grain (–); viscosity (Pa·s); enhancement factor (–)
λ	group defined by Equation (11.141)
ν	ratio of stoichiometric coefficients, ν_B/ν_A (–)
ν_i	stoichiometric coefficient of species *i* (–)
ν_{ij}	stoichiometric coefficient of A_i in the *j*th reaction (–)
$\boldsymbol{\nu}$	($N \times M$) matrix of stoichiometric coefficients (–)
θ	volume change modulus defined by Equation (11.87) (–)
θ_i	fraction of active sites occupied by species *i* (–)
θ_v	fraction of vacant active sites (–)
ρ	density (kg/m^3)
ρ_B	density of *B* (kg/m^3)
ρ_{Bm}	Molar density of *B* (mol/m^3)
ρ_b	bulk density (kg/m^3)
ρ_i	density of *i* (kg/m^3)
$\bar{\rho}_D$	average density of dispersion (kg/m^3)
σ	reaction modulus defined by Equation (11.153) (–); surface tension (dynes/m)
τ	total time given by Equation (11.66) (–)
τ'	dimensionless temperature in a reactor, T/T_0 (–)
τ_f, τ_a, τ_c	times for complete conversion of a solid if film transfer, ash diffusion, or reaction alone were controlling (s)
τ_G	time required for complete conversion of a grain (s)
τ_p	reaction or on stream time (s); time required for complete conversion of a pellet(s)
ω	dimensionless radial position in a reactor, r/R (–)
ξ	dimensionless position in a catalyst pellet or reacting solid (–)
ξ_i	dimensionless position of unreacted core, r_i/R (–)
ξ_j	moleculartiy of reaction *j* (i.e., number of kmoles reacting according to reaction *j* (–)
ψ	ratio y_{i0}/y_{A0}, F_{i0}/F_{A0} or $[i]/[i]_0$; cumulative gas concentration given by Equation (11.75) (–)
ψ'	structural parameter (–)
ψ_B	initial concentrations ratio, $[B]_0/[A]_0$ (–)
Ω	catalyst activity (–)
$\bar{\Omega}$	average catalyst activity (–)
ℓ	length coordinate (m)
$\Re_m$	mass transfer group, $d_p/u[A]_0$(m^3s/ kmol)
$\Re_H$	heat transfer group, $(-\ _r)d_p/uC_pT_0$ (m^3s/kmol)

Subscripts

b	bulk
bp	bubble generated at the sparger
bs	secondary bubble
CS	critical speed for solid suspension in the absence of gas
C	catalyst

D	dispersion
e	effective; exit (outlet) condition
er	effective radial
f	final condition (in time)
G	gas; grain
GD	gas in downcomer
GR	gas in riser
i	interface
L	liquid
LD	liquid in downcomer
LR	liquid in riser
mf	minimum fluidization
mix	mixing
O	initial (entry) condition
p	particle, pellet
r	reactor; radial
SG	critical speed in the presence of gas
s	solid; surface
	tube (reactor); tank
T	total
w	wall

Distillation is a physical process for separating a liquid mixture into its constituents. When such a mixture is partially vaporized, the vapor normally has a composition different from that of the residual liquid. Implied in the method is the condensation of the vapor to form a product liquid, called the *distillate*. The residual liquid product is often called the *bottoms*.

Distillation in crude form was practiced over 2000 years ago, usually for the concentration of alcoholic spirits. The first formalized documentation of distillation appears to be the treatise by Brunschwig in 1500.[1] Distillation has since emerged as the key method for separating liquid

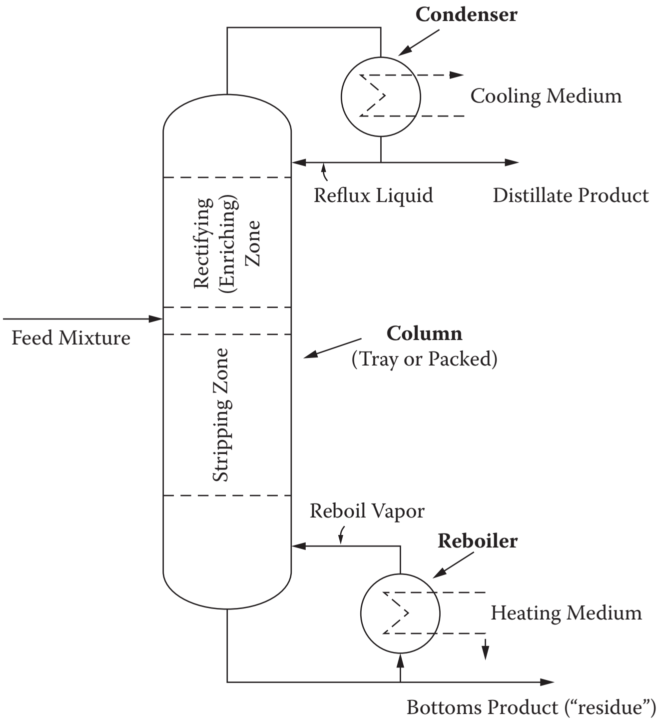

FIGURE 12.1 Distillation system operated in a continuous mode.

mixtures in chemical processing and related industries because of its versatility, simplicity, economy, and many years of experience.

Early distillations were of the batch, takeover type, sometimes called *simple distillation* or *differential distillation*. A charge of liquid mixture is vaporized from a *still*, or *stillpot*, by heat addition, and the product vapor is condensed into one or more fractions. Thus the term *fractional distillation*, or *fractionation*, has become associated with any distillation operation designed to obtain defined or specified constituent fractions.

Most distillations today are of the multistage rectification type, operated continuously or in the batch mode. They are characterized by vertical vessels *(distillation columns*) with internal contacting devices (usually trays or packings) that provide intimate contacting of vapor and liquid. When operated continuously (the usual preferred mode), the towers are normally fed with a liquid mixture near the center of the column, providing a *stripping zone* below the feed point and a *rectifying zone* (or "enriching zone") above the feed point. A diagram of a typical distillation column is shown in Figure 12.1. Heat is added at the base of the column by vapor from a *reboiler* and is removed at the top of the column in a *condenser* to provide the distillate product. Part of the distillate is returned to the column as reflux liquid.

The usual sequence of design steps for a distillation process as shown in Figure 12.1 is as follows:

1. Determine the feed composition including all minor components.
2. Establish the degree of separation to be achieved, including purities of key products as well as the fractions of certain feed materials to be recovered in one of the product streams.
3. Procure pertinent physical property data, especially including vapor-liquid equilibrium relationships ("equilibria") over the composition, temperature, and pressure ranges of

the separation. In many cases, computer-aided design packages predict physical properties such as equilibria, densities, viscosities, surface tensions, and diffusion coefficients.
4. Calculate the appropriate index of separability (usually *theoretical stages* but sometimes numbers of *transfer units*) for the separation required.
5. Specify the equipment needed for the process. Although the emphasis may be on the distillation column, heat exchangers, pumps, control systems, and so forth must also be included. This step includes determining the actual stages as some function of theoretical stages, or the height of the contacting zone as some function of transfer units.

12.1 BASIC MODELS

12.1.1 Phase Equilibrium

The fundamental basis of distillation is the physical equilibrium between the liquid and vapor phases of a system. Equilibrium is the condition reached after an infinite time of contact between the phases. In practice, liquid-vapor systems normally reach a state close to equilibrium in a comparatively short time of contact. At equilibrium, the composition in the vapor phase is usually different from that in the liquid. (If this is not the case, then an *azeotrope* is present, as discussed later.) The relationship of equilibrium concentrations of a component between phases is described by the *equilibrium ratio*. Other terms used for this ratio can include *distribution coefficient*, *equilibrium constant*, *K-constant*, or simply *volatility.*

The equilibrium ratio for a component i is defined as

$$K_i = y_i^* / x_i \quad \text{or} \quad y_i^* = K_i \, x_i \tag{12.1}$$

where

K_i = equilibrium ratio for component i
y_i^* = mole fraction of i in vapor at equilibrium
x_i = mole fraction of i in liquid

For example, if at equilibrium the liquid contains 0.1 mol fraction isobutane (iC_4), and if the equilibrium ratio of iC_4 under the system conditions is 2.5, then 0.25 mol fraction iC_4 is in the vapor. The equilibrium ratio is some function of temperature, pressure, and the composition of the liquid, which may be expressed as

$$K_i = f(T, P, x) \tag{12.2}$$

where

T = system temperature
P = system pressure
x = vector (set) of liquid molar concentrations for all components

The equilibrium ratios of two components in the system may be compared at the same conditions by means of the *relative volatility*, defined as

$$\alpha_{ij} = K_i / K_j \tag{12.3}$$

where α_{ij} = relative volatility of i with respect to j.

Often the relative volatility is expressed as the ratio of the more volatile component to the less volatile component so that the numerical value of α_{ij} is greater than unity.

Relative volatility is a useful tool to judge the feasibility and ease of a distillation separation. In general, the larger the relative volatility between two key components, the easier and less costly will be the separation of those keys. If the relative volatility between the keys is unity, then their separation by ordinary distillation is impossible. Such a situation exists with azeotropes. The relationship between relative volatility and difficulty of separation may be illustrated by application of a simple relationship (the Fenske equation, to be discussed later):

$$N_m = \frac{\ln\left[\dfrac{\left(x_i / x_j\right)_D}{\left(x_i / x_j\right)_B}\right]}{\ln \alpha_{ij}} \tag{12.4}$$

where

N_m = minimum number of equilibrium stages required at total reflux
D = distillate product
B = bottoms product

Since the optimum number of equilibrium stages for a column, based on economic considerations, is approximately 2.5 times the minimum value (to be discussed later), Equation (12.4) may be expressed in terms of design stages, while rearranging variables, as follows:

$$N_t = \frac{2.5 \ln\left(\dfrac{x_{iD} / x_{iB}}{x_{jD} / x_{jB}}\right)}{\ln \alpha_{ij}} \tag{12.5}$$

where N_t = number of equilibrium stages required.

For illustration, suppose a separation is to be made in which the light key component has a concentration in the distillate 100 times that in the bottoms, and the heavy key component has a concentration in the bottoms 100 times that in the distillate. Equation (12.5) may be applied with natural logarithms as follows:

$$N = \frac{2.5 \ln\left[{}^{100}\!\big/_{1/100}\right]}{\ln \alpha_{ij}} = \frac{2.5 \ln 10{,}000}{\ln \alpha_{ij}} \tag{12.6}$$

Application of Equation (12.6) over a range of relative volatilities gives results as shown in Table 12.1. Clearly, the phase equilibrium relationship is of paramount importance in distillation process economics.

12.1.2 The Contacting Stage

The basic building block for stagewise distillation processes is the contacting stage, illustrated in Figure 12.2. This stage receives liquid from the stage above and vapor from the stage below and passes vapor to the stage above and liquid to the stage below. It may also receive feed from the outside and/or produce a sidedraw product of liquid, vapor, or both. If a reaction occurs on the stage, as in reactive distillation (to be discussed later), the stage concentrations must reflect the

conversion obtained on the stage at its temperature and pressure conditions. For the hypothetical *theoretical stage,* the exit streams of liquid and vapor must be in equilibrium with each other.

A mass balance may be written around stage n as follows:

$$F_n z_{i,n} + L_{n-1} x_{i,n-1} + V_{n+1} y_{i,n+1} = (V_n + V'_n) y_{i,n} + (L_n + L'_n) x_{i,n} \tag{12.7}$$

An energy balance can be written around the contacting stage using the enthalpies of all vapor and liquid streams (Figure 12.3):

$$F_n H_{F,n} + L_{n-1} h_{n-1} + \mathrm{V}_{n+1} H + Q_n = (V_n + V'_n)\, H_n + (L_n + L'_n) h_n \tag{12.8}$$

where Q_n represents the heat added, removed, or generated within the stage either by a heat exchanger or an exothermic or endothermic reaction. In these balances, the stages are numbered downward from the top of the column.

The enthalpies of the vapor and liquid streams are functions of temperature, pressure, and composition:

$$H = f(T,P,y) \tag{12.9}$$

$$h = f(T,P,x) \tag{12.10}$$

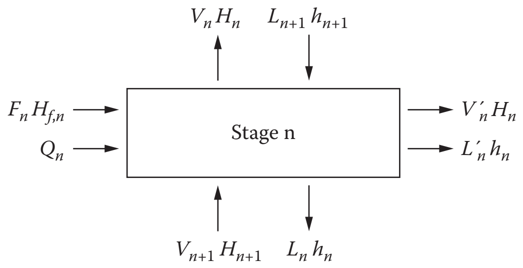

FIGURE 12.3 Stream energy flows on a contacting stage.

The approach to equilibrium for a contacting stage is called the *Murphree stage efficiency,* defined as the composition change in vapor across the stage divided by the composition change that would be achieved if true equilibrium existed:

$$E_{mv,i,n} = \frac{y_{i,n} - y_{i,n+1}}{K_{i,n}\ x_{i,n} - y_{i,n+1}} \tag{12.11}$$

Equation (12.11) is stated in terms of vapor compositions; an alternate form, not often used, utilizes liquid compositions to give a liquid efficiency $E_{ML,i,n}$. The exit vapor equilibrium $y_{i,n}* = K_{i,n} x_{i,n}$ is based on the exit liquid composition from the stage. For a real tray, the exit liquid may not have the same composition as the average liquid composition on the tray, i.e., there is often a composition gradient in the liquid. For this reason, Equation (12.11) sometimes gives efficiencies greater than 1.0. A more basic form of Equation (12.11) applies to any point within the stage, and this is the *Murphree point efficiency*, defined by Equation (12.11), but with point notations and given the symbol E_{og}. The point efficiency can never be greater than 1.0 and is a fundamental efficiency used in theoretical modeling.

12.1.3 Multiple Stages

The contacting stage shown in Figure 12.2 may be combined with other contacting stages to form a cascaded multiple-stage process as shown in Figure 12.4. This arrangement leads to the distillation column previously described. In more complex arrangements, the column can have multiple feeds and one or more sidedraw products and can be integrated with several columns in a *distillation train*.

12.2 VAPOR-LIQUID EQUILIBRIUM

The equilibrium ratio [Equation (12.1)] involves physical equilibrium between phases. The system involved may be binary or multicomponent and ideal or nonideal, according to the terminology used in solution thermodynamics. Methods for correlating or predicting equilibria are based on an application of thermodynamics to each phase and to the solutions of the components within each phase. The techniques are described in standard reference works such as Walas[2] and Reid et al.[3] For multicomponent systems, the usual approach is to model the equilibria for each of the binary pairs and then combine the binary models in special ways to obtain the multicomponent model.

The simplest situation occurs in a binary ideal system, such as benzene-toluene at low pressure (less than 2 atm). Here, Raoult's Law applies to the liquid phase:

$$p_i = p_i^{sat}\, x_i \tag{12.12}$$

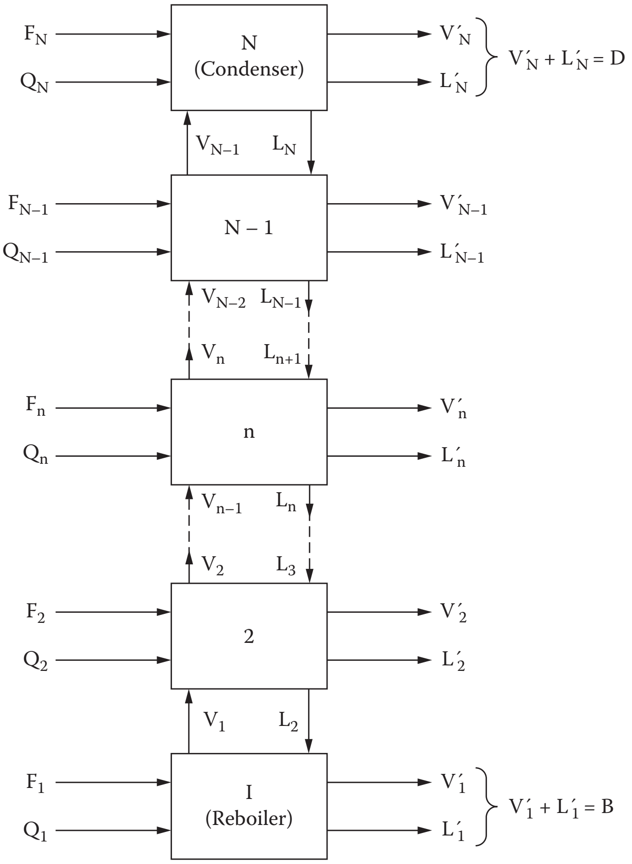

FIGURE 12.4 Cascaded stages in a distillation column.

where the vapor pressure p_i^{sat} is a function of temperature normally represented by the Antoine equation:

$$\ln p_i^{sat} = A + B/(T + C) \tag{12.13}$$

where constants A, B, and C have been evaluated for many elements and compounds.

If Dalton's law applies,

$$y_i^* = p_i/P \tag{12.14}$$

Combining Equations (12.1), (12.12), and (12.14) gives

$$K_i = \frac{y_i^*}{x_i} = \frac{p_i / P}{p_i / P_i^*} = \frac{P_i^*}{P} \tag{12.15}$$

The relative volatility between the two components i and j [Equation (12.3)] is

$$\alpha_{ij} = K_i/K_j \tag{12.16}$$

For the binary system, since $x_j = 1 - x_i$ and $y_j^* = 1 - y_i^*$,

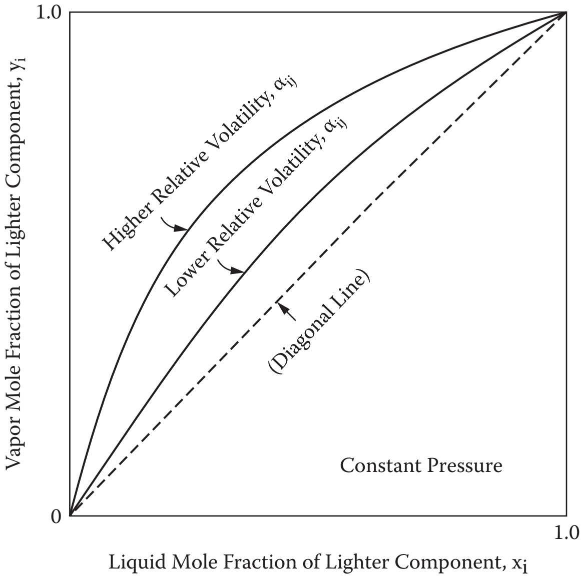

FIGURE 12.5 Equilibrium *y*-*x* diagram for ideal binary system *i*-*j*.

$$\alpha_{ij} = \frac{y_i^* / x_i}{\left(1 - y_i^*\right) / \left(1 - x_i\right)} \tag{12.17}$$

or

$$y^* = \frac{\alpha x}{1 + \left(\alpha - 1\right) x} \tag{12.18}$$

where x and y^* are the equilibrium concentrations of the more volatile component at equilibrium. These equilibrium concentrations may be computed from the relative volatility and, if the latter is constant, an equilibrium curve is obtained, as shown in Figure 12.5. For concentration ranges in which an average value of α is assumed, portions of the curve may be computed.

Most systems do not mix ideally in the liquid phase and, at lower pressures, their equilibria may be based on a modified form of Raoult's law:

$$K_i = y_i^*/x_i = (\gamma_i^L\, p_i^{sat})/P \tag{12.19}$$

where γ_i^L is the liquid phase activity coefficient for species i (sometimes called a "Raoult's law correction factor") and is a function of temperature and composition. This coefficient can range from as low as 10^{-8} (strong acids) to as high as 10^5 (immiscible liquids), but it usually falls in the range of 0.1 to 20.

Representative phase diagrams for the most common types of binary systems are shown in Figure 12.6, along with example systems. For each type, phase diagrams are presented in two ways: T vs. x and y, and y vs. x. Typical isothermal curves of activity coefficients for binary systems are illustrated in Figure 12.7.

Isothermal or isobaric activity coefficient relationships are modeled from experimental data by a variety of equations, all with a thermodynamic basis. The more useful of these equations are Van

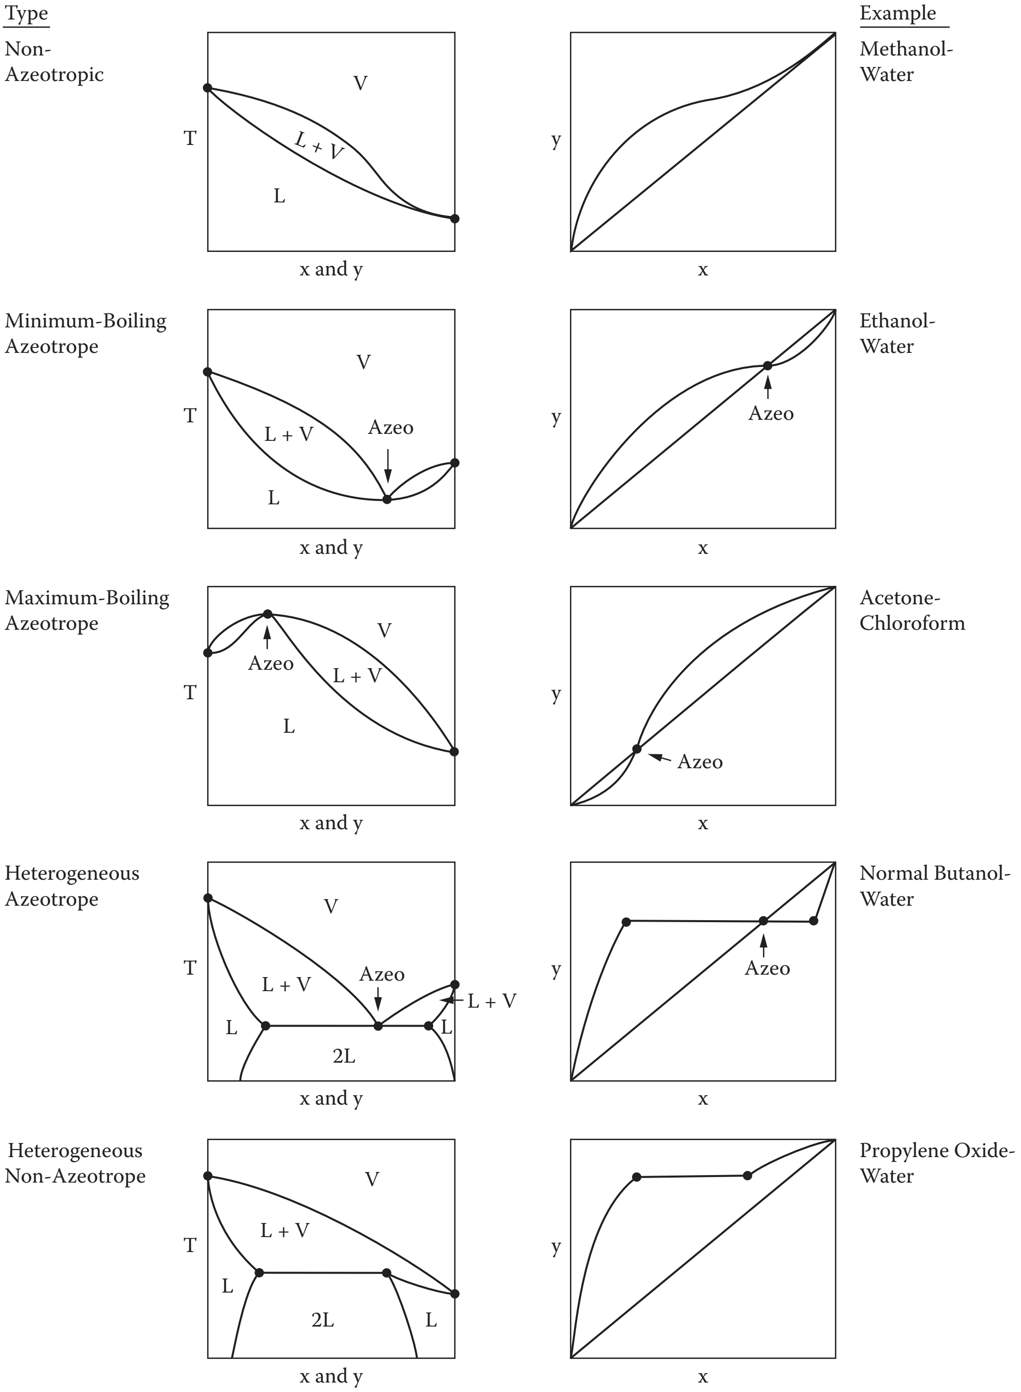

FIGURE 12.6 Common types of binary systems. (W. L. Bolles; J. R. Fair, 1982. *Encyclopedia of Chemical Processing and Design* 16: 51. Courtesy of Routledge/Taylor & Francis Group, © 1982.)

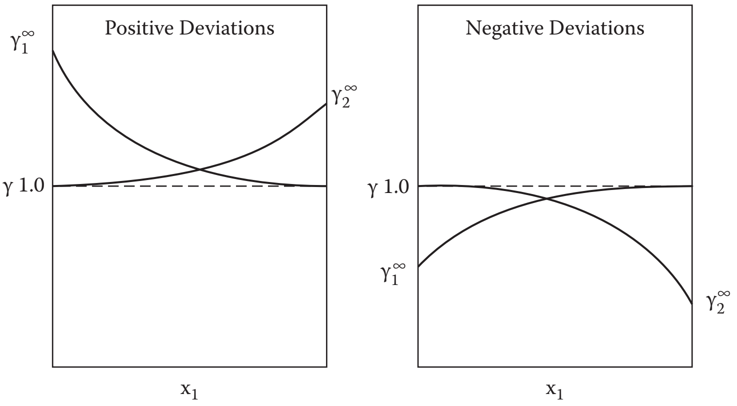

FIGURE 12.7 Typical isothermal curves of liquid-phase activity coefficients for binary systems.

Laar; Margules; Wilson; nonrandom, two liquid phases (NRTL), or Renon–Prausnitz; and Universal Quasi-Chemical Activity Coefficients (UNIQUAC). All of these equations have two constants except for the NRTL, which has three.

Perhaps the simplest, and surprisingly accurate, is the Van Laar.[4] Its use will be described here, but other equations can be handled in a similar fashion. References 2 and 3 provide details. For the binary system *i-j*, the Van Laar equation is

$$\ln \gamma_i = A_{ij}\left(\frac{A_{ji}\,x_j}{A_{ij}\,x_i + A_{ji}\,x_j}\right)^2 \tag{12.20}$$

$$\ln \gamma_j = A_{ji}\left(\frac{A_{ij}\,x_i}{A_{ji}\,x_j + A_{ij}\,x_i}\right)^2 \tag{12.20a}$$

where A_{ij} and A_{ji} are the constants determined from experimental y-x data or from azeotrope information. An important parameter in VLE studies is the nonideality at infinite dilution, where the activity coefficient normally is at a maximum. This terminal coefficient is called the *infinite dilution activity coefficient*, $\gamma_i^{L,\infty}$. From Equation (12.20), as $x_i \to 0$, $x_j \to 1.0$ and $\ln \gamma_i^{L,\infty} = A_{ij}$. Similarly, as $x_j \to 0$, $x_i \to 1.0$ and $\ln \gamma_j^{L,\infty} = A_{ji}$. There are special measuring devices that deal only with the infinite dilution case, and the total composition range is then handled with equations such as (12.20) and (12.20a). Evaluation of equilibria in the very dilute region can be critical when high-purity products are being obtained by distillation.

Activity coefficient modeling will be clarified later by Problem 12.1. The Van Laar equation, as well as the other equations listed above, can be used for multicomponent systems by first determining the constants for all possible binary pairs and then combining them according to certain rules. Values of the constants may be fitted from experimental data, and values for a large number of systems have been collected and checked by Gmehling et al.[5] One of their example pages is shown in Figure 12.8, covering one experimental study of the ethanol/water system at atmospheric pressure. Note that the activity coefficient constants for the above-listed equations are shown, together with their fit to the referenced experimental data (the fit is shown both for composition and equilibrium temperature).

FIGURE 12.8 Example tabulation of equilibrium data from the Chemistry Data Series. [J. Gmehling et al., 1979. *Vapor-Liquid Equilibrium Collection*, Chemistry Data Series (continuing series), DECHEMA, Frankfurt, Germany.]

Equation (12.19) applies primarily to lower pressures (below 2 to 3 atmospheres), where the equilibrium vapor mixes ideally and also behaves ideally according to the perfect gas law. The rigorous thermodynamic expression for the K value, taking all conditions into account, is

$$K_i = \left(\frac{\gamma_i^L}{\gamma_i^V}\right)\left(\frac{P_i^*}{P}\right)\exp\left[\frac{1}{RT}\int_{P_i^*}^{P}\left(v_i^L dP\right)\right]\exp\left[\frac{1}{RT}\int_{P}^{P_i^*}\left(v_i^v - \frac{RT}{P}\right)dP\right] \tag{12.21}$$

The modeling of activity coefficients in multicomponent systems and the application of the general model [Equation (12.21)] are discussed in detail by Walas[2] and Reid et al.[3]

12.2.1 Estimation and Measurement of Activity Coefficients

When equilibrium data can be found, as for example in the Gmehling compilations,[5] they should, of course, be checked for thermodynamic consistency and viewed critically. They may not cover all possible temperature, pressure, and composition conditions, thus they should be incorporated into a model such as described above. Then they can be extrapolated with some measure of reliability. Many distillation simulators have VLE built into them.

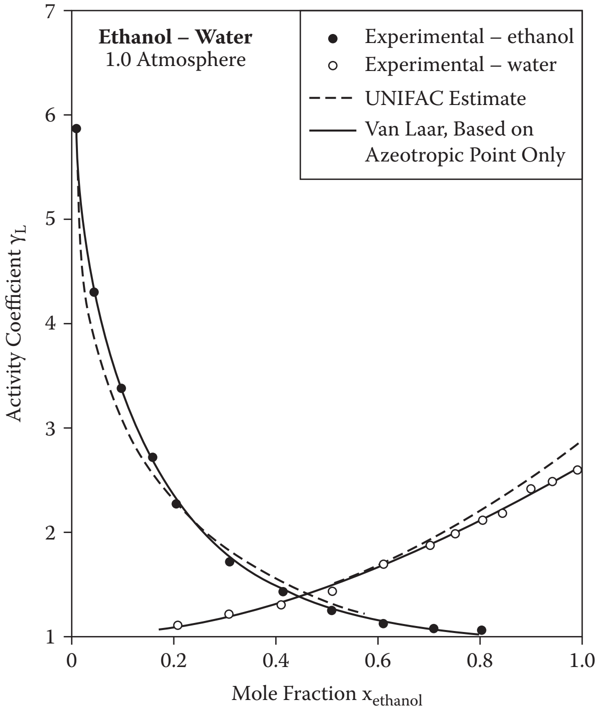

FIGURE 12.9 Representative activity coefficient–composition curves. Ethanol–water system, one atmosphere. Shown are the following: (i) experimental data [Figure 12.8], (ii) van Laar curves with constants computed from the aceotrope condition, and (iii) curves based on the UNIFAC model.

When the needed VLE data are simply not available, and for various reasons it is not feasible to measure them, then predictive methods might be considered. The most useful such method is called UNIFAC, based on Fredenslund et al.[6] and described by Walas[2] and Reid et al.[3] UNIFAC is a group contribution method, and one must have available the contribution parameters of the groups from which the molecules involved are derived. For example, the structure of the 2,2,4-trimethylpentane molecule comprises 5 CH_3 groups, 1 CH_2 group, 1 CH group, and 1 C group. Quantitative values of each group are available in the above references. Thus, one "builds" a total contribution of each molecule involved in the mixture, and the UNIFAC mixing rules are then applied. UNIFAC does not provide activity coefficients or *K* values of high accuracy, but they may be sufficient for exploratory purposes. The isobaric activity coefficient curves for the ethanol/water system, shown in Figure 12.9, show a comparison between the measured data (Figure 12.8) and the predictions by the Van Laar equation and the UNIFAC method.

When at least some experimental data are needed, a variety of equilibrium stills or other devices can be used. Perhaps the most complete descriptions of such devices are in the book by Hala et al.[7] Wiltech Research Co. in Provo, Utah is the best known place in the United States for custom VLE measurements. This company is prepared to make measurements on a variety of systems, including those that are corrosive or would foul the usual circulating equilibrium still. Laboratories in Europe for making such measurements include that of Professor Gmehling.

12.2.2 Summary—Vapor–Liquid Equilibrium

For mixtures that form ideal solutions in the liquid phase, handling of VLE relationships is relatively simple. One needs to know the vapor pressures of the components, and these are usually available.

TABLE 12.2
Procedure for Estimating VLE for Distillation Conditions

Steps	Comments
Obtain vapor pressure data for the components present in the mixture.	Antoine constants, thermo data, handbooks, etc.
Check vapor phase for departure from ideal gas, i.e., obtain fugacities.	Thermo data, eq. of state, generalized correlations.
View mixture for possible deviations from Raoult's law.	Homologs? Polar/non-polar mixtures? Azeotropes?
For hydrocarbon mixtures, K values may suffice at this point, with small departures from liquid phase idealities taken up by the convergence pressure.	K values from company files, API data book, GPSA data book, etc.
Find whether the mixture has been studied elsewhere (binary pairs).	Consult Hala et al., Gmehling et al., DIPPR data.
Find whether the mixture (total or by pairs) is in the Gmehling compilation.	Be careful about temperature and pressure variations.
If binary pair data are available from Ghehling or other sources, use appropriate model.	VanLaar, Wilson, NRTL, Uniquac, etc.
If still no data, check for azeotropes and calculate parameters for activity coefficient models	Consult Horsley or the new, extensive compilation by Gmehling and coworkers.
Failing the above, make estimates of activity coefficients:	
• Use UNIFAC structural contribution method.	Readily available on computer diskette (e.g., Sandler, S.I. *Chem. and Eng. Thermo.,* 2nd ed., Wiley, NY, 1989).
• As a variation for hydrocarbon mixtures, consider the Chao-Seader version of regular solution theory.	Occasionally the basic Scott-Hildebrand regular solution model might be useful for non-hydrocarbon mixtures.
• For critical cases where small errors could result in large costs, have experiments made to confirm estimated VLE.	Outside laboratories are available for this work if it is not feasible to do it in-house.
• Finally, recognize the importance of variations in composition, temperature, and pressure on the values of the K values used for design.	

Note: Process simulators can aid in some of the steps listed above.

If the pressure is high, corrections for departure from ideal gas behavior must be taken into account; equations of state or generalized compressibility charts are usually sufficient.

Mixtures with nonsimilar molecular structures, and in particular mixtures containing water, generally exhibit nonideal behavior. When this situation prevails, recourse must be made to published experimental data or correlations of liquid phase activity coefficients. With a minimum of experimental data, some very good models are available to provide activity coefficients over a broad range of conditions. If no experimental data are available, and there is no azeotrope, then approximate results can be obtained from the UNIFAC model. But it is better to make some experiments.

A procedure for approaching the problem of liquid phase nonideality through the use of activity coefficients is given in Table 12.2.

Problem 12.1

At 1.0 atm, ethanol and water form an azeotrope at 78.17°C and 0.9037 mole fraction ethanol. From this information, calculate the $\gamma^L - x$ relationships for ethanol (i) and water (j), and compare the results with the experimental data shown in Figure 12.8. Make a comparison also with curves generated by the UNIFAC method.

At 78.17°C and use of the Antoine constants in Figure 12.8,

$$\text{Ethanol: } \log_{10} p^{sat} = 8.11220 - \frac{1592.864}{°C + 226.184}; \; p_i^{sat} = 756.27 \text{ mm Hg}$$

$$\text{Water: } \log_{10} p^{sat} = 8.07131 - \frac{1730.630}{°C + 233.426}; \; p_j^{sat} = 329.08 \text{ mm Hg}$$

[Note: This form of the Antoine equation is an alternate to that given in Equation (12.13) in that common logarithms are used. This form enables use of the Antoine constants given in Figure 12.8.]

Because

$$\frac{y_i}{x_i} = \frac{\gamma_i^L \, p_i^{sat}}{P} = 1.0 \text{ (at the azeotropic point)}$$

then

$$\gamma_i^L = \frac{760}{756.27} = 1.0049$$

Similarly,

$$\gamma_j^L = \frac{760}{329.08} = 2.309$$

Equations (12.20) and (12.20a) may be rearranged to become explicit in the constants:

$$A_{ij} = \ln \gamma_i^L \left[1 + \frac{x_j}{x_i} \frac{\ln \gamma_j}{\ln \gamma_i} \right]^2 \quad A_{ji} = \ln \gamma_j^L \left[1 + \frac{x_i}{x_j} \frac{\ln \gamma_i}{\ln \gamma_j} \right]^2$$

Substituting,

$$A_{ij} = 1.8100, \; A_{ji} = 0.9311$$

The infinite dilution activity coefficients may be obtained from $\ln \gamma^{L,\infty} = A$, giving

$$\gamma_i^{L,\infty} = 6.110 \; \gamma_j^{L,\infty} = 2.537$$

These compare with the values of Gmehling (Figure 12.8) extrapolated from experimental data of

$$\gamma_i^{L,\infty} = 5.87 \; \gamma_j^{L,\infty} = 2.56$$

Figure 12.9 shows the experimental data points (Figure 12.8), curves based solely on the azeotrope evaluation of activity coefficients, and the curves determined from the UNIFAC model. The agreement is remarkably good.

12.3 STAGE CALCULATIONS

As noted earlier, distillation columns may be designed as a series of contacting stages, with each stage having a finite approach to an equilibrium stage. (An alternative approach, to be discussed later, is needed when the column does not contain discrete stages or plates.) Calculations for multistage columns are based on the assumption that equilibrium is attained, and correction is made later to account for the failure to reach equilibrium. Stage calculations are made to evaluate the parameters required for the column to meet the separation specifications. These parameters are commonly the number of stages, reflux ratio, distillate:feed ratio, and feed location. More details on stage calculations may be found in references 9 and 10.

12.3.1 Separation Specifications

These specifications define the desired degree of separation. For a simple distillation process (separation of a single feed into two products, distillate and bottoms), the specifications consist of one (and only one) variable related to the distillate quality and one (and only one) variable related to the bottoms quality. For example, consider a feed of 60 mole-% benzene and 40% toluene, benzene being the more volatile. One specification might be that the distillate contain no more than 1.0 mole-% toluene and the bottoms no more than 1.0 mole-% benzene. This would fix the overall material balance and show that over 99% of the entering benzene is recovered in the distillate. Alternatively, one could specify that 95% of the benzene in the feed be recovered in the distillate at 99.0% purity. This would fix the material balance.

12.3.2 Single-Stage Process

In some cases, a single stage is sufficient to effect the desired degree of separation between feed components. The single-stage process may be either *continuous* (steady state) or *differential* (batch). The continuous process is frequently referred to as flash vaporization, because one way of carrying out this process is to superheat the liquid feed and "flash" it across a valve to a vessel operating at a lower pressure, where the single-stage equilibrium between vapor and liquid is achieved.

The principal design and operating variables in the single-stage process are pressure, temperature, and L/V (liquid/vapor) ratio. Application of Gibbs' phase rule shows that these three variables are not entirely independent: fixing two of them automatically fixes the third. Ordinarily, two of the variables are specified, and computations are employed to determine the value of the third variable as well as the compositions of the vapor and liquid products.

There are two limiting cases. One is the *dew point*, where $L/V = 0$ and the product is entirely vapor but at the threshold of condensation. The relationship between pressure and temperature at the dew point is obtained by a summation of mole fractions:

$$\sum x_i = 1 \tag{12.22}$$

where

$$x_i = z_{iF} / K_i \tag{12.23}$$

The other limit is the bubble point, where $L/V = \infty$, and the product is entirely liquid at the threshold of vaporization:

$$\sum y_i = 1.0 \tag{24}$$

where

$$y_i = K_i\, z_{i,F} \tag{12.25}$$

In the region between bubble point and dew point conditions, application of a mass balance on the *i*th component results in

$$y_i\, V = \frac{z_i}{1 + L / VK_i} \tag{12.26}$$

Summing up for all components gives

$$V = \sum_i \frac{z_i}{1 + L / V\, K_i} \tag{12.27}$$

These equations can be combined to yield

$$y_i = \frac{z_i\ / \left(1 + L / VK_i\right)}{\sum_i z_i / \left(1 + L / VK_i\right)} \tag{12.28}$$

$$x_i = \frac{z_i - y_i V}{L} \tag{12.29}$$

In addition, it is required that

$$\sum y_i = 1 \quad \text{and} \quad \sum x_i = 1 \tag{12.30}$$

Equations (12.28) through (12.30) are solved by trial and error, by hand, or with the aid of a computer. For example, if P and T are specified, then the iteration must proceed on L/V. When a final temperature is specified, an *isothermal flash* results.

When no heat is added or withdrawn from the process, an *adiabatic flash* occurs. For this case, Equations (12.28) through (12.30) still apply, but in addition the enthalpy balance must be satisfied:

$$F\, h_F = Lh_L + VH_v \tag{12.31}$$

The single-tray differential process will be discussed later in connection with batch distillation.

12.3.3 Multistage Processing

If a single stage is insufficient to meet the desired separation, then multistage processing must be employed (see Figure 12.4).

12.3.4 Binary Systems

The simplest case of multistage distillation is the continuous distillation of binary systems where the feed contains only two components. Here the most widely used method of analysis is that of

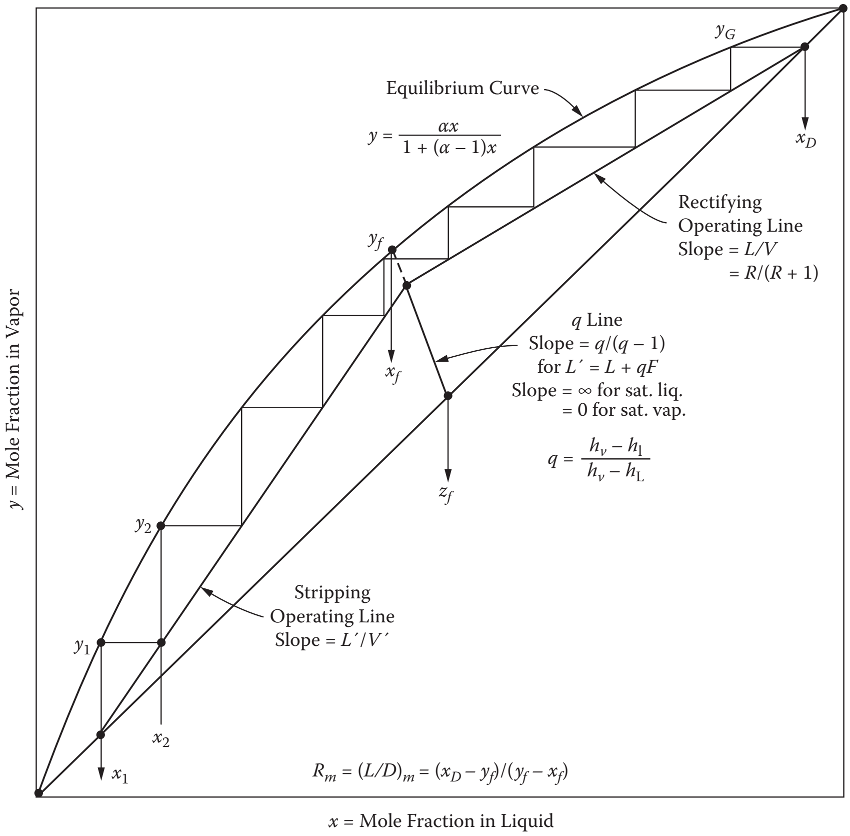

FIGURE 12.10 McCabe–Thiele diagram for a binary system.

McCabe and Thiele[8] as summarized in Figure 12.10. First, equilibrium mole fraction coordinates are plotted to obtain the y-x curve. Then the feed, distillate, and bottoms compositions are located on the diagonal. Next, the *q-line* is drawn from the feed point with a slope as determined by its enthalpy as noted on the graph. (For a saturated liquid feed, the line is vertical, and for a saturated vapor feed, the line is horizontal.) Then the *rectification operating line* is drawn from the distillate composition point with a slope determined from the *reflux ratio*. Next, the *stripping operating line* is drawn from the bottoms composition point up to the intersection of the *q*-line and the rectification operating line. (These lines will be straight if the molal latent heats of vaporization of the pure components are equal; if these heats are unequal, then the lines will be curved and can be located only by running intermediate heat balances.) Finally, the equilibrium stages are stepped off as indicated in Figure 12.10 to give the required number of equilibrium stages. Nine equilibrium stages are shown in Figure 12.10. Details on the construction and use of McCabe–Thiele diagrams (Figure 12.10) are found in standard texts.[4,9,10]

In the above procedure, the reflux ratio is specified and the required stages calculated. Alternatively, the number of stages is specified and the required reflux ratio calculated. This implies a fitting procedure on the chart, with the operating lines adjusted to give the correct number of stages. Such a procedure is useful when conditions are changed in an operating column; e.g., the feed composition changes and the proper reflux ratio adjustment can be predicted. The McCabe–Thiele approach can also be used to determine the minimum number of stages at total reflux and the minimum reflux ratio corresponding to an infinite number of stages.

The McCabe–Thiele approach is applicable to any binary system, even if nonideal, as will be evidenced by an unusual shape of the equilibrium curve. As normally used, the procedure requires

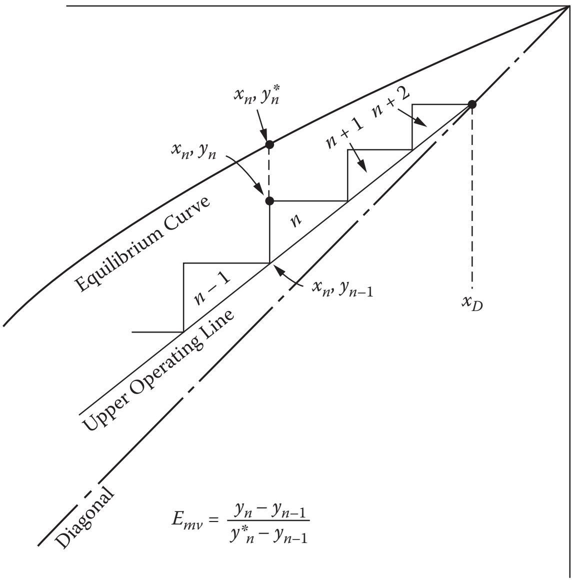

FIGURE 12.11 Modified McCabe-Thiele plot to show approach to equilibrium on real stages. The relative height of the real stage to the equilibrium stage height denotes Murphree stage efficiency.

the assumption of constant molal overflow in each of the sections (above and below the feed), leading to straight operating lines. Negligible heat losses to the surroundings is a usual assumption. The method can also be used for more than one feed and for side drawoffs of product.

In Figure 12.10, it is not required that the steps touch the equilibrium curve. They may take stage efficiency into account and go only part way to the curve, as shown in Figure 12.11. If for some reason the efficiencies of all stages are not the same, this can be taken into account easily. The fractional approach to the height of an equilibrium stage is the Murphree efficiency as defined in Equation (12.11) and discussed later.

Another graphical design method for binary systems is that of Ponchon[11] and Savarit.[12] This method includes an energy balance on each stage and is totally rigorous for binary systems. However, it requires mixture enthalpy data, often unavailable, and is cumbersome in application.

12.3.5 Stages–Reflux Relationships

For a specified separation of a feed stream, the required stages and the required reflux ratio are related as shown in Figure 12.12. While the curves are somewhat idealized, they show the limiting conditions of the design parameters. As the curve increases in the y direction, it approaches an asymptote value of reflux ratio. This is the *minimum reflux ratio* and corresponds to an infinite number of theoretical stages. Along the x-axis, the asymptote value represents the *minimum number of stages* equivalent to infinite (i.e., total) reflux. A practical design point lies somewhere in between these limiting conditions.

The case of total reflux also represents a practical condition for operating a distillation system during startup or for determining the efficiency of various contacting devices for a distillation column. Performance data for such devices, shown later herein, are likely obtained under total reflux conditions.

12.3.6 Multicomponent Systems

For systems with more than two components, there are two approaches to stage calculations: *approximate methods,* which can be done quickly by hand, and *rigorous methods,* which require a computer. The approximate methods will be discussed first.

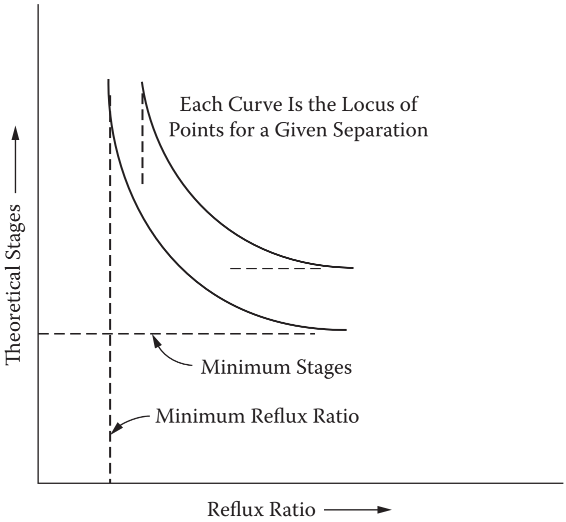

FIGURE 12.12 Representative plot of theoretical stages vs. reflux ratio for a given separation. Note the limiting conditions of minimum reflux and minimum stages.

For the limiting case of total reflux (Figure 12.12), the minimum number of stages may be determined by the Fenske[13] equation:

$$N_m = \frac{\ln\left[\frac{(x_i / x_j)_D}{(x_i / x_j)_B}\right]}{\ln \alpha_{ij}} = \frac{\ln\left[\frac{(x_D / x_B)_i}{(x_D / x_B)_j}\right]}{\ln \alpha_{ij}} \tag{12.32}$$

where i and j are usually the light and heavy key components. The Fenske method is rigorous if the relative volatility is constant throughout the section of the column being considered. It can be used for binary systems to obviate the need for the McCabe–Thiele graphics if the relative volatility is constant, i.e., the y-x curve is uniform.

The other limiting parameter, minimum reflux ratio at infinite stages, may be calculated by means of the Underwood[14] equations:

$$R_m = \sum_i \left[\frac{\alpha_i \, x_{iD}}{\alpha_i - \theta}\right] - 1 \tag{12.33}$$

where θ is the root of

$$\sum_i \frac{\alpha_i \, x_{iF}}{\alpha_i - \theta} = 1 - q \tag{12.34}$$

and q is computed as in the McCabe–Thiele method (see Figure 12.9).

The relationship between stages and reflux ratio was quantified empirically by Gilliland[15] and presented graphically in Figure 12.13a. Numerous authors have published mathematical fits to the Gilliland curve, a representative fit being that of Rusche:[16]

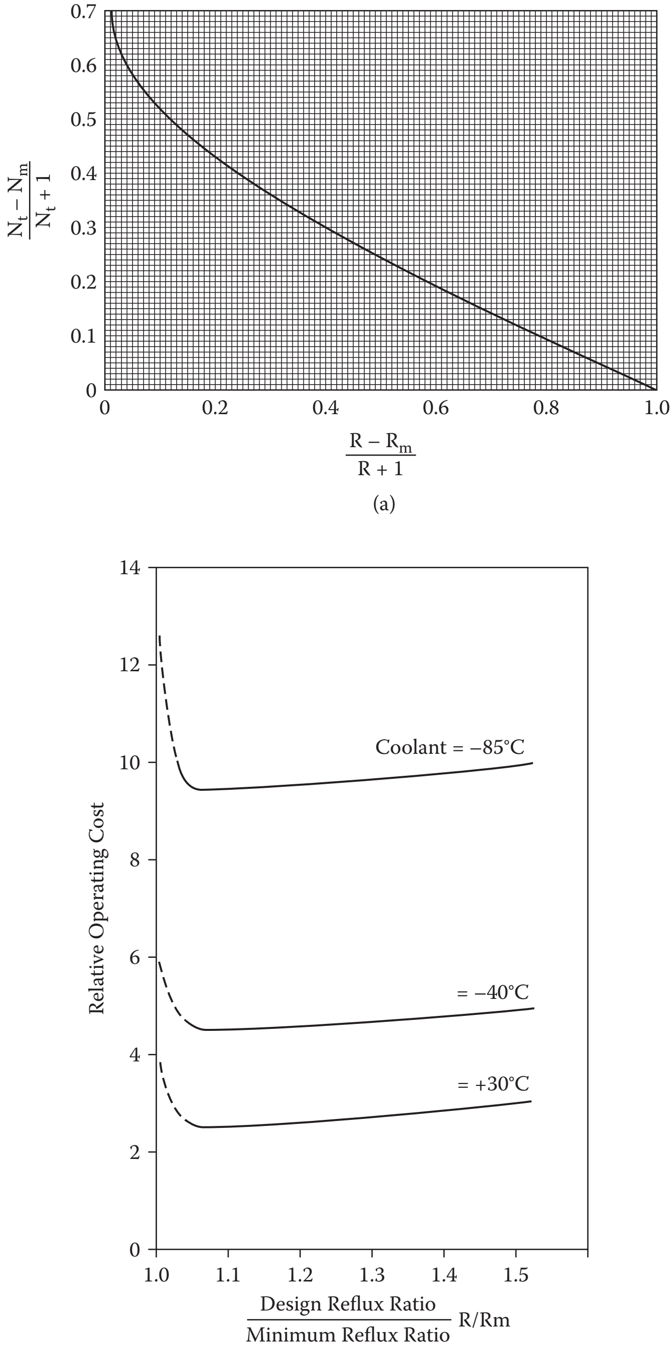

FIGURE 12.13 (a) Gilliland relationship between actual reflux ratio R, minimum reflux ratio R_m, theoretical stages N_t and minimum theoretical stages N_m. (b) Optimum reflux ratio as a function of operating temperature level. (E. R. Gilliland, 1940. *Ind. Eng. Chem.* 32: 1220.)

$$Y = 1.0 - 0.1256X - 0.8744X^{0.2910} \tag{12.35}$$

where

$$Y = \frac{N_t - N_m}{N_t + 1} \tag{12.36}$$

$$X = \frac{R - R_m}{R + 1} \tag{12.37}$$

The relationship shown in Figure 12.13a is equivalent to that shown in Figure 12.12, with the separation parameters absorbed in the values of N_m and R_m.

As Figure 12.12 indicates, many combinations of reflux ratio and stage number can be used to obtain a required separation. The question is: what is the optimum combination? This is a classical problem in chemical engineering economics: a greater number of stages makes the column higher and more expensive, and this is balanced against the savings of utilities at the lower reflux ratio. Thus it is a matter of balancing capital and operating costs in some rational fashion. The usual approach is to express the optimum condition in terms of an optimum ratio of R to R_m.

12.3.7 Optimum Reflux

A popular rule of thumb is to use a ratio R/R_m of about 1.2. Fair and Bolles[17] made a detailed study of this ratio, and three cases of their work are shown in Figure 12.13b. The cases represent different levels of coolant ranging from –85°C (requiring expensive two-level refrigeration) to +30°C (cooling water). The shapes of the curves are strikingly similar, with an optimum R/R_m of about 1.05. However, the computation of minimum reflux R_m is imprecise, especially for multicomponent systems, owing to inaccuracies of phase equilibrium and stage model execution. To avoid the danger of an impossible design, optimum R/R_m values in the range of 1.15 to 1.25 should be used, The curves are fairly flat at higher R/R_m values, so the selection of the design value has flexibility and may very well be influenced by such practical concerns as maximum allowable diameter, plant limitations on maximum height, and so on.

Figure 12.13a or Equation (12.35) may be used to obtain an approximate number of theoretical stages from the simple Fenske equation for minimum stages. Equations (12.36) and (12.37) may be modified to

$$Y = \frac{N_t/N_m - 1}{N_t/N_m + 1/N_m} \tag{12.36}$$

$$X = \frac{R/R_m - 1}{R/R_m + 1/R_m} \tag{12.37}$$

For example, if $N_m = 5$ and $R_m = 0.70$ (from Fenske and Underwood relationships), and optimum $R/R_m = 1.15$, $X = 0.058$ and, from Figure 12.13a, $Y = 0.57$. Solving, $Nt/N_m = 2.59$. While this ratio will vary with conditions, the heuristic of $N_t/N_m = 2.5$, given in Section 12.1.1, is often used.

12.3.8 Design Procedure

First, the minimum number of stages is computed by the Fenske method. Then, the minimum reflux ratio is computed by the Underwood method. Next, the design (operating) reflux ratio is chosen as some multiple of the minimum reflux ratio, e.g., 1.15 × R_m. (The optimum multiple is in the

range of 1.15 to 1.25.) Next, the required number of equilibrium stages is determined by the Gilliland correlation. Finally, the required number of actual trays is determined using a stage efficiency [Equation (12.11)]; elaboration of this last step will follow in later sections of this work.

Problem 12.2

To demonstrate the application of approximate stage calculations, an example design problem will be solved. The elements of the problem are tabulated below, including the specified material balance in moles. The particular case is a six-component de-ethanizer required to separate between ethane (light key) and propylene (heavy key). Such a column is needed in some large ethylene plants. An elaboration of this problem may be found elsewhere.[17]

	Feed	Distillate	Bottoms
Methane	5.00	5.00	—
Ethane (LK)	35.00	31.89	3.11
Propylene (HK)	15.00	0.95	14.05
Propane	20.00	—	20.00
i-Butane	10.00	—	10.00
n-Butane	15.00	—	15.00
	100.00	37.84	62.16

Minimum reflux ratio (Underwood)	1.378
Minimum theoretical stages (Fenske)	6.8
Operating reflux ratio (1.25 × minimum)	1.722
Theoretical stages (Gilliland graph)	14.5
Theoretical stages (Rusche equation)	14.8

12.3.9 Computer Methods

Digital computer programs are widely available for making rigorous stage calculations. They can handle many components (25+) and many stages (100+), and their accuracy is limited only by the reliability of the input thermodynamic data. They can handle multiple feeds; multiple sidedraws; stage heat exchangers; and chemical reactions occurring in the liquid and/or vapor, for reactive distillation applications. They can also handle the approximate design approach discussed above.

Two approaches are available to solve the multicomponent separation problem: the design method and the rating method. These methods have different input-output specifications, as shown in Table 12.3.

The *design method* is best described by Lewis and Matheson.[18] It is called "design" because it starts with the design specifications in terms of key components in the terminal products. The concentrations of all other components in the terminal products must be assumed. The stage

TABLE 12.3
Design versus Rating Models for Rigorous Distillation Stage Calculations

Design Method		Rating Method	
Input	**Output**	**Input**	**Output**
Feed	No. of stages	No. of stages	Distillate composition
Distillate composition	Feed stage	Feed stage	Bottoms composition
Bottoms composition	Distillate rate	Distillate rate	
Reflux/min. reflux	Reflux ratio	Reflux ratio	
		Feed	

calculations proceed from the ends of the column toward the feed [or from one end to the other, taking into account the addition of the feed(s)]. In each stage, four criteria must be satisfied: material balance, equilibrium between phases, summarion of phase mole fractions to 1.00, and heat balance.

From the first letters, the familiar MESH equations are identified. These equations must be solved rigorously at each stage before moving to the next. When the traverse of the column is completed, there must be a match between the computed and assumed overall material balance. If not, another trial is necessary. Especially onerous are the points of addition of components not present in both distillate and bottoms streams. While the Lewis–Matheson method is straightforward (although extremely laborious) for hand calculations, it was the standard method before large computers became available. With large computers, it often presents serious programming problems with respect to the convergency algorithm—particularly the assumptions of splits of nonkey components.

The *rating method* for rigorous stage calculations was developed by Thiele and Geddes.[19] Their approach is a "rating" method in that it starts with a specified number of stages and reflux ratio and then rates the separation possible with that combination. The method is more amenable to computer implementation and now is the standard. The Thiele–Geddes derivation begins with a component mass balance on the general contacting stage, counting downward from the top of the column:

$$V\,y_{n+1,i} + L\,x_{n-1,i} - V\,y_{n,i} - L\,x_{n,i} + F\,z_{n,i} = 0 \tag{12.38}$$

Equation (12.38) may be rewritten in terms of the molar flow rates of a specific component:

$$v_{n+1,i} + \iota_{n-1,i} - v_{n,i} - l_{n,i} + f_{n,i} \quad = 0 \tag{12.39}$$

The phase equilibrium relationship is defined by

$$y_{i,n} = K_{i,n}\,x_{i,n} \tag{12.40}$$

which may be rewritten as

$$\frac{v_{n,i}}{V} = K_{i,n}\frac{l_{n,i}}{L} \tag{12.41}$$

from which

$$l_{n,i} = \left(\frac{L}{K_{i,n}V}\right)v_{n,i} \tag{12.42}$$

Introducing the "absorption factor" A_n, defined as

$$A_{n,i} = L/K_{i,n}\,V \tag{12.43}$$

Equation (12.42) becomes

$$l_{n,i} = A_{n,i}\,v_{n,i} \tag{12.44}$$

Introducing Equation (12.44) into Equation (12.39) gives

$$v_{n+1,i} + A_{n-1,i}\ v_{n-1,i} - v_{n,i} - A_{n,i}\, v_{n,i} - A_{n,i}\, v_{n,i} + f_{n,i} \quad = \quad 0 \tag{12.45}$$

which can be rearranged to

$$A_{n-1,i}\, v_{n-1,i} - \left(1 + A_{n,i}\right) v_n + v_{n+1,i} \quad = \quad -\, f_{n,i} \tag{12.46}$$

One should note that Equation (12.46) is a linear equation in three unknowns (for each component): v_{n-1}, v_n, and v_{n+1}. The equation may be written *N* times for every stage of an *N*-stage column. The result is a matrix of *N* linear equations in *N* unknowns for the *i*th component. This matrix is a *sparse matrix* of the *tridiagonal* type. The matrix is easily solved by a computer to yield the component flows on each stage of the column. This procedure is repeated for each component of the system.

The Thiele–Geddes method is simple and straightforward for the case of constant molal overflow (L = constant) and constant component equilibrium ratios K_i throughout the column, because this results in constant absorption factors. Actually, in the general case, the molal overflow is not constant but is governed by the stage energy balances, and the equilibrium ratios are not constant since they depend on changing temperature, pressure, and composition. Accordingly, some elaborate iterative schemes are necessary to make the method work

Problem 12.3

The design of Problem 12.2 was solved by means of a rigorous computer program based on the Thiele–Geddes model. Since the approach is the rating method, start with input values of the column configuration and operating conditions, and choose the results of the approximate calculations from Problem 12.2 (reflux ratio = 1.722, 14 equilibrium stages, excluding reboiler and condenser).

The resulting computer output is reproduced in Table 12.4. Now compare the predicted performance by the hand and computer methods:

	Approximate	**Rigorous**
Mole-% propylene in distillate	2.50	2.40
Mole-% ethane in bottoms	5.00	5.79

The approximate method gives an overall separation reasonably close to that computed by the rigorous method. This agreement is aided by the problem selected—distillation of a homologous series of hydrocarbons, a fairly ideal case. Even so, it is clear that some adjustment in the input conditions for the rigorous method is necessary if the original specifications are to be met.

12.4 SPECIAL DISTILLATIONS

12.4.1 Azeotropic Distillation

12.4.1.1 General Principles

An *azeotrope* is a mixture of two or more components that, when brought to boiling, issues a vapor with the same composition as the liquid. Hence, separation by simple distillation is not possible. Binary systems containing azeotropes have y-x equilibrium curves as shown in Figure 12.6. On either side of the azeotropic composition, separation by simple distillation is possible.

The occurrence of a minimum or maximum on the temperature vs. composition surface is caused by positive or negative deviations from Raoult's law [see Equation (12.19)]; a system is *positive* if the logarithm of the activity coefficient γ_i^L is greater than zero, and *negative* if the logarithm is less than zero. Deviation from Raoult's law is not sufficient to cause the occurrence of an azeotrope; the boiling points of the pure components must also be sufficiently close to permit a minimum or maximum temperature to occur. Close-boiling components with small deviations from ideality may form an azeotrope. On the other hand, compounds that form very nonideal liquid mixtures may not exhibit an azeotrope because of a wide difference in their boiling points. Azeotropes seldom occur between compounds whose boiling points differ by more than 30°C.

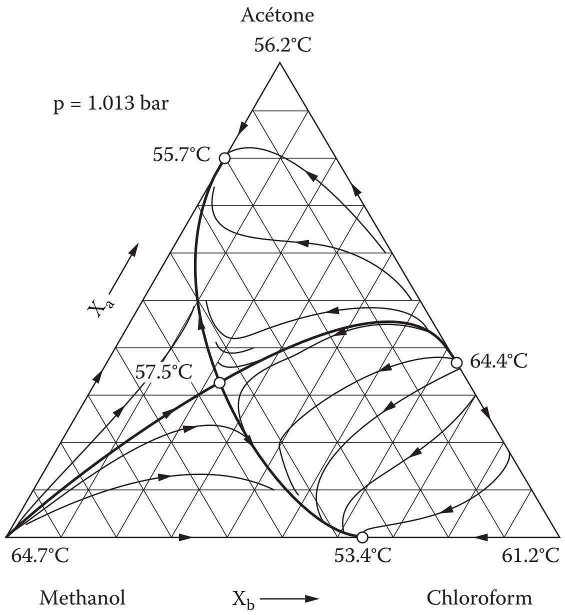

FIGURE 12.14 Ternary diagram of a system containing three binary azeotropes and one ternary azeotrope. Arrows denote direction the distillation will proceed in, based on starting mixtures. (J. Stichlmair, J. R. Fair, 1998. *Distillation—Principles and Practices.* New York: Wiley-VCH.)

Figure 12.6 shows five of the most common types of binary systems. Types B, C, and D are azeotropic, whereas Types A and E are not. Types B and C are called *homogeneous azeotropes* of a single liquid phase; in like fashion, a *heterogeneous azeotrope* derives from two immiscible liquid phases. Type B is a *minimum-boiling azeotrope* (boiling temperature lower than those of the pure components), whereas Type C is a *maximum-boiling azeotrope* (boiling temperature above the pure components). Minimum boiling azeotropes are the most prevalent. Azeotropes can occur in multicomponent systems; an example case is shown in Figure 12.14.[20] Here, a three-component system has three binary azeotropes and one ternary azeotrope. The curves in Figure 12.14 show likely distillation paths for a multistage system.

The only way to be certain that an azeotrope exists in a mixture is to make the equilibrium measurements. Measurements have been made and are reported by Horsley[21] and by Gmehling et al.[22] Most systems reported are binaries.

12.4.1.2 The Azeotropic Distillation Process

Azeotropic distillation involves either an *embedded azeotrope*, present in the feed mixture, or a *contrived azeotrope,* formed by the addition of an extraneous component called an *entrainer*. Benzene-water may be separated into high-purity benzene and the benzene–water azeotrope; this is frequently practiced to remove water from benzene when very dry benzene is needed for chemical processing. More commonly encountered are distillation separations that are enhanced through the addition of an entrainer to form an azeotrope. Perhaps the best known separation of this type is the production of anhydrous ethanol from the ethanol–water azeotrope. Here, benzene is added as the entrainer, with the result that a low-boiling ternary azeotrope is formed between benzene, ethanol, and water. This permits the higher-boiling ethanol to be taken from the bottom of the column. The distillate condenses to a heterogeneous mixture of benzene and alcohol–water phases.

In Problem 12.4, it may be recognized that the water layer can be further distilled to produce the ternary azeotrope (b.p. 64.86°C, 1 atm) from a bottoms material containing water and the water-

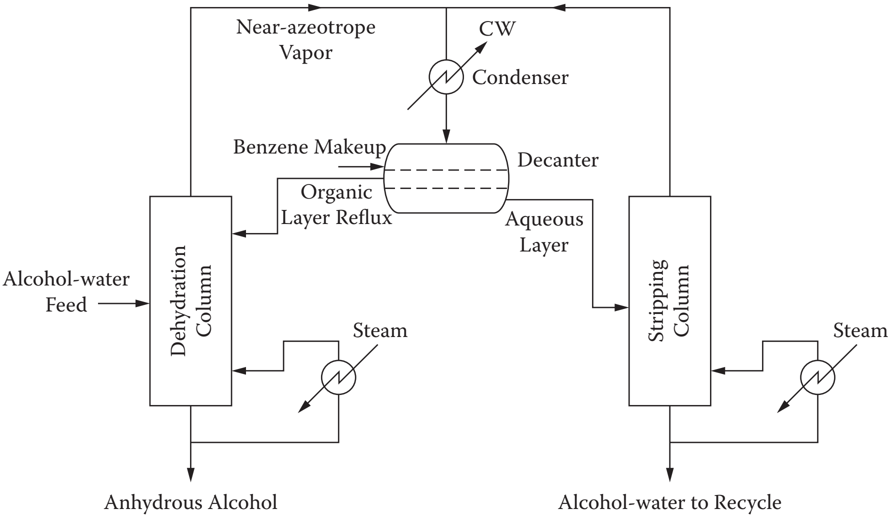

FIGURE 12.15 Flow diagram of azeotropic distillation system to obtain anhydrous ethanol.

alcohol azeotrope. Figure 12.15 shows a flow diagram of the entire process, starting with the water-ethanol azeotrope as feed. Thus, in the total process, the following could be involved:

	B.P., °C at 1 atm	Comp., wt-%
Benzene–alcohol–water azeotrope	64.86	H_2O 7.4, EtOH 74.1, C_6H_6 74.1
Benzene–alcohol azeotrope	68.3	EtOH 32.0
Benzene–water azeotrope	69.0	H_2O 8.8
Alcohol–water azeotrope	78.2	H_2O 4.0
Alcohol	78.3	
Benzene	80.1	
Water	100	

If alcohol is to be produced in high purity as a bottoms stream, then the water and benzene must be tied up in lower-boiling azeotropes and pure compounds and distilled overhead.

For approximate calculations, the azeotropes may be considered pseudocomponents with their individual vapor pressures, as indicated in Figure 12.16. The vapor pressure of the psuedocomponent (butanol-water azeotrope) roughly parallels the lines for *n*-butanol and water, and relative volatilities between the three components could be established.

Problem 12.4

Consider producing anhydrous ethanol from a feed stream containing 85 mole-% C_2H_5OH and the remainder water. Since this system exhibits a minimum-boiling azeotrope at 78.1°C containing 89.43 mole-% C_2H_5OH (at 1 atm), the separation is impossible by ordinary distillation.

However, the addition of benzene as an entrainer results in a minimum-boiling heterogeneous ternary azeotrope at 64.86°C (1 atm) of the following molar composition:

Ethanol	22.8%
Benzene	53.9%
Water	23.3%
	100.0%

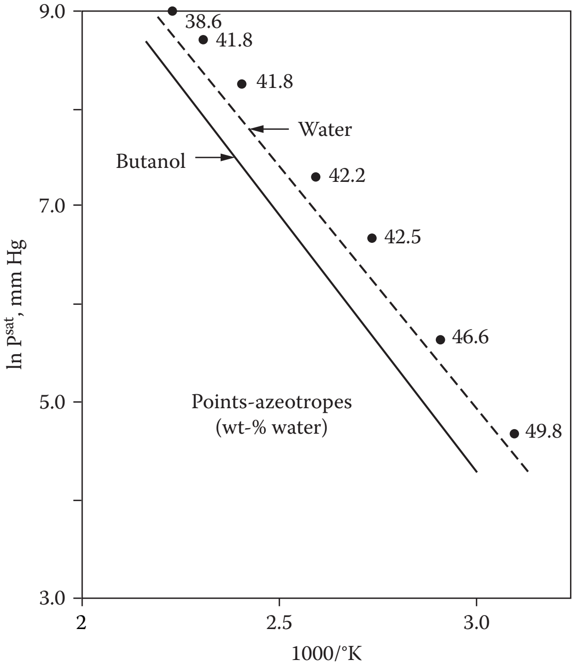

FIGURE 12.16 Vapor pressures of *n*-butanol, water, and *n*-butanol/water azeotrope. (Data from L. H. Horsley, 1973. *Azeotropic Data III,* Washington, DC. Am. Chem. Soc.)

On condensation, this azeotrope separates into two immiscible liquid phases of the following compositions (mole-%)

Component	Benzene layer	Water layer
Ethanol	23%	22%
Benzene	65%	3%
Water	12%	75%
	100%	100%

That benzene is an effective entrainer can be confirmed by comparing the ethanol/water molar ratio in the binary and ternary azeotropes:

Binary	89.43/10.57 = 8.46
Ternary	22.8/23.3 = 0.98

The fact that these two ratios are different indicates that separation of anhydrous alcohol is feasible.

Clearly, the azeotrope has vapor pressure characteristics of a single component. It is also clear that pressure has an effect on the location of the azeotrope, and this pressure influence is used commercially to make separations (see reference 23). In some cases, a change in pressure can cause the azeotrope to disappear; for ethanol-water, distillation at a pressure of 75 mm Hg or less results in an azeotrope-free operation.

12.4.1.3 Prediction of Azeotropes

For a system to be azeotropic, the components are not only close-boiling but of different structures. When an agent (entrainer) is added, its function is to interact so that the volatility of one component

is affected to a degree different from that of the other component. Horsley[21] and Gmehling et al.[22] discuss methods for estimating the azeotropic composition and temperature for numerous systems.

One of the mechanisms for identifying possible entrainers is hydrogen bonding. Ewell et al.[23a] have classified liquids into five groups according to their hydrogen bonding characteristics. For example, the following are considered strong and weak in their hydrogen bonding:

Strong	Weak
O → HO	N → HN
N → HO	O → $HCCl_3$
O → HN	HCCl-CCl
	N → $HCNO_2$
	HCCN

The hydrogen bonding grouping provides insight for screening suitable entrainers in the development of a feasible azeotropic distillation process. Selected entrainers are then tested experimentally for their quantitative effect on VLE.

12.4.2 Extractive Distillation

In extractive distillation, an *extractive agent* is added to the mixture to be distilled for the purpose of modifying the relative volatility of the key components without forming an azeotrope. Extractive distillation is usually employed to improve the separability between close-boiling components for which ordinary distillation would not be economically feasible.

Like azeotropic distillation, extractive distillation involves highly nonideal phase equilibria as well as the addition of an agent, often called a *solvent*, that modifies and improves the phase equilibria among the system components. However, extractive distillation is different in that no azeotropes are involved, and the agent added is essentially nonvolatile and introduces no new azeotropes.

Extractive distillation is a simpler process than azeotropic distillation. Because of its low volatility, the solvent always leaves the column with the bottoms product, and thus an additional distillation step is required to separate the solvent for recycle. To maintain the solvent throughout the column, the solvent must be introduced with or above the fresh feed. It is customary to employ a rectification section with reflux, above the solvent feed point, so as to prevent loss of solvent with the distillate.

Methods of analysis based on simple distillation may often be used on a solvent-free basis. The relative volatility between key components, i and j, is based on the simple relationship

$$\alpha_{ij} = \frac{p_i^*}{p_j^*}\left(\frac{\gamma_i^L}{\gamma_j^L}\right)_{solvent} \tag{12.47}$$

When the vapor pressures are very close, searches for effective solvents involve simple measurement of the activity coefficient ratio. The searching process is easier than that for azeotropic distillation. The usual approach is to select a solvent that is similar in structure to the heavy key component. Since the light key component is of a different structure (as it must be, or simple distillation could be employed), the solvent serves to increase the volatility of the light key relative to the heavy key.

An example of an extractive distillation process is the separation of methylcyclohexane (MCH) from toluene using a phenol solvent, as shown in Figure 12.17. Since MCH boils at 101.0°C and toluene boils at 110.7°C (1 atm), their separation by ordinary distillation is very difficult even though they do not form an azeotrope. Phenol is an effective solvent, since it has a structure more similar to the aromatic than to MCH (a naphthene), and it is relatively nonvolatile. The rectification

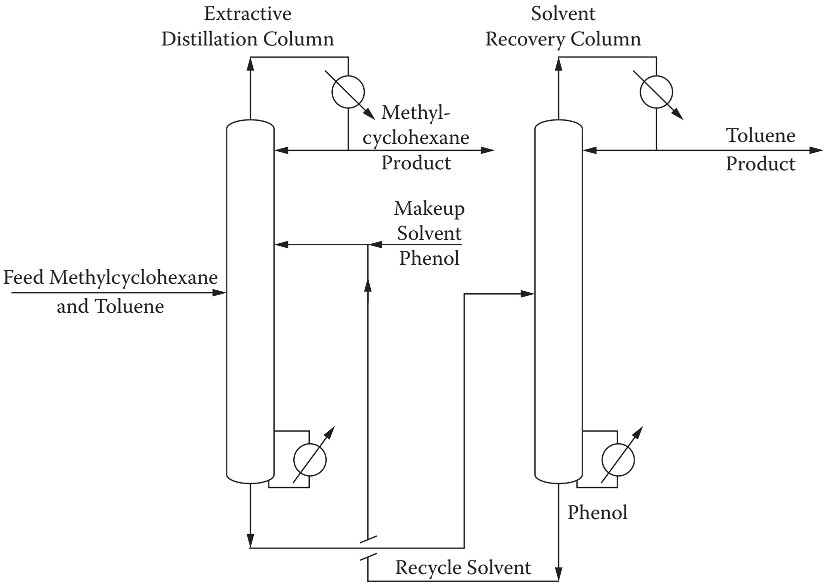

FIGURE 12.17 Extractive distillation process for separating methylcyclohexane and toluene.

section at the top of the extractive column prevents contamination of the MCH product with solvent. The second column employs ordinary distillation to recover the solvent from the toluene product. Since the toluene/solvent separation cannot be complete (excessive stages), and since minor amounts of solvent can be lost with the MCH, provision for a makeup solvent is required.

12.4.3 Complex System Distillation

A complex system is one containing so many components that they cannot be separated into discreet pure components by the distillation process. An example of such a system is naturally occurring petroleum, which contains hundreds of chemical constituents. Crude tall oil from paper pulping is another example of a complex system.

A complex system may be compared with a defined multicomponent system on the basis of a true boiling point curve (TBP) diagram as shown in Figure 12.18. The TBP curve is a close

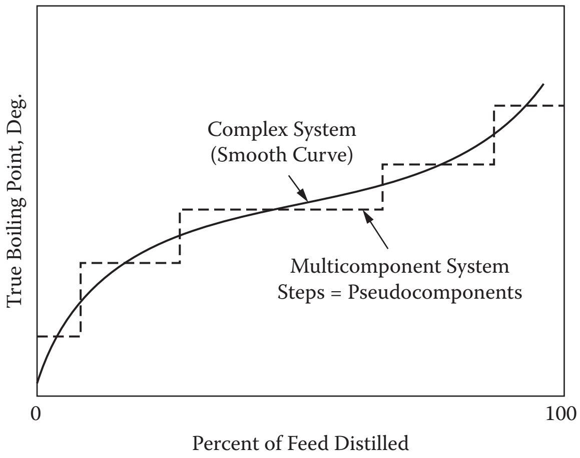

FIGURE 12.18 True boiling point curve diagram for a complex system and a defined multicomponent system.

approximation to the true boiling point as a function of the percent of feed distilled. The TBP curve was traditionally obtained by subjecting the feed to distillation in a batch column with several hundred equilibrium stages operated at a reflux ratio of 100:1 or higher. A precision chromatograph is currently used to obtain the TBP curve.

Figure 12.18 shows how a complex system differs from a multicomponent system. The complex system exhibits a smooth TBP curve, because even the high separating power of the TBP apparatus cannot resolve all the many close-boiling constituents. The multicomponent system, on the other hand, is easily resolved by the powerful TBP apparatus, although any azeotropes will be distilled over as though they were pure (pseudo) components.

To design complex distillation columns, multicomponent methods are used. The true boiling curve is replaced by an approximate stepwise representation as a shown in Figure 12.18. Each step represents a pseudocomponent with a boiling point as indicated and a fraction of the total feed mixture based on the length of the horizontal portion of the step.

12.4.4 Steam Distillation

A steam distillation is simply a distillation in which steam is involved as a process component. Steam (water) is inexpensive and immiscible with many chemical compounds (e.g., hydrocarbons and many organic chemicals) and hence is a special case of azeotropic distillation. In the usual application, very little of the steam condenses in the liquid phase, and thus problems of handling two liquid phases in the contacting equipment are avoided.

If an organic compound is essentially immiscible with water in the liquid phase, then vapor pressures are additive to make up the system total pressure:

$$p_{org}^{sat} + p_{water}^{sat} = P \tag{12.48}$$

This simple equation is based on very little miscibility such that the activity coefficients for each phase are essentially unity.

Application of Equation (12.48) with the Antoine equation [Equation (12.13)] shows that steam distillation can be used to distill an organic compound at much lower temperatures than would otherwise be possible. Considering the system pressure P as constant, then the more steam introduced, the lower will be the partial and vapor pressures of the organic and thus the lower its boiling point. The other key element of the choice of water as the entrainer is that it is easily separated from the product (organic) by simple condensation followed by decanting.

Thus, steam distillation finds application in the purification of heat-sensitive materials as an alternative to vacuum distillation, since the dilution effect of steam enables lower effective boiling points of the materials.

12.4.5 Batch Distillation

Batch distillation is performed on a fixed charge quantity—the batch. The original charge is replenished by another charge at the end of each cycle.

This process is used extensively in the laboratory and in small production units where the same equipment can serve different applications. Between each batch operation, the equipment can be cleaned as necessary. When the charge is a multicomponent mixture, batch distillation in a single column can separate all constituents, whereas continuous distillation would require several columns.

For a binary system with a single equilibrium stage, i.e., a reboiled stillpot with no rectification column, the mass balance is given by the Rayleigh equation:

$$\ln \frac{L_o}{L_t} = \int_{x_t}^{x_o} \frac{dx}{y - x} \tag{12.49}$$

where the subscripts o and t refer to initial and final times, and L represents the amount of total liquid in the stillpot. The mole fraction of a given component in the stillpot at time t is denoted by x. By introducing relative volatility, Equation (12.49) can be integrated with the following result:

$$\ln \frac{L_o}{L_t} = \frac{1}{\alpha - 1}\left(\ln \frac{x_o}{x_t} + \alpha \ln \frac{1 - x_t}{1 - x_o} \right) \tag{12.50}$$

Problem 12.5

One hundred moles of a 50-50 mixture of benzene and toluene are to be batch distilled in a simple takeover process. The relative volatility of benzene with respect to toluene is 2.5. The distillation is to proceed until the mole fraction of benzene in the stillpot is 0.20. How many moles remain in the stillpot at the end of the distillation?

By Equation (12.50),

$$\ln \frac{L_o}{L_t} = \frac{1}{2.5 - 1}\left(\ln \frac{0.5}{0.2} + 2.5 \ln \frac{1 - 0.2}{1 - 0.5} \right) = 1.394$$

From which L_t = 24.8 moles are left in the stillpot.

For single-stage multicomponent batch distillation, the stage mass balance may be applied successively to any two components, j and k, as follows:

$$\ln \frac{L_{jt}}{L_{jo}} = \alpha \ln \frac{L_{kt}}{L_{ko}} \tag{12.51}$$

For the production of relatively pure products by batch distillation, the stillpot is usually augmented by a multistage rectification column with reflux. Shown in Figure 12.19 is a flow diagram for a typical batch distillation process. The feed in this example contains components A, B, and C. First, pure A is distilled into the first receiver. Then, an intermediate cut consisting of a mixture of A and B is collected in the second receiver. Following this, pure B is collected in the third receiver, followed by collection of an intermediate B/C mixture in the fourth receiver. At this point, relatively pure C remains in the stillpot. After removal of the products from their holding receivers, the intermediate cuts are drained back to the stillpot, to be joined by fresh feed for the next batch.

The plan for control of the reflux ratio in batch distillation is called the *operating policy*. One operating policy is to distill at constant reflux ratio throughout a given cut, collecting a composite mixture that meets specifications. The required reflux ratio is usually different for each cut. Another operating policy is to maintain a constant purity in the receiver by varying the reflux ratio. There are obviously other possible policies. Figure 12.20 shows a y-x diagram for operation at constant composition of the material being collected. For three theoretical stages, during the course of the distillation, the reflux ratio (indicated by the slope of the operating line) must be changed as shown. The diagram is representative only and applies to a binary mixture.

Stage calculations for multistage batch distillation are much more complicated than for continuous distillation, for two reasons. First, all conditions change with time. Second, the holdup in

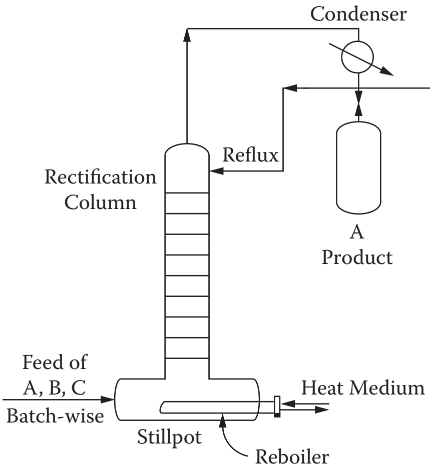

FIGURE 12.19 Typical batch distillation system.

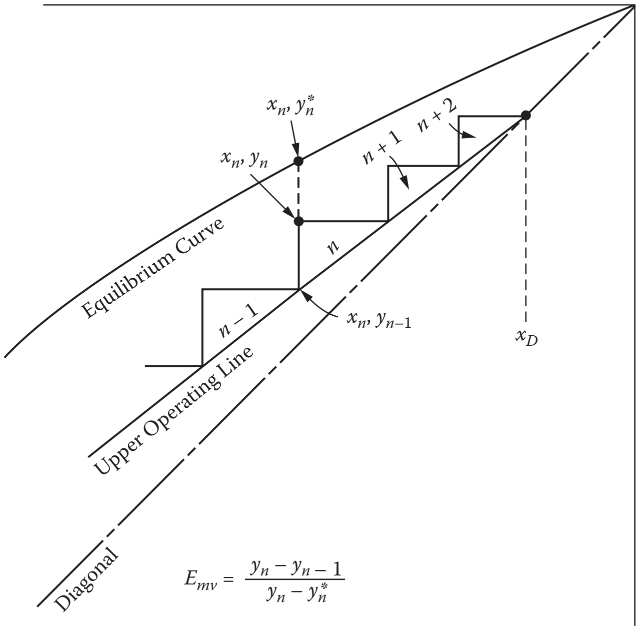

FIGURE 12.20 Upper quadrant of a McCabe–Thiele diagram for batch distillation at constant reflux. Four theoretical stages shown.

the column affects the concentration gradients in the column. The equation for the effect of holdup on the mass balance around a general batch contacting stage n is

$$J_n\left(\frac{dx_{i,n}}{dt}\right) = L_{n-1}\,x_{i,n-1} + V_{n+1}\,y_{i,n+1} - L_n\,x_{i,n} - V_n\,y_{i,n} \tag{12.52}$$

where J_n is the stage molar holdup, and dx/dt is the rate of change of liquid concentration with respect to time.

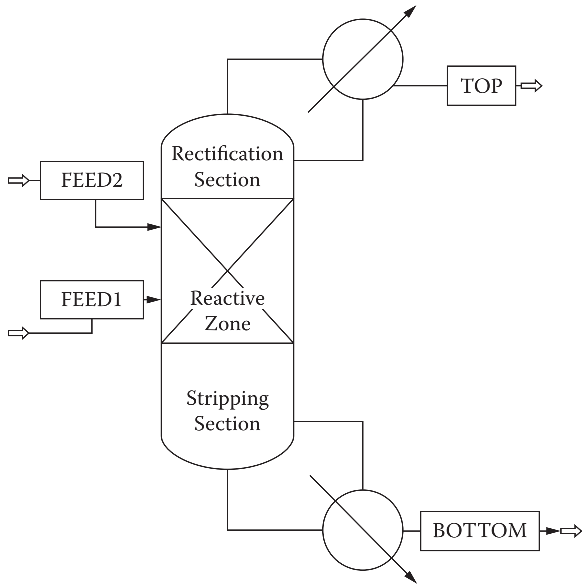

FIGURE 12.21 Typical reactive distillation configuration showing two feed streams and a reaction zone that can comprise multiple beds.

Equation (12.52) for batch distillation is the same as the mass balance equation for continuous distillation except for the term on the left side of the equation, which is normally zero for continuous distillation. Thus, it is theoretically possible to employ the same approach for batch distillation as previously presented for continuous distillation, provided an accumulation term is introduced. However, although apparently simple, it is actually very difficult in practice because of problems in solving the many simultaneous differential equations involved. In any event, it is erroneous to neglect tray and column holdup in stage computations for batch distillation.

The rigorous computation of multicomponent, multistage batch distillation is extremely complicated, and one should resort to available computer programs.[24–26] These programs can give a reasonable approximation for scaleup.

12.4.6 Reactive Distillation

If a chemical reaction occurs inside a distillation column, with reactants and products subject to the usual requirements of the distillation process (phase equilibria, fractionation, and contacting device hydraulics), it is possible to shift the reaction equilibrium in a favorable direction. A soluble or insoluble catalyst is likely to be involved; thus, the operation is often known as *catalytic distillation*. Reactive distillation has been used successfully for etherification and esterification reactions and, to some extent, for alkylation, nitration, and amidation reactions. In most applications, the reaction has occurred in the liquid phase, and an example of this application, where methyl acetate is produced from methanol and acetic acid using a soluble catalyst, has been described in detail.[27] Flows for a generalized reactive column are shown in Figure 12.21.

Advantages of reactive distillation include the elimination of complicated product recovery, and separation and recycling of unconverted reactants, all of which lead to savings in equipment and energy costs. Compared to the conventional approach (reactor followed by distillation equipment), reactive distillation may also improve other factors such as selectivity and rates of mass transfer.

In deciding whether to consider reactive distillation, there are several key considerations:[28]

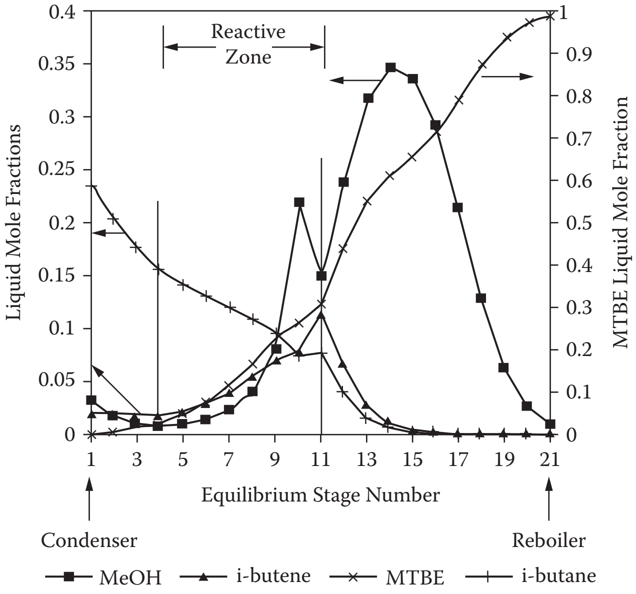

FIGURE 12.22 Computed composition profiles in an MTBE reactive column. Composition of the diluent, *n*-butane, may be obtained by difference. (H. E. Subawalla, 1997. Ph.D. dissertation, Univ. of Texas at Austin.)

- Is there an advantage in shifting the chemical equilibrium? A reaction with a highly favorable equilibrium is not likely to be a candidate.
- The reaction product must boil in an appropriate range and be separable by distillation. If the boiling point of the desired product instead falls within a range of other products, more distillation columns will be needed.
- The optimum temperature and pressure conditions for the reaction must be the same as those required for separation.
- Only one liquid phase should be present. A second liquid phase can introduce problems in the hydraulic design of the distillation column. In some cases, this problem can be avoided through the use of a separate cosolvent, which then must be separated for recycle.
- If the catalyst is a solid, it must create neither excessive pressure drop nor an excessively large column. An optimal arrangement of solid catalysts in the column is needed.
- A suitable model must be available for determining concentration profiles throughout the column and judging needs for reflux and boilup. This implies knowledge of the reaction kinetics, likely obtained separately in laboratory equipment.

A representative profile for a column in which methanol and *i*-butene are reacted to form methyl tert-butyl ether (MTBE) is shown in Figure 12.22. Note that an inert *n*-butane, is not shown. The reactants are fed at different stages, and the desired product, MTBE, is removed from the bottom of the column in high purity.

Many patents and publications relating to reactive distillation have been published. A paper on the heuristics of reactive distillation column design contains many references.[29]

12.5 DISTILLATION COLUMNS

As noted earlier, distillations are performed in vertical, cylindrical columns when more than a single contacting stage is required, as indicated in Figure 12.23.

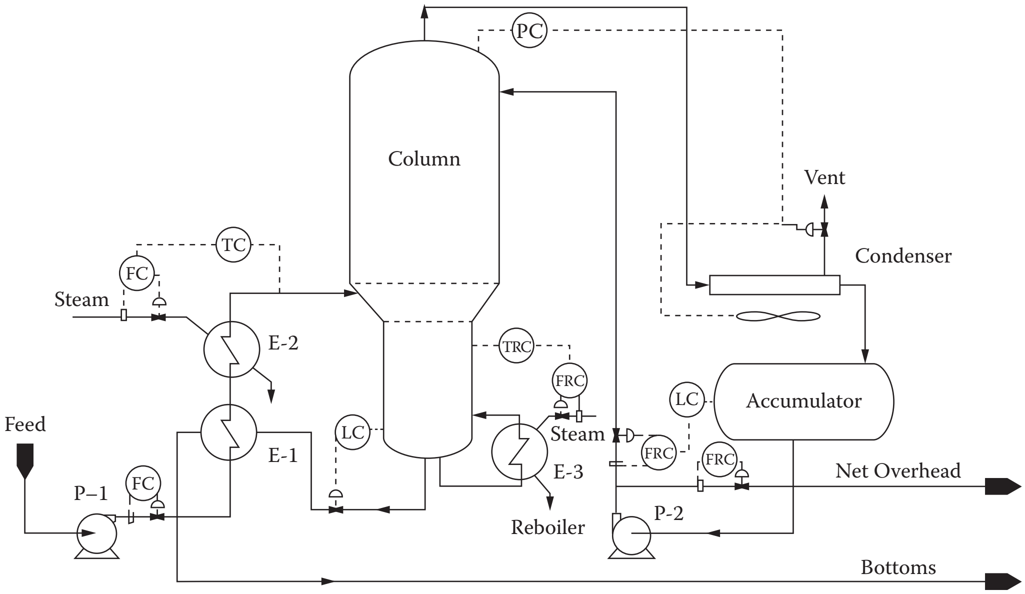

FIGURE 12.23 Flow diagram of a full distillation system. While the design of the column is emphasized in this chapter, auxiliaries such as heat exchangers, pumps, and controls must not be neglected.

After computations have been made to establish the number of required theoretical contacts, the equipment must be designed. Our central focus is the column, even though the system comprises heat exchangers, pumps, vessels, controls, and so forth. Supporting equipment design and characteristics are covered elsewhere in this handbook. The sequence of steps that applies to the design of a new distillation system, or to the analysis of an existing system, is as follows.

Define the system means identifying and quantifying each component in the mixture to be separated. Unexpected components such as intermediate boilers often play havoc with the intended separation. If the mixture is complex, as discussed earlier, proper steps to identify pseudocomponents are required.

Establish separation criteria means determining product purities, or feed component recoveries, or some combination of the two. A cogent comment here is that one should "look down the road" to anticipate future changes in product purity requirements, variations in feed composition, shifts in throughput rates, and so on.

Obtain physical data for the calculations. In some cases, the data might be stored in an easily retrieved format. In any case, however, the designer must verify data, especially for mixtures, and determine the possible effects of data errors on the outcome of the design work. This important step should be done with care. One of the most important areas of data gathering deals with vapor-liquid equilibria.

Determine stages or transfer units, which are parameters that characterize the difficulty of the separation. The model for obtaining the parameters might be rigorous or nonrigorous, depending on the needs.

Develop complete specifications for the distillation column: diameter, spacing of trays, type and size of packing, height of contacting zone, and so on, as reported in the present section.

The final requirement involves the development of the complete system design, for example, the typical system shown in Figure 12.23. The fact that more than just the column is involved was mentioned earlier.

The required theoretical stages or transfer units will have been determined. Also, some value of the stage efficiency will have been obtained for starting purposes and to be verified later, after

TABLE 12.5
Criteria for Selecting a Distillation Column Device

Vapor-handling capacity	Entrainment flooding. At incipient flooding, the minimum column diameter is fixed.
Liquid-handling capacity	Fixes the size of downcomers. Downcomer backup can also lead to flooding.
Mass transfer efficiency	Sets the required height, for a given number of theoretical stages. The efficiency can be a function of column diameter.
Flexibility	Is a concern when the column must be operated under a wide range of feed rates, or when future capacity needs must be considered in the initial design.
Pressure drop	Low pressure drop is critical for vacuum columns, especially when there are needs to maintain a low bottoms temperature.
Cost	The total cost of the system must be considered, including auxiliary equipment. A more expensive device might lead to lower operating costs.
Design limitations	The device should have been proven commercially. Also, the user needs to understand how the device was designed (if by a vendor)
Special concerns	Fouling, corrosion Ease of installation or removal Potential foaming problems Adequate residence time for reactions Special heat transfer needs

the effects of the geometry of the column have been taken into consideration. (This is the *rating approach,* common in chemical engineering practice, where a device geometry is contrived and then rated for capability to perform the needed service.) Thus, as a result of earlier studies, the following information will be at hand: actual stages (or packed height), vapor flow rate, liquid flow rate, vapor and liquid compositions, temperatures, and pressures.

Ideally, this information will be available for a number of points in the column. As a bare minimum, it must be available at the top, bottom, and center (above and below the feed point for a single column). Some approximations may be in order, e.g., assumed: pressure profile, equal molal downflow and upflow, and constant efficiency throughout the column. Normally, these assumptions will in turn be verified or modified.

The general objective of equipment process design is to establish specifications for the optimum fractionating system hardware. (Alternatively, an objective could be to gain an understanding of an existing system under analysis.) For the column only, criteria for selection of the internal contacting devices are given in Table 12.5. Each of these criteria should be considered carefully.

The function of the device is to bring vapor and liquid into intimate contact. Many devices have been developed through the years.[30] Three important tray-type devices are shown in Figure 12.24, and several packings are shown in Figure 12.25. All devices vary in their ability to provide intimate contacting, effect sharp separations, realize low pressure drops, and handle liquids that might foul or plug the system.

An enormous amount of study has been made to evaluate the performance of many contacting devices, using a variety of test mixtures. Only a portion of the results have been published in the open literature, on a random basis with unification through handbooks, texts, and review papers. Fractionation Research, Inc. (FRI), an industry-sponsored organization for conducting commercial-scale tests of devices under carefully controlled experimental distillation or absorption conditions, has been a leader, performing thousands of experiments.[31,32] An updated state-of-the-art review of equipment types and characteristics has been published by FRI and collaborators.[33]

Devices for effecting contact of vapor and liquid may be classified as shown in Table 12.6. Recently, there has been a trend away from the conventional crossflow devices, in the direction of counterflow devices, mostly packings. Still, an enormous number of older columns are operating with trays, and thus the technology of tray design and analysis is important.

12.6 TRAY COLUMN HYDRAULICS

12.6.1 Crossflow Tray Columns–Sieve Trays

12.6.1.1 Performance Profile

A representative performance profile for a commercial crossflow sieve tray is given in Figure 12.26.[34] The zone of "good operation" is variable in extent and rarely is covered by a constant value of efficiency. The profile is influenced by tray type and dimensions, system properties, and liquid-vapor throughput rates. A second profile, for pressure drop, will be discussed later.

12.6.1.2 Vapor-Handling Capacity

The first step in sizing a fractionator is usually to calculate its approximate diameter based on the required vapor capacity. In a simplified way, column cross-sectional area required is given by the following relationship:

$$A_t = A_a + 2A_d = A_n + A_d \tag{12.53}$$

where *net area* A_n is usually 85 to 95% of A_t, the total tower cross-sectional area. Thus, the total downcomer area is 5 to 15% of the total cross section. See Figure 12.27.

A schematic diagram of a perforated tray is shown in Figure 12.28. The zone marked "froth" (liquid-continuous) can sometimes invert to a "spray" (vapor-continuous), but quantitative procedures dealing with the spray regime have not yet been developed. Such a regime prevails at very

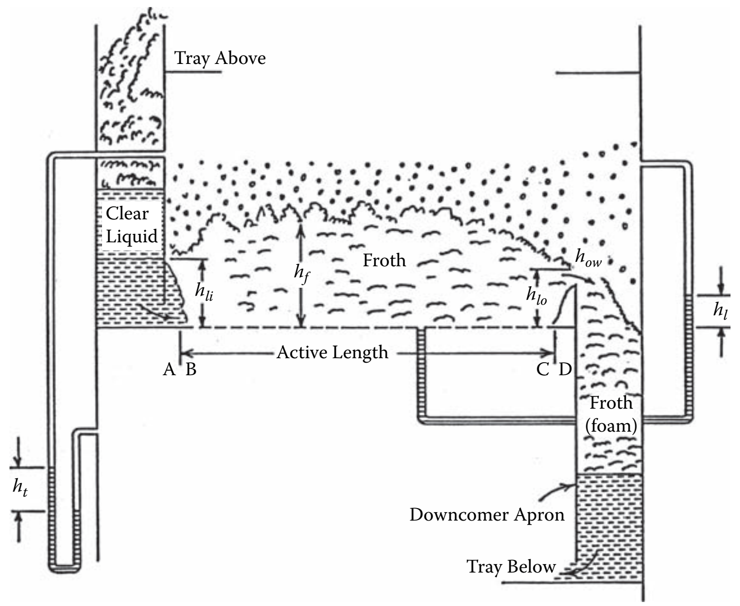

FIGURE 12.28 Schematic diagram of a crossflow sieve tray. Valve trays and bubble-cap trays have equivalent diagrams.

low liquid-to-vapor volumetric flow ratios such as occur in high-vacuum distillations. Liquid is distributed to the tray by flow under the downcomer apron; additional distribution can be obtained from an inlet weir (not shown). The active length BC normally includes the total distance from downcomer apron (or inlet weir) to outlet weir, i.e., A and D lengths are effectively zero.

The droplets carried above the froth may return to the froth or, for very small droplets, are entrained to the tray above. When the froth level approaches the tray above, as at high rates of vapor flow, even the large droplets cannot complete their trajectories and thus impact the tray above, possibly moving through the perforations as entrained liquid. Such a phenomenon drastically reduces tray efficiency.

Allowable flows of vapor through the froth are correlated on the basis of liquid entrainment. Balancing of the drag force of the vapor on a representative drop of liquid against the gravitation force on the drop has led to the relationship,

$$U_N = C_{sb}\left(\frac{\rho_L - \rho_v}{\rho_v}\right)^{0.5} \tag{12.54}$$

where U_N is the superficial vapor velocity based on A_N (Figure 12.27) and C_{sb} is a correlating term called the Souders–Brown capacity parameter.

Values of C_{sb} may be obtained from Figure 12.29 and are based on tray spacing, surface tension, vapor velocity through the perforations, and liquid flow rate. The abscissa group, $L/G\sqrt{\rho_v/\rho_L}$, is an important correlating term called the *flow parameter* and represents a ratio of kinetic energies of liquid to gas. It is used for several correlations involving vapor-liquid ratios. Figure 12.29 represents experimental data, including recent FRI work, and should be used for design purposes.[35] It has the following restrictions: (1) low- to nonfoaming system, (2) weir height less than 15% of tray spacing, (3) hole diameter 0.5 in. (12.7 mm) or less (sieve trays), and (4) hole (or riser) area 10% or more of the active (bubbling) area. Smaller hole areas tend to produce jetting because of high hole velocities, and corrections are as follows:

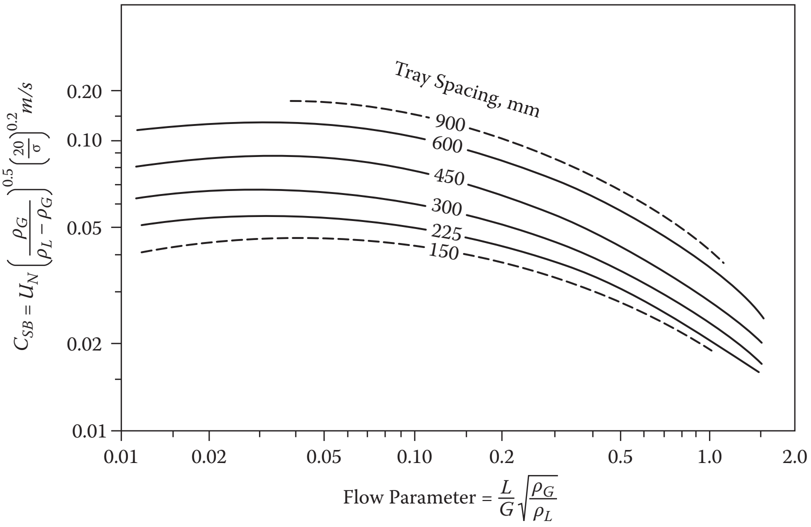

FIGURE 12.29 Design chart for estimating maximum vapor capacity of crossflow trays (both bubble cap and sieve trays). The lower values at the left indicate that liquid capacity prevails over vapor capacity as the limiting parameter.

A_h/A_a	U_{des}/U_{chart}
0.10	1.00
0.08	0.90
0.06	0.80

An alternative model for predicting entrainment flooding was published recently.[36] The concept of entrainment flooding is discussed by Silvey and Keller.[37]

The value of A_N has been modified by new tray designs in which the downcomer is suspended above the tray floor ("hanging downcomer"), enabling the net area to include the area under the downcomer. For this case, $A_N = A_t - A_d$.

Figure 12.30 shows qualitatively the region of "satisfactory operation." We have just looked at flooding; at low vapor rates, there are limits of weeping or dumping, i.e., a portion of the cross-flowing liquid flowing down through the perforations. At high liquid rates, the downcomers may not be able to pass the required amount of liquid. These limits are discussed below.

12.6.1.2.1 Entrainment

As the flood point is approached, liquid entrainment becomes a problem. Entrained liquid is recycled back to the tray above, negating the countercurrent effect and decreasing tray efficiency. The recirculation resulting from entrainment is indicated in Figure 12.31. The molar ratio of liquid entrainment rate to the "dry" liquid flow rate is $\psi = e/(L_{MD} + e)$. A chart for estimating ψ as a function of approach to flooding, $C_{sb}/C_{sb,flood}$, and the flow parameter, defined earlier, is given in Figure 12.32.[38] This graph has the same limitations as Figure 12.29. As discussed later, the term ψ corrects the "dry" tray efficiency:

$$\frac{E_w}{E_d} = \frac{1}{1 + E_d \psi / (1 - \psi)} \tag{12.55}$$

where E_w and E_d are wet and dry efficiencies.

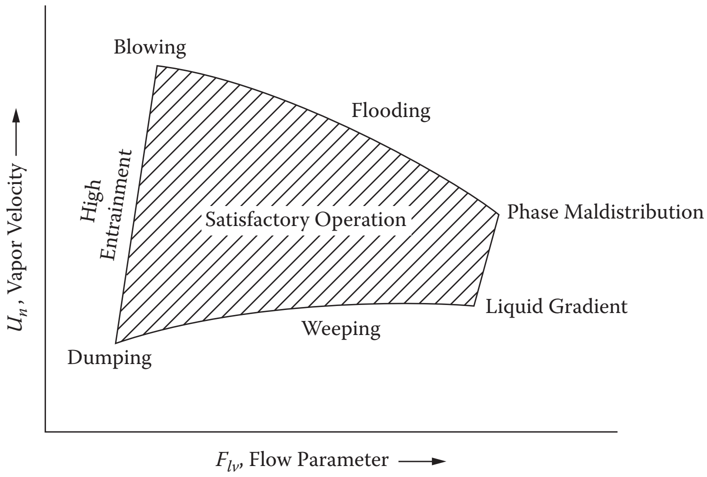

FIGURE 12.30 Generalized plot showing operating zones of a crossflow tray.

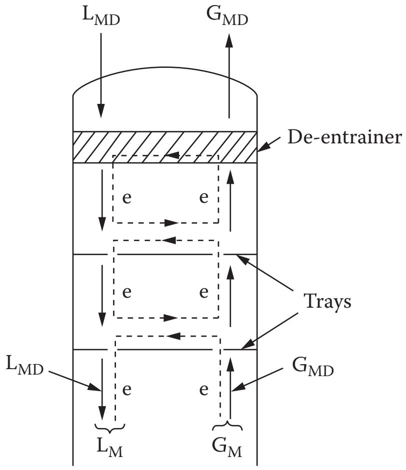

FIGURE 12.31 Diagram showing the recirculation effect of liquid entrainment, and the definition of terms used in design Equation (12.55).

12.6.1.2.2 Pressure Drop

The decrease in pressure, as the vapor flows upward through a tray, is the sum of the pressure drop through the perforations and the residual drop through the froth or spray:

$$h_t = h_d + h_L \tag{12.56}$$

where pressure drop is expressed in terms of head of clear liquid on the tray. For flow through the perforations, the simplified orifice equation is used (assuming uniform flow through all the holes):

$$h_d = \frac{50.8}{C_v^2} \frac{\rho_v}{\rho_L} U_h^2 \tag{12.57}$$

The discharge coefficient C_v may be obtained from Figure 12.33[39] or from the relationship

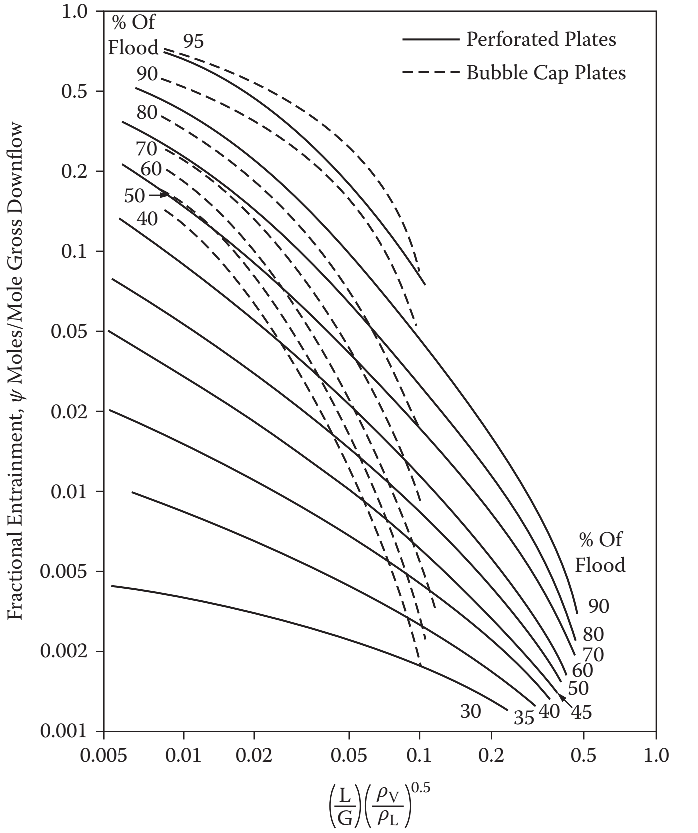

FIGURE 12.32 Chart for estimating entrainment parameter as a function of flow parameter and approach to entrainment flood. (J. R. Fair, 1997. *Perry's Chemical Engineers' Handbook*, 7th ed., R. H. Perry, D. Green, eds., New York: McGraw-Hill.)

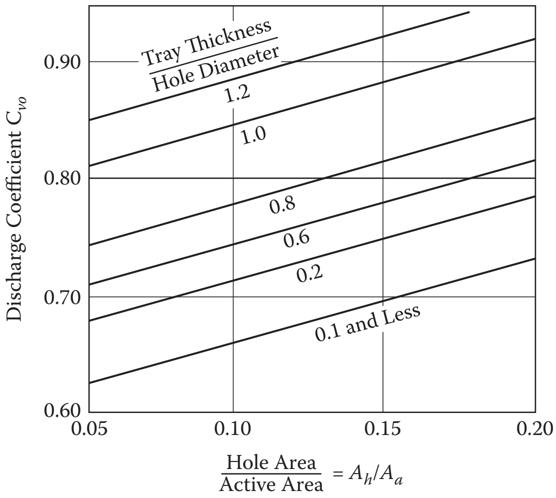

FIGURE 12.33 Chart for estimating the orifice coefficient for dry tray pressure drop.

$$C_v = 0.74(A_h/A_a) + \exp[0.29(t_t/d_h) - 0.56] \tag{12.58}$$

where t_t/d_h is the tray thickness/hole diameter ratio. Equation (12.58) and Figure 12.33 predict pressure drops that check well with observations of commercial scale sieve tray columns.

For pressure drop through the froth or spray,

$$h_L = h_t - h_d \tag{12.59}$$

where h_L is simply regarded as a residual term and is correlated on the basis of dry tray pressure drop measurements, standardizing on Equation (12.58) for the orifice coefficients when actual data are not available, along with overall tray pressure drop measurements (usually available in operating columns). Values of h_L are determined as a function of vapor hole velocity and liquid flow rate as shown in Equations (12.60) and (12.61):

$$\beta = h_L/(h_w + h_{ow}) \tag{12.60}$$

$$\beta = 0.19 \log_{10} L_w - 0.62 \log_{10} F_{vh} + 1.679 \tag{12.61}$$

where

β = dimensionless aeration factor

h_w and h_{ow} = weir height and weir crest (clear liquid basis), mm

L_w = flow rate of liquid over the outlet weir, m^3/s-m weir length

F_{vh} = vapor "F-factor" based on hole velocity, $F_{vh} = U_h(\rho_v)^{0.5}$

The value of the weir crest *how* in Equation (12.60) employs the classic Francis weir equation:

$$h_{ow} = 664\, L_w^{0.667} \tag{12.62}$$

Even though froth actually flows over the weir (unless calming zones are used), h_{ow} is expressed on an equivalent clear liquid basis, assuming that the Francis relationship also represents froth flow.

Later, in connection with mass transfer in tray froths, we will discuss a relative froth density:

$$\phi_f = \rho_f/\rho_L \tag{12.63}$$

This is a ratio of the average density of the two-phase mixture to the liquid density (it approaches unity for lightly aerated liquids). Equation (12.62) may thus be modified by Equation (12.63) to give

$$h_{ow} = 664\, \phi_f^{1/3}\, L_w^{2/3} \tag{12.64}$$

This area of sieve tray froth hydraulics has been the subject of considerable study. While the relationships thus far presented are not completely fundamental, they are simple to apply and are sufficiently reliable for most engineering purposes.

12.6.1.1.3 Liquid-Handling Capacity

The downcomer serves to transfer the downflowing liquid between the trays in a column and can become a bottleneck under high liquid flow conditions (as in high-pressure absorbers and fractionators). Downcomers are normally sized such that they do not fill completely with the combination of clear liquid and froth (Figure 12.28). Overloaded downcomers lead to a flood condition in the entire column. Thus, we distinguish between "entrainment flood" and "downcomer flood" but recognize that one often leads to the other.

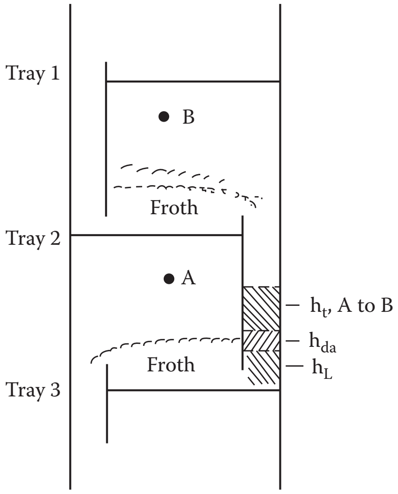

FIGURE 12.34 Pressure balance across two crossflow trays.

Downcomer backup h_{dc} is obtained from a pressure balance:

$$h_{dc} = h_t + h_L + h_{da} \tag{12.65}$$

which should be clear from Figure 12.34, with the datum being a level just above the floor of the lower tray. The head loss for liquid flow under the downcomer apron h_{da} is calculated from

$$h_{da} = 165\ (q/A_{da})^2 \tag{12.66}$$

If an inlet weir is used, h_{da} obtained from Equation (12.66) should be increased by about 50%. If hanging downcomers are used, special and proprietary relationships may be needed, as discussed later.

The backup relationship [Equation (12.65)] is used with pressure head on a clear liquid basis. The actual height in the downcomer is

$$h'_{dc} = \frac{h_{dc}}{\phi_{dc}} \tag{12.67}$$

where ϕ_{dc} is the average value of relative froth density in the downcomer. The computed value of h_{dc}' should be less than the value of the tray spacing. A value of $\phi_{dc} = 0.5$ is often used, but its proper value depends on the disengaging tendency of vapor and liquid. (Note that a countercurrent phase flow occurs in the downcomer when vapor disengages from the froth and rises against the overflowing stream of froth.)

If the flow over the weir is a relatively clear liquid, then there is no disengagement problem, and $h_{dc}' \sim 1.0$. If the vapor bubbles are slow to rise against the flow of liquid, the superficial velocity of liquid in the downcomer (at its narrowest cross section) must not be greater than the free rise velocity of the vapor bubbles. A minimum velocity of 0.1 m/s (0.4 ft/s) is usually satisfactory. Conditions favoring rapid disengagement include low liquid viscosity and low vapor density. For high-pressure fractionators operating near the critical point, liquid and vapor densities tend to merge, and disengagement is slow. Hoek and Zuiderweg[40] analyzed FRI tests at high pressure and concluded that a considerable amount of vapor passes to the tray below as entrainment in the liquid, accompanied by a significant loss of tray efficiency.

TABLE 12.7
Capacity Discount Factors for Foaming Systems

Nonfoaming systems	1.00
Moderate foaming, as in oil absorbers, amine, and glycol regenerators	0.85
Heavy foaming, as in amine and glycol absorbers	0.73
Severe foaming, as in MEK units	0.60
Foam-stable systems, as in caustic regenerators	0.15

When the liquid has foaming tendencies, additional residence time must be allowed for phase disengagement. System discount factors, recommended by Koch–Glitsch, Inc. on the basis of field experience, are shown in Table 12.7. As an example, the "maximum allowable velocity" of 0.1 m/s would be multiplied by the discount factor so as to provide adequate downcomer volume.

12.5.1.1.4 Minimum Vapor Rate

As shown previously in Figure 12.25, the performance of tray devices drops off at low velocity because of weeping and/or poor vapor dispersion. Weeping is usually associated with sieve trays or fixed valve trays, which have no built-in protection against liquid flow through the openings at low vapor velocities. Movable valve trays can also weep, since the valve units are designed not to close completely at zero vapor rate. In theory, at steady state and with equal vapor velocity through all of the holes, there will be no weeping on a sieve tray when

$$(h_d + h_\sigma) > h_L \tag{12.68}$$

Then the pressure drop through the hole plus the head of liquid necessary to overcome surface tension can act against the liquid head above the hole to prevent liquid from entering the hole. The term h_σ in Equation (12.68) may be estimated from the following *dimensional* equation:

$$h_\sigma = 409\left(\frac{\sigma}{\rho_L\, d_h}\right), \text{ mm liquid} \tag{12.69}$$

where

σ = surface tension, mN/m
d_h = hole diameter, mm
ρ_L = liquid density, kg/m^3

Equation (12.68) applies only to a steady-state condition, and this rarely happens. Some holes pass neither vapor nor liquid. There is considerable sloshing, froth pounding, oscillation, and so on. A modified Equation (12.68) is shown in Figure 12.35. The lines of the figure may be approximated by

$$h_d + h_\sigma = 0.036(h_w + h_{ow}) + 0.25 \text{ (20\% open)} \tag{12.70}$$

$$h_d + h_\sigma = 0.013(h_w + h_{ow}) + 0.25 \text{ (6–14\% open)} \tag{12.70a}$$

While weeping may occur over a broad range of operating rates, it does not necessarily detract from the mass transfer capability of the tray, so long as loadings are reasonably high. At some very low vapor rate, efficiency plunges, and the flow condition is often called the *dump point.* Figure

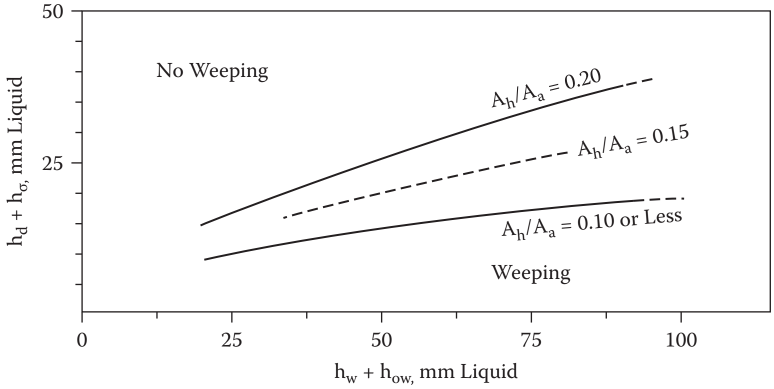

FIGURE 12.35 Chart for estimating the vapor load at the point of efficiency drop-off. The drop-off can be due to weeping or dumping. (B. D. Smith, 1963. *Design of Equilibrium Stage Processes*, New York: McGraw-Hill.)

12.35 should be used to develop the performance profile of a sieve tray, and no quantitative measures of weeping should be attempted.

Often, a question is asked about the *design turndown ratio* of a device. It is practical to express this as a ratio of the design loading to the loading at the "point of efficiency drop-off," whether represented by physical weeping or dumping. Figure 12.35 represents this lower limit.

12.6.1.2 Other Crossflow Trays

12.6.1.2.1 Bubble-Cap Trays

These devices are currently used only occasionally. They (see Figure 12.36) were the industry standard before 1950, and at very low vapor flows they do not weep, as do sieve trays and valve trays. Vapor flows upward through a central riser, reverses direction, flows downward through an annular space, and exits under the skirt (or through slots cut into the skirt). As the vapor issues from the cap, it is dispersed in the crossflowing liquid. Bubble caps are heavy and more expensive to fabricate than the simple holes of a sieve tray, and the dispersion of the vapor is not as effective as with a sieve tray.

The design of a bubble-cap tray is similar to that for a sieve tray. The vapor capacity is determined from Figure 12.29, which represents bubble-cap trays as well as sieve trays (see original reference). Entrainment may be estimated directly from Figure 12.32, which shows that the caps entrain more than the sieve holes. Pressure drop utilizes the same general equations as the sieve tray, except that the dry tray drop through the caps is much larger and utilizes different parameters. A detailed analysis of the pressure drop function is reported by Bolles.[41] Finally, computations for liquid capacity through the downcomer utilize exactly the same relationships as for sieve trays except for one correction term in Equation (12.65): on the right side, a term is used to represent hydraulic gradient on the tray. This gradient results from the resistance to crossflow provided by the caps themselves. Bolles deals with hydraulic gradient extensively since, if severe, it can cause vapor to maldistribute as it flows upward through each tray.

Today the main process application for bubble cap trays is in reactive distillation columns or in chemical absorption columns; in either case, it may be necessary to control very carefully the residence time of the liquid to complete a reaction step. For example, bubble-cap trays are used for the methyl acetate column described earlier and published by Agreda et al.[27] An abridged version of the Bolles treatment of bubble-cap tray design is given in the fifth edition of Perry's handbook.[42]

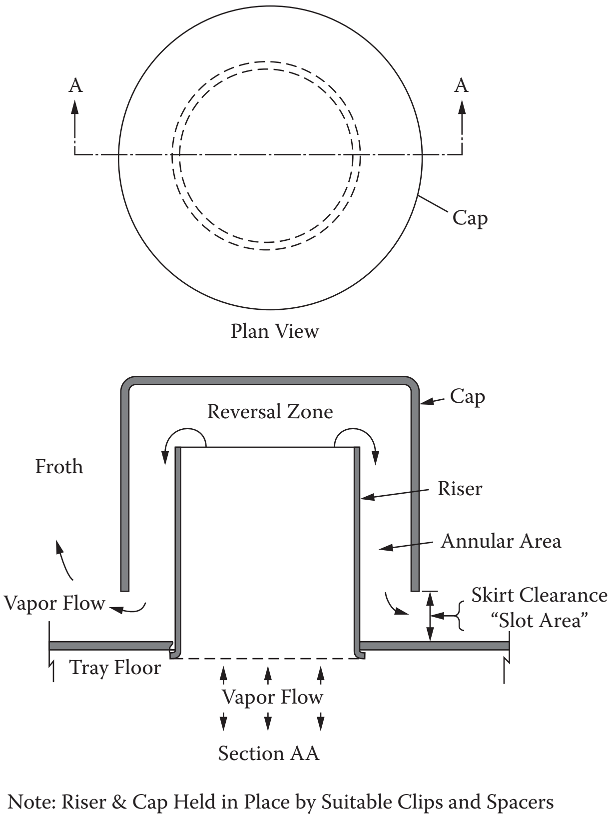

FIGURE 12.36 Diagram of a typical bubble cap.

12.6.1.2.2 Movable Valve Trays

These contacting devices can extend the operating range of a crossflow sieve tray, as indicated by Figure 12.26, which shows that the sieve tray under observation loses efficiency at an F-factor of about 1.0 $m/s(kg/m^3)^{0.5}$, whereas the addition of valves permits operation down to an F-factor of 0.6 or below. A movable valve is shown in Figure 12.37 alongside a fixed valve counterpart. Note that valves can have various shapes, often circular (see Figure 12.24).

Manufacturers of valve trays, such as Koch–Glitsch, Inc., of Wichita, Kansas (Ballast trays and Flexitrays), and Sulzer–Chemtech (formerly Nutter Engineering Co.), of Tulsa, Oklahoma (Float Valve Trays), have prepared proprietary design manuals. Hence, only limited discussion will be given here. As for bubble-cap trays, design methods follow those for sieve trays. The vapor capacity chart (Figure 12.29) covers valve trays, as does the alternate method of Kister and Haas.[36] Information on liquid entrainment is proprietary, but measurements have been made by Fractionation Research, Inc.[31] Because of the vapor flow reversal, one would not expect entrainment from valve trays to be greater than that from sieve trays. Liquid capacity considerations follow exactly those for sieve trays.

Pressure drop prediction follows the same approach as for sieve trays, with the primary difference being in the determination of dry tray pressure drop. Values of dry drop for fully open and fully closed valves may be estimated from relationships such as those of Klein[43]:

$$\text{Closed: } h_d = K_c \frac{\rho_v}{\rho_L} U_c^2 \tag{12.71}$$

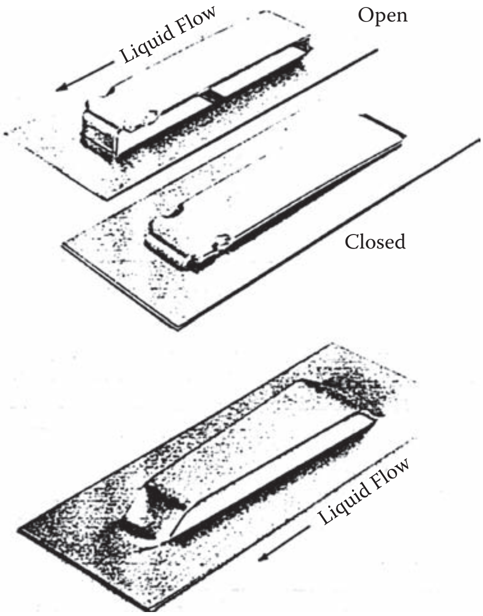

FIGURE 12.37 Views of a rectangular, movable valve and a rectangular fixed valve (the V-grid). (Courtesy of Sulzer Chemtech USA, Inc.)

$$\text{Open: } h_d = K_o \frac{\rho_v}{\rho_L} U_o^2 \tag{12.72}$$

with Klein giving rather complicated equations for coefficients K_c and K_o. Klein also provides a relationship for predicting the aeration factor β so that the equation

$$h_t = h_d + \beta(h_w + h_{ow}) \tag{12.60}$$

can be applied. Bolles[44] provides a good example of the hydraulic relationships for movable-valve trays.

12.6.1.3 Fixed Valve Trays

For this device, valves are fixed in place (extruded from the tray metal), and Figure 12.37 shows a comparison between fixed and movable valves of the same general design. The fixed valve, known as the "V-grid," was introduced in 1979 with a useful paper by Nutter.[45] More recently, a modern version of the V-grid was compared with a sieve tray with 12.7-mm holes by Nutter and Perry,[46] showing that the valve tray has about the same efficiency but slightly greater capacity when compared with a sieve tray. As might be expected, the design of the fixed valve tray follows that of the sieve tray, the basic difference between the trays being the simple hole versus an elevated opening that can be irregular in shape. Valve tray manufacturers offer many variations of the basic design.

A variation of the fixed valve tray design is the elevation of the downcomer floor and discharging downflow liquid through openings in the lower part of the downcomer. A sketch of such a device is given in Figure 12.38, which shows the "hanging downcomer." This modification frees up space for valves or perforations in the area normally used for the bottom of the downcomer. Depending on the downcomer area, this can promise 10 to 15% additional vapor flow capacity. This additional

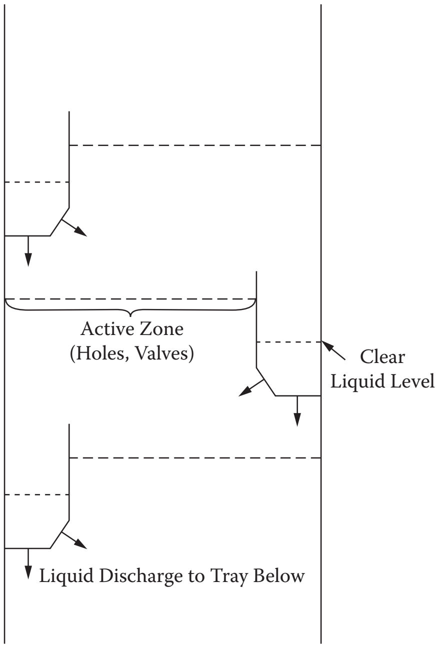

FIGURE 12.38 Hanging downcomer tray. Note that the part of the tray floor normally used as the bottom of the downcomer is converted to bubbling (active) area.

capacity has not always been achieved, however, and the design of the downcomer is critical, because too big of an opening at its bottom can allow vapor to bypass the contacting zone.

12.6.2 Counterflow Perforated Trays

These trays, often called *dualflow trays*, are perforated and occupy the entire column cross section. Similar devices are known as *turbogrid trays* and *ripple trays.* Their simplicity is evident from the view in Figure 12.39. Since there are no downcomers, liquid must compete with vapor for passage through the perforations, and this complicates the hydraulic analysis of the device. Observations show that a given perforation passes either vapor or liquid, but not both at the same time. Furthermore, the phase flowing through the perforation shifts with time in a random way. This alternative flow is believed to be the reason why trays of this type can often handle systems that foul conventional trays and packings.

Extensive commercial-scale performance data on counterflow devices were released by FRI in 2000. Detailed information on tray performance and modeling was reported.[47] Figure 12.40, from reference 48, shows the influence of open area on efficiency and also makes clear the sensitivity of efficiency to loading. The figure is quite revealing: One can obtain increased capacity at the expense of efficiency by going to larger open areas. The figure also shows that the counterflow device has a characteristically narrow operating range.

Geometric variables for design are few: perforation type and size, open area, and tray spacing. The perforations are usually round and in the range of 12.7- to 25.4-mm diameter. Open areas run from 15 to 25%. Vapor flow capacity (entrainment limitation) is correlated in a fashion similar to that for crossflow trays, as shown in Figure 12.41, from reference 47. The figure is based on FRI data taken in a 1.2-m diameter column.

Zuiderweg and coworkers[49] identified a segregation effect on turbogrid trays and found that towers in the range of 3- to 4-m diameter have 80% or less of the efficiency of a small (0.5 m) tower, because of phase segregation and channeling.

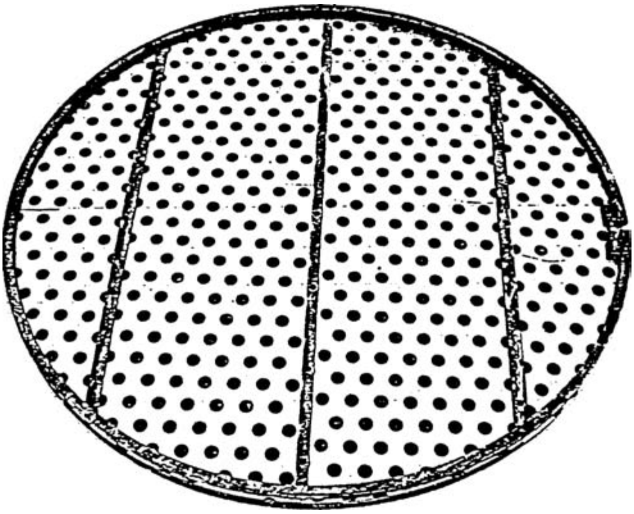

FIGURE 12.39 View of a 1.2-m dualflow tray. (Courtesy of Fractionation Research, Inc.)

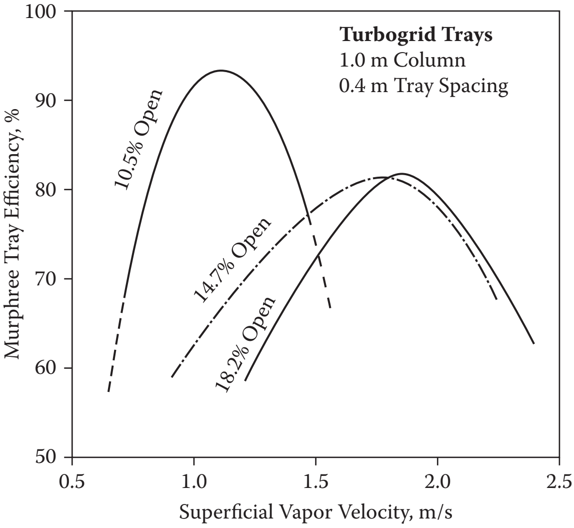

FIGURE 12.40 Efficiency of stamped turbogrid trays, methanol/water system. One-meter column, atmospheric pressure, total reflux. (Kastanek et al., 1969. *IChemE Symp. Ser. 32,* 5–100.)

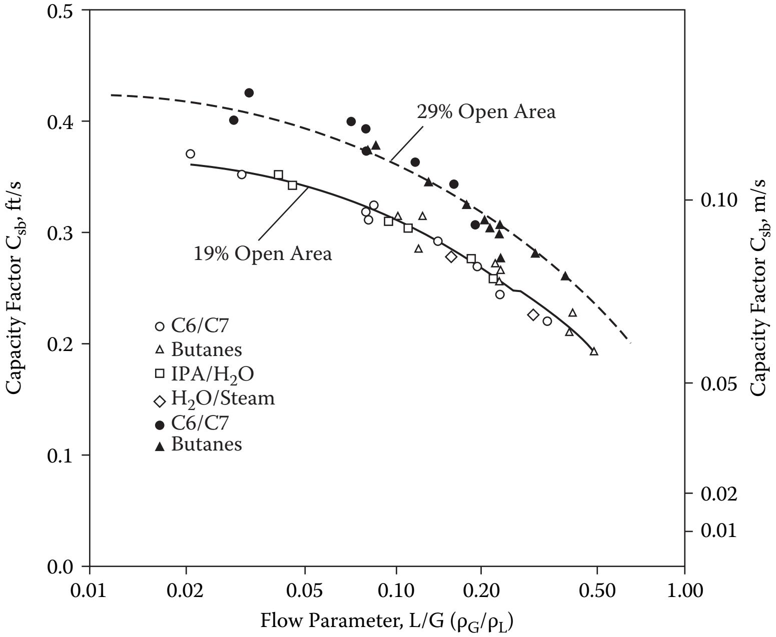
Pressure drops of counterflow perforated trays are difficult to predict, because the open area used by the vapor varies with loading, and one must predict the fraction of opening for vapor at a given load point. Forms of the simple two-resistance equation are used:

$$h_t = h_d + h'_L \tag{12.61}$$

but with variable open area (vapor velocity through openings) and orifice coefficient.

The character of the two-phase mixture above the tray floor is different from that of a conventional crossflow tray because of the counterflow of the phases, and this makes it possible for a counterflow tray to achieve more than one theoretical stage. A paper by Garcia and Fair[47] provides approaches to modeling pressure drop and efficiency of dualflow trays, based on the FRI database.



Note: Data normalized to 610 mm (24-in) Tray Spacing and 12.7 mm (0.5-in) Holes.
Factor = 0.81 for 304 mm (12-in) Spacing, 1.16 for 914 mm (36-in) Spacing.
Factor = 1.06 for 25.4 mm (1.0-in) Holes

FIGURE 12.41 Flooding capacity of dualflow trays, based on FRI data. Column diameter = 1.2 m. (J. A. Garcia; J. R. Fair, 2002. *Ind. Eng. Chem. Res.* 41: 1632.)

12.6.3 Baffle Trays

As in the case of counterflow trays, baffle trays are often used for fouling services, e.g., handling slurries that would plug conventional crossflow trays. Their simplistic design does not lead to mass transfer efficiencies as high as those for counterflow trays, but their pressure drop and capacity can have advantages over the conventional devices.

The internals for these columns have also been called "splash decks" or "shower decks," descriptive terms to indicate the type of phase contacting expected. Vapor (or gas) flows upward through the baffle openings and there contacts the liquid showering down from one baffle to the next. Figure 12.42 shows a representative baffle tray column containing segmental baffles.

Geometric design variables for baffle tray columns are simple and few. The horizontal opening for gas flow is known as the *window area.* The vertical opening through which gas passes in a more horizontal direction is the *curtain area*. Much of the vapor-liquid contacting occurs within a zone bounded by the curtain area. Excessive constrictions in either area can cause higher pressure drop and flooding. Normally, it is desirable to make the two areas about equal in size.

A recent paper[50] provides a most complete analysis of design methodology for baffle columns. Figure 12.43 provides flooding prediction and uses the same parameters as the charts for crossflow trays (Figure 12.29) and counterflow perforated trays (Figure 12.41). The data points on Figure 12.43 include results from Fractionation Research, Inc. (FRI) for total reflux tests with the several systems indicated.[50a] These tests were run in a 1.2-m diameter column, and some variation in baffle geometry was employed. The term "cut" is the percentage of open area for phase flows.

Pressure drop through baffle columns is primarily a function of vapor flow rate, with about two velocity heads per opening being a good rule of thumb. For high liquid rates, this estimate must be increased. FRI tests indicate that the efficiency of a baffle column will be about half that for a

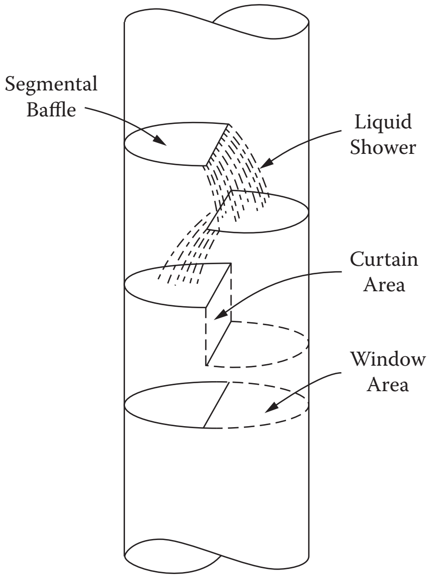


FIGURE 12.42 Section of a baffle tray column, containing side-to-side segmental baffles.

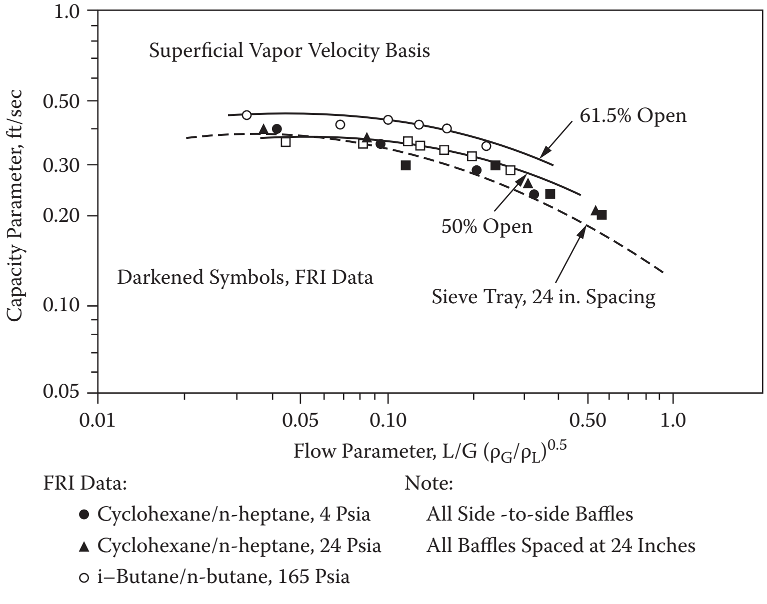

FIGURE 12.43 Flooding capacity of baffle tray columns. [J. R. Fair, 1993. *Hydrocarbon Proc*. 72 (5): 75.]

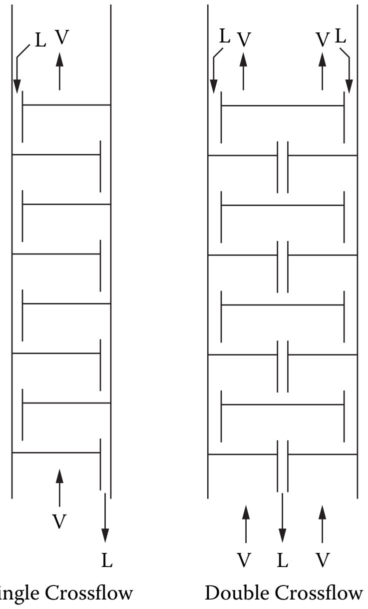

FIGURE 12.44 Multipass liquid flow arrangements for crossflow tray columns.

crossflow tray column under the same loading conditions. Hence, it may be better to estimate mass transfer rates from heat transfer rates using the mass transfer–heat transfer analogy. This is covered in some detail by Fair.[51]

12.6.4 Multiple Downcomer Trays

These devices are suitable for high liquid flow services (e.g., high-pressure fractionation), and their operating characteristics are described by Delnicki and Wagner.[52] Multiple downcomer trays (MD trays) have several small downcomers spread over the tray area, each downcomer being the hanging type. The vapor is normally dispersed through sieve-type holes. In general, their hydraulic behavior resembles that of crossflow trays, even though they exhibit some characteristics of counterflow trays. Their design is normally handled by the proprietor of the tray technology.

12.6.5 General Comments on Tray-Type Columns

For high liquid flow cases, it may be necessary to split the flow into two or more passes. This creates separate contacting zones, as shown in Figure 12.44. For the *two-pass tray* shown, liquid flows side to center and center to side on successive trays; this means that the effective weir crests differ because of differing weir lengths. The center weir is about the same length as the column diameter, whereas the side weir may be only 70% or so of the diameter.

The downcomer aprons can be sloped to give a larger cross section of downcomer at the top than at the bottom. Although this can aid in vapor disengagement from the downcomer liquid, the larger area can detract from the available vapor flow area, and this must be taken into account in estimating the approach to flood. Because of changing vapor and liquid flows throughout the column, hydraulic studies should include, as a minimum, conditions at top and bottom, and above and below the feed tray. This variation in flow is particularly pronounced in high-vacuum columns, where the vapor density can change twofold or more in a single column. With a feed stream that is partially vaporized, volume must be provided to allow adequate phase separation.

TABLE 12.8
Starting Dimensions for Crossflow Sieve Trays

	Vacuum	Atmospheric	Pressure
Tray spacing, in.	24	24	24

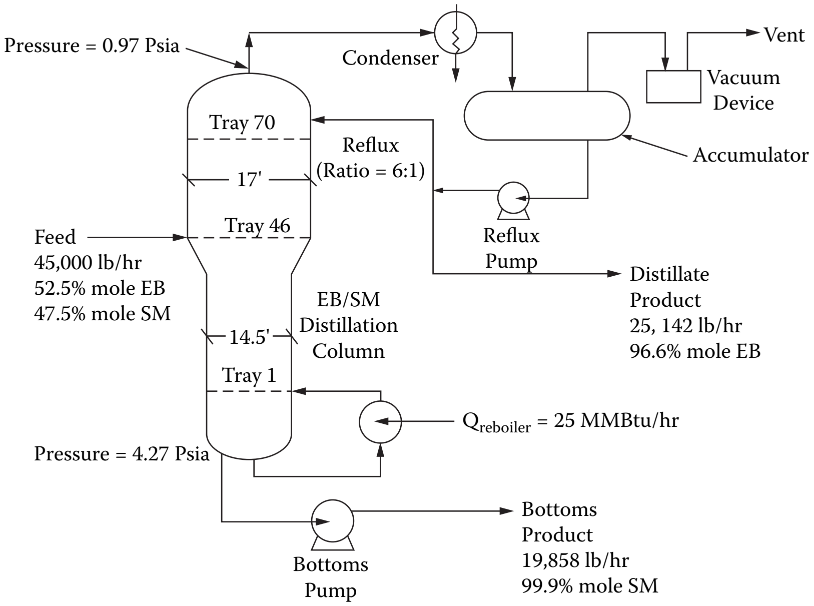

FIGURE 12.45 Flow diagram, ethylbenzene/styrene fractionation. For Problem 12.6. [J. C. Frank et al., 1969. *Chem. Eng. Prog.* 65(2): 79.]

As a starting point for crossflow tray design, the dimensions shown in Table 12.8 may be considered. While the table is designated for sieve trays, dimensions for valve trays are easily juxtaposed.

Problem 12.6

A large fractionator to separate ethylbenzene (EB) as overhead from styrene monomer (SM) plus small amounts of tar as bottoms is being designed along the lines of the flow diagram and material balance published by Frank et al.,[53] reproduced here as Figure 12.45. A point in the rectifying section is being considered, where the properties are as follows:

Temperature	172°F	78°C
Pressure	100 mm Hg abs.	13.4 kPa

Relative volatility, EB/SM = α= 1.40		
Vapor density	0.030 lb/ft^3	0.481 kg/m^3
Liquid density	52.2 lb/ft^3	837 kg/m^3
Surface tension	25 dyn/cm	25 mN/m

The flow conditions are

Vapor	126,000 lb/hr = 1,200 lb-moles/hr = 1,167 ft^3/s
	15.88 kg/s = 33.0 m^3/s
Liquid	108,000 lb/hr = 1,028 lb-moles/hr = 0.57 ft^3/s
	13.61 kg/s = 1.162 (10^{-2}) m^3/s

Develop dimensions of a crossflow sieve tray for these conditions, plus these specified parameters:

Tray spacing	24 in.	0.61 m
Weir height	1.0 in.	25.4 mm
Hole diameter	0.1875 in	4.8 mm
Tray metal thickness	0.078 in	2.0 mm
Downcomer area = 5% of total cross section	Hole area = 14% of active (bubbling) area	
Weir length	79.2 in.	2012 mm
Downcomer clearance	0.75 in.	19 mm

Solution:

Column Diameter: First, the abscissa value for Figure 12.29 is calculated: 13.61/15.88 $\sqrt{0.481/837}$ = 0.021. From that figure, for 0.61 m spacing, C_{sbf} = 0.37 ft/s = 0.11 m/s, based on net area, which is 95% of the total cross section. This gives a flooding vapor velocity (corrected for surface tension) = 4.91 m/s through the net area. Thus, minimum net area = 33.0/4.91 = 6.72 m^2.

Use 80% of flood for design; therefore, design vapor velocity = 0.8(4.91) = 3.93 m/s through net area. This gives a required net area = 6.72/0.80 = 8.40 m^2 and a required total cross section of 8.40/0.95 = 8.85 m^2. *Required column diameter = 3.36 m (11.0 ft).*

For this geometry, several useful parameters emerge:

Active area A_a = 7.98 m^2	Active area vapor velocity U_a = 33.0/7.98 = 4.14 m/s
F-factor for active area	F_{va} = 2.87 m/s(kg/m3)0.5
F-factor for hole area	F_{vh} = 2.87/0.14 = 20.5 m/s(kg/m^3)$^{0.5}$

Pressure Drop: From Figure 12.33, for A_h/A_a = 0.14 and tray thickness/hole diameter of 2/4.8 = 0.42, the orifice coefficient is 0.76. Then, by Equation (12.5),

$$h_d = \frac{50.8}{(0.76)^2}\frac{0.481}{837}\left(\frac{33.0}{1.12}\right)^2 = 43.9\,\text{mm liquid}$$

By Equation (12.62), $h_{ow} = 664\ L_w^{0.667}$, and L_w = 1.615(10^{-2})/(2.012)

$$\therefore\ h_{ow} = 26.6\ \text{mm}$$

From Equation (12.61), β = 0.47

$$\therefore\ h_t = h_d + \beta(h_w + h_{ow}) = 43.9 + 0.47(25.4 + 26.6) = 68.3\ \text{mm total drop/tray}$$

from which h_L = 24.4 mm liquid

Downcomer Backup
By Equation (12.66), $h_{da} = 165\ (0.0162/0.0382)^2 = 29.5$ mm
By Equation (12.65), $h_{dc} = h_t + h_L + h_{da} = 68.3 + 14.6 + 29.5 = 122.2$ mm
(This is well below the tray spacing of 610 mm, $\therefore$ no backup problem.)

Lower operating limit
At 50% of design,

By Equation (12.69), $h_\sigma = 409\ 25\ (837(4.76) = 2.57$ mm

And $h_d + h_\sigma = 11.0 + 2.57$ mm. From Figure 12.35, this appears to be close to the lower limit. Accordingly, can operate down to 50% of design rate without serious weeping or dumping.

12.7 PACKED COLUMN HYDRAULICS

The packed column used for distillation separations is a vertical, cylindrical vessel containing a bed of packing elements, suitably supported and irrigated by liquid flowing through a special distributor. The height of the bed is determined by the mass transfer capability of the packing; limitations are governed by allowable pressure drop and overall column height. The overall arrangement of a column is shown in Figure 12.46.

Packings for distillation columns come in many types, shapes, and sizes. So-called *random packings* (or "dumped packings") are relatively small pieces, or elements, that are placed in the column (usually by pouring) in a random arrangement to produce a *packed bed*. The counterparts

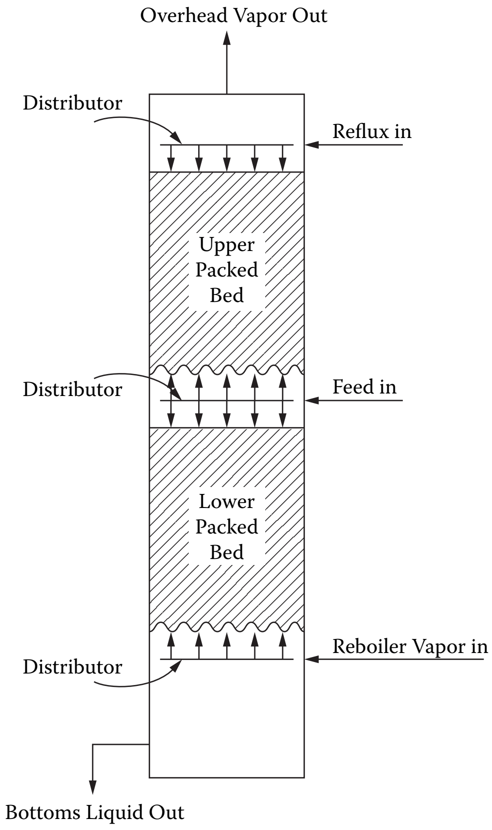

FIGURE 12.46 Overall arrangement of a simple packed distillation column.

of random packings are *ordered* or *structured packings*, which are relatively large, fabricated to close dimensional tolerances, and carefully positioned in the column. Random packings and ordered packings are usually competitive for a given problem, and the designer must know the characteristics of each, as discussed separately below.

12.7.1 Packing Characteristics

Representative random packings were shown in Figure 12.25; properties of important packings of the class are given in Table 12.9. The first three packings listed are the "through-flow" type in which the phases can flow freely through the elements with reduced form drag. The others listed are of the "around flow" type, with increased form drag and therefore higher pressure drop.

Source: Packing factors from Kister & Gill (*Chem. Eng. Prog*. 87 (2) 32 (1991), and Houston AIChE Meeting, March 19-23, 1995.

Random packings are fabricated from a wide variety of materials. Originally, most were made of ceramic and were popular for corrosive services despite their friability. Perhaps the most popular material of construction today is polypropylene, which gives a bed of light weight, reasonable resistance to corrosion by many fluids, and low cost. Plastic random packings are frequently used in air stripping columns where dissolved volatile organic compounds are removed from groundwaters.

A representative structured packing was shown in Figure 12.25. Packings of this type are designed specifically to do three things: minimize form drag (pressure drop), provide considerable active surface area for mass transfer, and maintain uniform liquid distribution so that most of the surface area is active for mass transfer.

Structured packings are generally more expensive than random packings on a volumetric basis but provide better efficiencies and significantly lower pressure drops. Table 12.10 shows typical characteristics of structured packings. Figure 12.47 indicates the key advantages of low pressure drop per theoretical stage for packed columns as compared to a sieve tray.

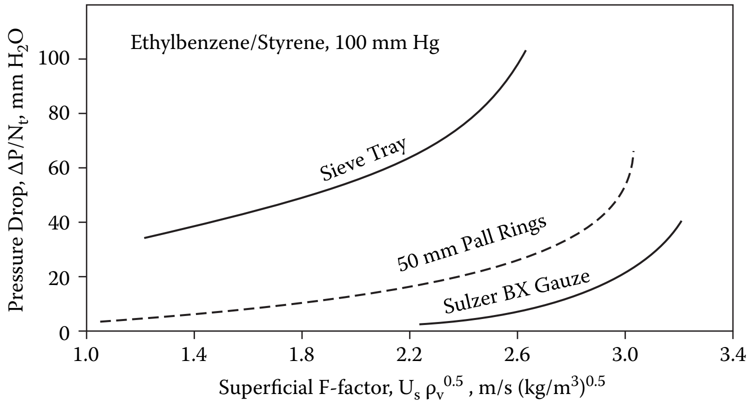

FIGURE 12.47 Comparison of devices for vacuum service, pressure drop/theoretical stage.

Most structured packings are of the corrugated sheet type. In these packings, crimped, corrugated sheets of metal or metal gauze are positioned to create flow channels for the gas and promote distribution. Some details of their fabrication and assembly are shown in Figure 12.48. (Less common types of ordered packings, involving meshes and grids, are not discussed here.) Structured packings can also be made from a variety of materials; the choice of material depends not only on corrosion resistance and cost but also on the wettability of the surface by the liquid being used. For example, water does not wet clean metals well but spreads almost completely on many ceramic surfaces. Aspects of packing wetting will be discussed below, in the "Mass Transfer Efficiency" section.

As in the case of trays, the important hydraulic considerations for packings are pressure drop and flooding. To a lesser extent, liquid holdup is also important. The hydraulics affect the performance profile for a given separation in a specific packing. A typical profile for efficiency and pressure drop is shown in Figure 12.49.[54] The equivalence to the tray profile is evident (see Figure 12.26). The ordinate is given in theoretical stages per unit of bed height, but a more common description of efficiency is the inverse of this, the *height equivalent to a theoretical plate (HETP)*. A generalized profile for a packed column is shown in Figure 12.50, which shows the importance of having uniform liquid distribution to the bed. (The distributor for the tests shown in Figure 12.49 was of exceptionally high quality.)

Some random packings correct a poor initial distribution of liquid, whereas others (especially the high-void, low-form-drag packings) must always be fed a uniformly distributed liquid at the top of the bed if they are to perform efficiently. Still other packings exhibit a deterioration of a good distribution with bed depth, making the use of *redistributors* mandatory at depths beyond around 3 to 6 m.

Liquid and vapor flow countercurrently through openings between and within packing elements. At low vapor rates, there is relatively little disturbance of liquid by the vapor, and mass transfer proceeds in a fashion similar to that in a wetted wall column. At higher rates, there is considerable interaction between the phases, with vapor flow causing increases in liquid turbulence and holdup. In the so-called "loading zone," there is an enhancement of mass transfer but, as rates are increased further, flooding occurs.

The loading/flooding phenomena are best understood through a study of pressure drop curves such as those shown schematically in Figure 12.51. For a dry packing (with no liquid irrigation), pressure drop follows a traditional friction factor, orifice-type relationship. When there is irrigation at a constant liquid rate, increasing the gas rate leads to a change in the slope of the pressure drop curve, indicating the onset of loading. Further gas rate increase leads to a rapid and continuing increase in pressure drop, indicating flooding. Flooding can also be reached by increasing the liquid rate at

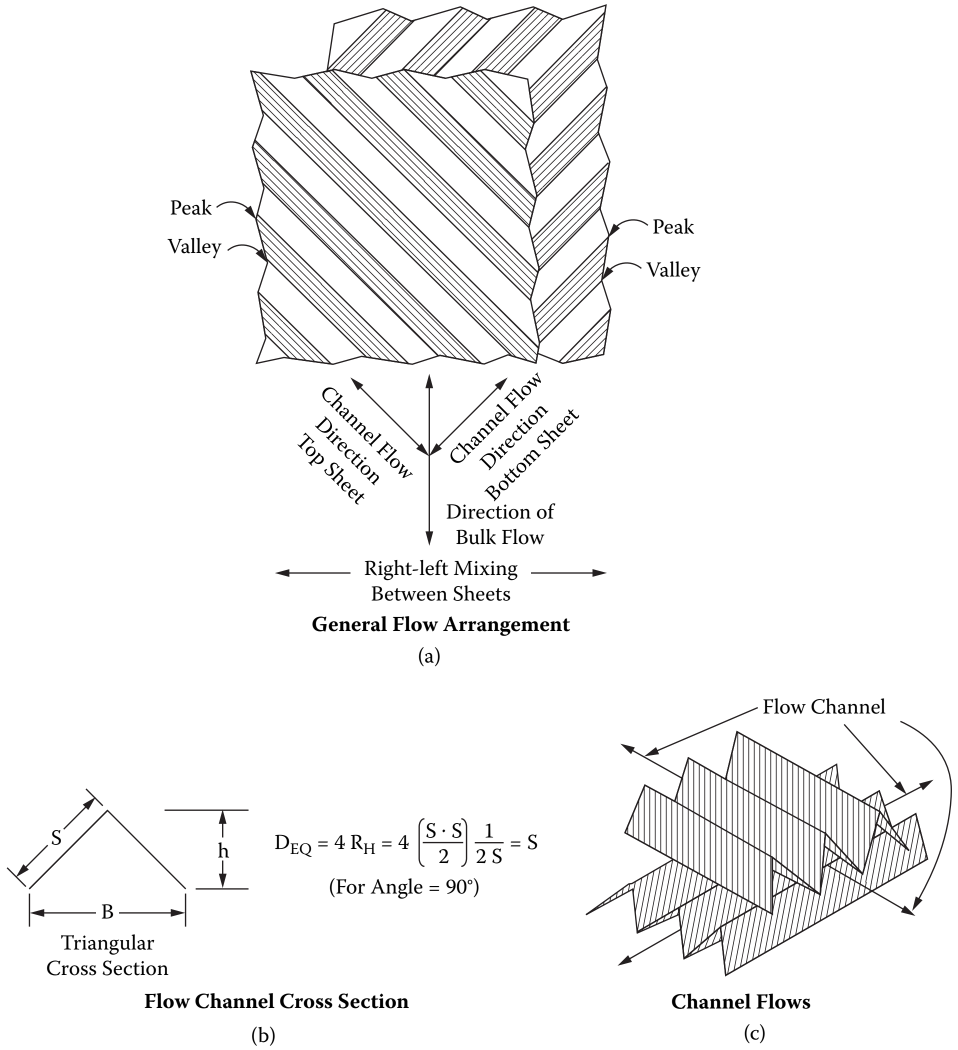

FIGURE 12.48 Dimension details for structured packing analysis.

constant gas rate. For distillation applications, both liquid and vapor rates are increased to approach the flood point. Vendors provide pressure drop curves for each of the packings listed in Tables 12.9 and 12.10, but the experiments conducted to develop such curves are usually done with the air-water system. For distillation at total reflux, curves such as those in Figure 12.49 are more realistic.

Regions below the loading point as well as the loading region itself are apparent from liquid holdup and interfacial area data as shown in Figure 12.52.[55] At low rates, there is little influence of vapor rate on holdup and interfacial area. This behavior is typical of random as well as structured packings. In the latter, the effects of the rates on interfacial area seem to be less pronounced than for random packings. The appearance of the flood point in the holdup and area plots will undoubtedly match the flood point in the pressure drop.

12.7.1.1 Maximum Vapor–Liquid Capacity

The hydraulic flood point, as illustrated in Figure 12.50, is reached at a combination of countercurrent gas and liquid rates such that the pressure drop exhibits a relatively large increase with a

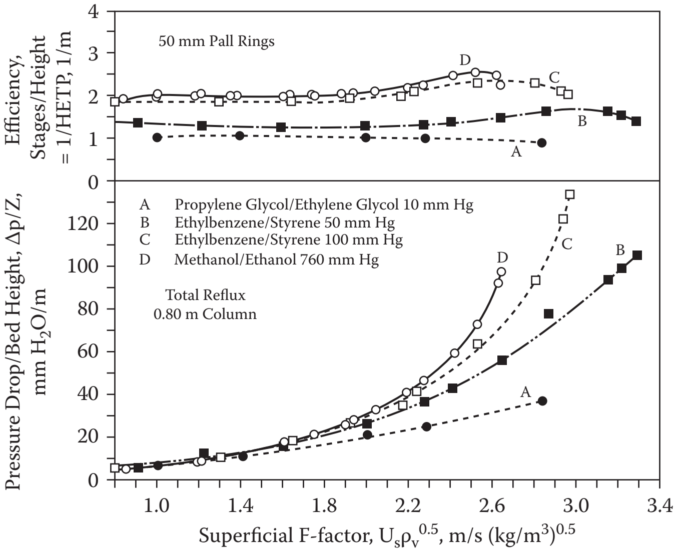

FIGURE 12.49 Performance of 50-mm Pall rings, various services. (R. Billet, 1969. *IChemE Symp. Ser. 32*, 5: 111.)

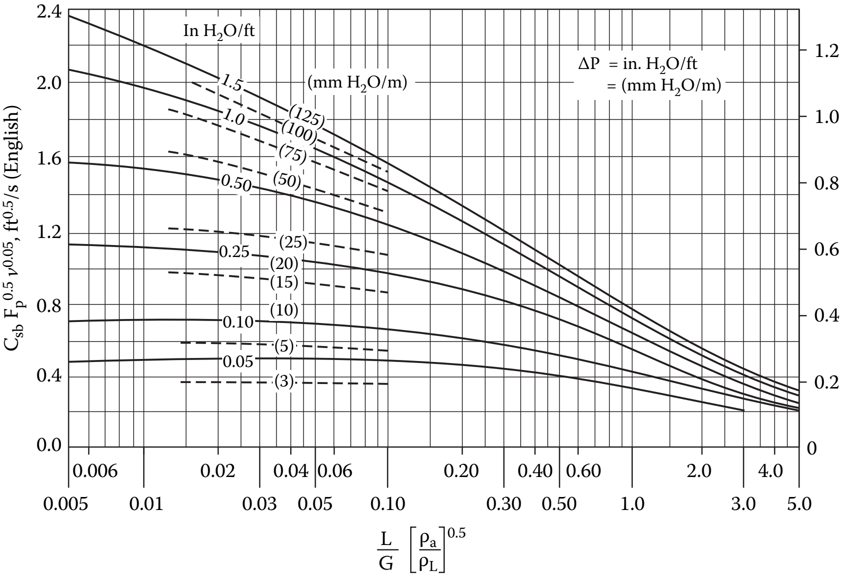

FIGURE 12.53 Generalized chart for estimating pressure drop and maximum capacity of packings. (R. F. Strigle, 1994. *Packed Tower Design and Applications*, 2nd ed., Houston: Gulf Publ. Co.)

small increase in flow rate of either phase. Methods for estimating maximum hydraulic capacity for a packing provide a basis for design (optimum approach to flood). Such methods employ one of three separate approaches:

- Generalized pressure drop correlation (GPDC)[56,57]
- Empirical flow parameter versus capacity parameter plots
- Friction factor–dry pressure drop correction methods

The first approach has been modified several times in use for a longer period of time, and several updates and modification have been made over the years. The modification by Strigle[58] is described here. Two other approaches are described elsewhere;[59,60] the graph of Strigle is shown in Figure 12.53.

The Strigle diagram provides both limiting capacity and pressure drop predictions. Packing size and type effects merge through the use of a *packing factor* that is presumed to be constant for a given packing size and type. Packing factors are included in Tables 12.10 and 12.11.

For flooding, an estimate can be made from Figure 12.53, although manufacturers often like to omit the flood line from the chart. Maximum throughput is assumed to occur at the top curve (125 mm H_2O/m), although slightly more capacity is sometimes available. The presumption that flooding occurs at a constant value of pressure drop is not necessarily correct, since the more open-type packings flood at lower pressure drops. Also, flooding occurs at lower pressure drops under high liquid loadings and gas densities for a given packing.

The ordinate value of the Strigle chart is, in fact, a capacity parameter, with a slight correction for liquid viscosity,

$$\text{ordinate} = C_s F_p^{0.5}\,\nu^{0.05} \text{ which has units of ft}^{0.5}\text{/sec or m}^{0.5}\text{/s}$$

where

$C_s = U_s\,[\rho_v/(\rho_L - \rho_V)]^{0.5}$, ft/sec or m/s

ν = liquid kinematic viscosity = centistokes (centipoises/density, g/ml)

F_p = packing factor, 1/ft or 1/m (Tables 12.9 and 12.10)

For a given packing type and size (F_p = constant), and for the kinematic viscosity term close to unity (usually the case), the ordinate is obviously closely related to the Souders–Brown capacity parameter used for trays.

The abscissa value is the flow parameter, also used for trays:

$$FP = \frac{L}{G}\sqrt{\frac{\rho_v}{\rho_L}} \tag{12.62}$$

The F-factor $F_s = U_s \rho_v^{0.5}$ $\therefore$ $F_s \sim C_{sb}/\rho_L^{0.5}$. Thus, the ordinate is closely related to the capacity parameter used for trays, with a correction for packing type and size, and a minor adjustment for liquid viscosity. (Unlike trays, however, there is no correction for surface tension.)

12.7.1.2 Pressure Drop

Predictions of flooding and pressure drop are discussed by Kister,[60] who has developed charts similar to Figure 12.53 (Strigle chart) for individual packing types and sizes. Kister suggests that the most fundamental approach to estimating pressure drop and flooding has been provided by Stichlmair et al.[61] However, this approach requires two constants for each packing type and size, and sets of constants have been developed for relatively few packings.

For the usual design case, Figure 12.53 is recommended. When the estimate is critical and requires the best possible reliability [e.g., for high-vacuum distillation or high-throughput scrubbing (to minimize blower horsepower)], the method of Stichlmair et al.[61] should be used for random packings. A second choice would be the individual packing charts of Kister.[60] For structured packing, the method of Rocha et al.[62] is recommended, which takes into account surface wettability and texturing, liquid holdup, geometric details, and fluid properties. The model is complex and requires a computer program but is supported by considerable commercial test data, mostly under distillation conditions. The input data for a particular packing are straightforward. The Separations Research Program at the University of Texas at Austin can provide more information.

Problem 12.7

Performance data for 50-mm metal Pall rings in ethylbenzene/styrene (EB/SM) separation service are shown in Figure 12.45. For the conditions given in the figure, estimate (a) the flood point and (b) the pressure drop for a loading of F-factor = 2.4 m/s(kg/m^3)$^{0.5}$. Compare the results with the values given in Figure 12.45.

Relevant properties at a selected point in the column are

ρ_L = 837 kg/m^3	M_{EB} = 106
ρ_v = 0.480 kg/m^3	M_{SM} = 104
μ_L = 0.38 cP	ν = 0.45 cSt
σ = 25 dynes/cm	

At total reflux, the flow parameter is $FP = L/G[\rho_v/\rho_L]^{0.5} = 1.0[0.480/837]^{0.5} = 0.021$.

For 50m-mm metal Pall rings, F_p = 88 m^{-1} (Table 12.9).

From Figure 12.53, for FP = 0.021,

$$C_{sb}F_p\nu^{0.05} = 1.10 \text{ m}^{0.5}/\text{s (highest } \Delta P \sim \text{flood limit)}$$

from which C_{sb} = 0.122 m/s, and U_s = 16.7 ft/s = 5.10 m/s flood superficial velocity.

Converting to F-factor, to make the comparison,

$$F_s = U_s \rho_v^{0.5} = 5.10\,(0.480)^{0.5} = 3.50$$

(a) Flood F-factor = 3.50 m/s $(kg/m^3)^{0.5}$
Note that performance curve C of Figure 12.49 *indicates flooding at F ~ 3.0 m/s(kg/m³)^0.5^.*
(b) For pressure drop at F = 2.4, convert to $C_{sb} = F_s/\rho_L^{0.5} = 2.4/(837)^{0.5} = 0.0830$.
C_{sb} = 0.0830 m/s. Then, ord. of Figure 12.53 = $0.0830\,(88)^{0.5}(0.46)^{0.05}$.
ord =0.748 m0.5/s for which, at FP = 0.021, ΔP = 40 mm H_2O/m.
The experimental value was about 50 mm H_2O/m.

12.7.1.3 Liquid Distribution

Good liquid distribution is essential to the effective performance of packed columns. While there are no quantitative measures for "good distribution," experience leads to the following guidelines: for dumped packings, the ratio of column diameter to packing element diameter should be 8 or greater, and the liquid distributor should produce at least 10 inlet streams, evenly distributed, per square foot (100 per square meter) of cross section. The "around flow" bluff body packings (e.g., Raschig rings) may require fewer inlet liquid streams.

Problem 12.8

Problem 12.6 deals with the dimensioning of a large ethylbenzene/styrene tray-type fractionator. Because high pressure drop in this separation leads to increased tar production, a packing (instead of trays) is to be considered. The conditions are the same as for Problem 12.6. For 80% flood, determine the required column diameter and associated pressure drop for a 50-mm Pall ring random packing.

Solution. For both capacity and pressure drop, Figure 12.53 will be used. For the mixture, the absolute viscosity is 0.38 cP, giving a kinematic viscosity of 0.45 cSt. From Table 12.8, the packing factor F_p for 50-mm metal Pall rings is 88 m^{-1} or 26.8 ft^{-1}. The abscissa for the figure (the flow parameter) is the same as before: FP = 0.021. For Figure 12.53, the ordinate term is

$$C_{sbf}F_p^{0.5}\nu^{0.02} = C_{sbf}(5.18)(0.45^{0.02}) = 5.10\ C_{sbf}\ \text{ft/s}$$

At the highest curve of Figure 12.53 (assumed equivalent to flooding), the ordinate value is 2.05, from which C_{sbf} = 0.40 ft/s. At 80%, the ordinate value is 2.05(0.80) = 1.64, and the pressure drop is 55 mm H_2O/m (0.66 in H_2O/ft) or 66 mm liquid/m.

The column diameter is based on C_{sb} = 0.80, C_{sbf} = 0.32 ft/s = 0.98 m/s. For a vapor flow of 33.0 m^3/s, the required diameter is 3.21 m or 10.5 ft.

Comparison with Trays. The pressure drop for a tray with 0.61-m spacing was found to be 58.4 mm liquid. The comparative packing pressure drop is 66(0.61) = 40.3 mm liquid. The diameter for the packed column is 3.21 m vs. 3.36 m for the trays. If a lower approach to flood for the packing is used, to make the column diameter 3.36 m, the packing pressure drop becomes less than half that of the trays.

Once the liquid has been introduced to the top of the bed, the question arises as to whether the initial distribution is maintained throughout the bed. Silvey and Keller[63] used internal bed liquid samplers and total reflux, and found that bluff body packings such as ceramic Raschig rings correct an inadequate initial liquid distribution and also maintain a good distribution throughout the bed. But the "through-flow" random packings and the structured packings cannot correct an initial problem. Potthoff[64] elucidated in-bed distribution effects, and representative plots of his findings are shown in Figure 12.54. The difference between a single-point distributor (the worst possible case) and a multipoint distributor is dramatic. The effect of bed height on efficiency is discussed in the next section.

In any event, the optimum number of pour points per unit of tower cross section depends on the type and size of packing selected, and also on the practical limits of distributor design and

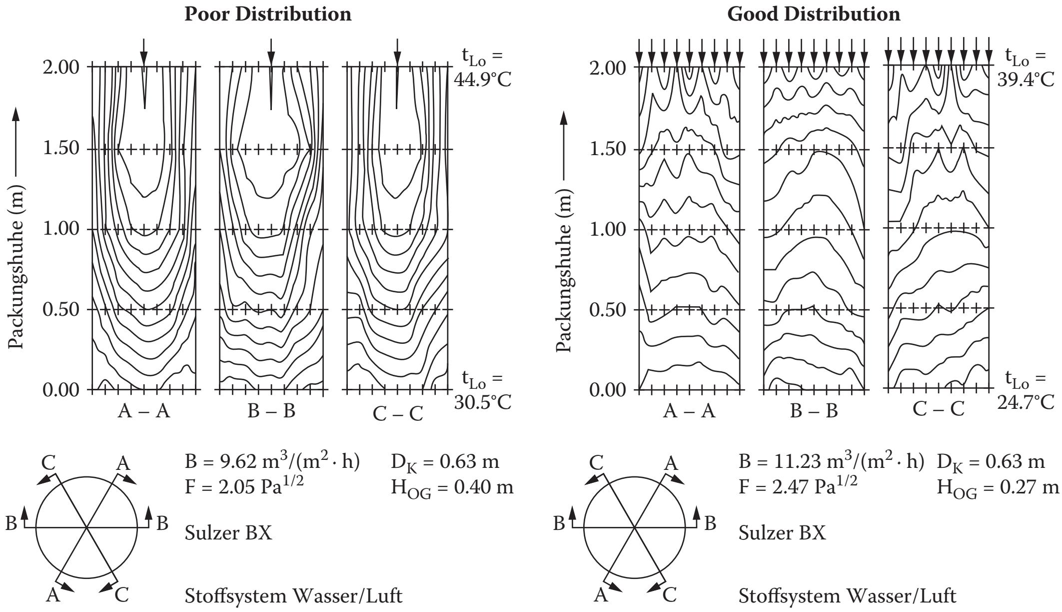

FIGURE 12.54 Constant composition profiles in a bed of structured packing. Left, single-point distributor; right, multipoint distributor. Packing: Ralu-Pak 250YC. Column diameter: 0.63 m. Air-water. B = liquid rate, m^3/m^2-hr H_{og} = height of an overall transfer unit, m, F = gas rate, m/s $(kg/m^3)^{0.5}$. (R. Potthoff, 1992. Ph. D. dissertation, Univ. of Essen, Germany.)

operation. Several workers have found that it is not practical or even necessary to design for more than 10 streams per square foot (100 per square meter).

12.7.1.5 Liquid Distributors

For single- or multiple-bed columns, a distributor is needed for each bed. A center-fed packed distillation column, for example, requires at least two beds. In some cases, the cost of the distributor(s) can approach that of the packing. One can select from several different types of liquid distributors, including trough, orifice/riser, perforated pipe, and spray nozzle. These are illustrated in Figure 12.55 and described below.

The *trough distributor* provides good distribution under widely varying flow rates of gas and liquid. The liquid may flow through simple V-notch weirs or through tubes that extend from the troughs to near the upper level of the packing. Some deposition of solids can be accommodated. Some phase contacting occurs during liquid distribution, providing incremental mass transfer but also introducing possible entrainment problems. The trough is a general-purpose unit that can be adapted to special distribution requirements at relatively low cost.

The *orifice/riser distributor* provides numerous uniformly distributed pour points. The vapor risers must be designed for variations in flow rate, often with a minimum of pressure drop. Typically, risers occupy 20% of the column cross section; if the percentage is much lower, there is danger of liquid backing up into the risers. More exact allocation of riser area can be obtained from the simple relationship

$$h_L = h_{holes} + h_{risers} = 2.42\ u_{Lh} + 5.19\ (\rho_g/\rho_L)U_r^2 \qquad (12.63)$$

where

h_L = liquid height in distributor (around the risers), cm

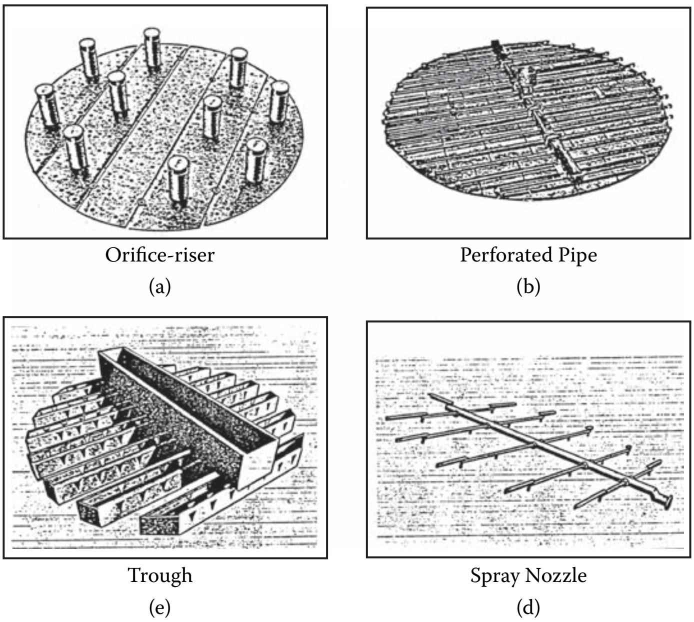

FIGURE 12.55 Examples of liquid distributors.

u_{Lh} = liquid velocity through the distributor holes, m/s
U_r = vapor velocity through the risers, m/s

Thus, liquid backup can be attributed to both orifice area and riser area.

For distribution-sensitive packings, some pour points are needed near the wall (to within 2 cm). For larger-diameter columns, and for low liquid rates, the distributor must be level within ±5 mm for a 3-m diameter column. In addition, the risers must be high enough to accommodate backup for high liquid and vapor flow rates.

The *drip tube/riser distributor* is a variation of the orifice/riser device, with tubes added to the orifices to ensure close contact with the packing (not shown in Figure 12.55). When it is necessary that all tubes discharge evenly, a double tubesheet affair can be used with liquid under pressure; pressure drop through the orifices and tubes must be estimated carefully for this arrangement.

The *perforated pipe distributor* has a central feed sump with pipes that branch out to provide the liquid discharge. The level in the sump varies with liquid total flow rate, and the size of the lateral pipes and their orifices must be dimensioned carefully to ensure that the ends of the pipes are not starved for liquid. The orifice sizes are typically 0.125 to 0.25 in. (3 to 6 mm) in diameter and can plug if foreign matter is present. The pipes must be leveled carefully, especially in large-diameter columns.

The spray nozzle is not widely used. If more than one nozzle is used, it is difficult to obtain a uniform spray pattern because of overlap and underlap of the patterns. Also, liquid entrainment from the sprays is a problem. Spray distributors are sometimes used in petroleum refinery vacuum columns.[65] The full cone nozzle is normally used, singly or in banks.

12.7.1.6 Liquid Redistribution

For bed heights greater than 6 to 8 m, the total bed is subdivided. This is because of natural deterioration of mass transfer efficiency with height. Since each bed must have good initial distribution, it is necessary to collect the liquid flowing from a bed (which may have become maldis-

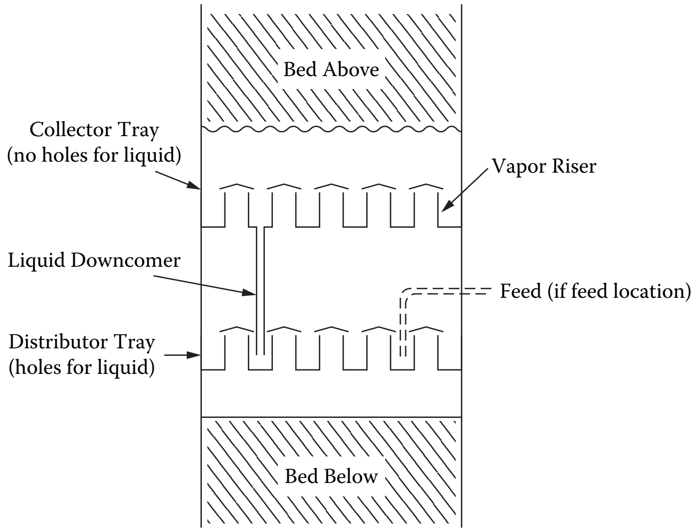

FIGURE 12.56 Collection/redistribution arrangement in a packed column.

tributed) and pass it through a liquid distributor for the bed below. The concept is shown in Figure 12.56. Packing vendors have different recommendations on maximum allowable bed height.

12.7.1.7 Vapor Distribution

While the emphasis is usually on promoting good liquid distribution to the top of a packed bed, poor vapor distribution also leads to poor liquid distribution. The assumption is often made that if there is not good initial vapor distribution, pressure drop in the bed will correct it. This assumption is good for higher pressure drop packings, but for the through-flow packings, an initially poor distribution often persists throughout the bed.

Reasonable care should be used to disperse a side-entering gas (e.g., vapor/liquid return from a reboiler) across the tower cross section. For extremely critical cases, one or two crossflow trays may be used to improve distribution—but they cause increased pressure drop.

The kinetic energy of the gas or vapor entering the tower and the position of the entrance are both critical. Packing vendors can provide guidelines; in some cases, multipoint gas introduction into a tower will be required. Also, the vertical distance between the point of injection and the bottom of the bed is important; for small columns, this distance should be at least one diameter, and at least 0.5 m for larger columns. Studies of vapor distribution in packed beds have been reported.[66]

12.7.1.8 Turndown

An attractive feature of packed beds for mass and heat transfer operations is that the bed itself offers better turndown characteristics than the equivalent tray column. The mass transfer efficiency of a packed column with a good distributor is about as good at both low and high loadings. This favorable comparison is evident from the data in Figures 12.26 and 12.49 (same column and test mixture). The liquid distribution is the key, as indicated in Figure 12.50.

12.8 MASS TRANSFER EFFICIENCY

Equipment design, as discussed in the preceding section, requires preliminary evaluation of column efficiency. There is a close coupling between geometry and efficiency. Several different efficiency terms will be used for tray columns, but the one ultimately needed for design is *overall column efficiency:*

$$E_{oc} = {}^{N_t}\!\!\diagup\!_{N_a} \tag{12.64}$$

where the theoretical tray count *for the column* (not including theoretical stages for reboiler and partial condenser) is N_a, and the actual number of column trays needed is N_t. The number of trays actually specified for the column may be greater than *Na* if allowance is made for column upsets or for alternate operating conditions (e.g., different feed composition or different separation).

For packed columns, mass transfer efficiency is related to transfer rates in counterflow vapor-liquid contacting. A *height equivalent to a theoretical plate* is often used:

$$HETP = {}^{Z}\!\diagup\!_{N_t} \tag{12.65}$$

where Z is the height of packing required to achieve a separation equivalent to that of N_t theoretical stages. As in the case of trays, *HETP* often should be adjusted to allow for upsets or alternative separating conditions.

Thus, the total height of contacting zone is determined as follows:

$$\text{Tray columns: } Z = \frac{N_t}{E_{oc}} TS \quad (TS = \textit{tray spacing}) \tag{12.66}$$

$$\text{Packed columns: } Z = N_t\, HETP \text{ or } Z = N_{og} H_{og} \tag{12.67}$$

12.8.1 General Mass Transfer Relationships

Mass transfer relationships in a distillation column are based on the basic interphase transfer model for a differential slice of the cross section, as shown in Figure 12.57. The slice is taken from the packed bed or from the tray froth. For component i,

$$Ldx_i + x_i dL = Vdy_i + y_i dV \tag{12.68}$$

For equimolar counterdiffusion (approximately the case for distillation), $dV = dL$, and for net transfer of i from bulk vapor to bulk liquid,

$$Vdy_i = K_g a_i\,(y_i - y_i^*)dZ \tag{12.69}$$

where y_i is the mole fraction of i in the vapor, and y_i^* is the mole fraction of i in the vapor that would be in equilibrium with bulk liquid composition x_i. Note that y_i^* is not a real composition but rather a calculated term from the equilibrium expression $y_i^* = K_i x_i$.

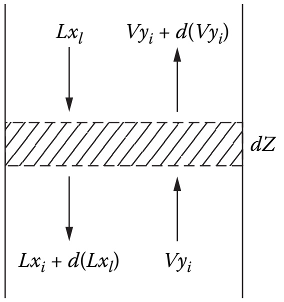

FIGURE 12.57 Flows in a differential section of a countercurrent contactor.

Equation (12.69) may be rearranged and the *overall transfer unit* defined as follows:

$$\frac{dy_i}{y_i - y_i^*} = \frac{K_{og} a_i dZ}{V} = \frac{1}{H_{og}} dZ \tag{12.70}$$

Thus, the overall transfer unit $H_{og} = V/(K_{og}a_i)$ is defined, where a_i is the effective interfacial area on a volumetric basis, e.g., $a_i = m^2/m^3$ transfer volume. [The symbol H_{og} is often reported as $(HTU)_{og}$)]. Integration of Equation (12.70) yields a convenient design relationship:

$$\int_1^2 \frac{K_{og} a_i dZ}{V} = \int_1^2 \frac{1}{H_{og}} = \int_1^2 \frac{1}{y_i - y_i^*} = N_{og} \tag{12.71}$$

where N_{og} is the *number of overall transfer units* based on vapor concentrations. Equation (12.71) is normally used in connection with counterflow packed columns [Equation (12.67)] but is also the basis for mass transfer calculations for tray columns. N_{og} is related to theoretical stages, and H_{og} is an efficiency term based on the intensity of phase contacting, in turn related to the geometry of the contacting device, the flow rates of the phases, and the diffusional properties in the vapor-liquid dispersion. For more details see Hines and Maddox.[67]

12.8.2 Tray Column Efficiency

The mass transfer efficiency of a tray is a crucial parameter in the design or analysis of a distillation column (as well as absorption and stripping columns). The actual trays (plates) are determined from theoretical stages using overall column efficiency as indicated by Equation (12.64) or (12.66). A more basic parameter is the *point efficiency, E_{og}*. This is the efficiency at a single point on the tray, and for uniform tray concentrations (liquid and vapor well mixed) equals the overall tray efficiency E_{MV} (often called the "Murphree efficiency"). When all the trays in the column are taken into account, the average of the E_{MV} values becomes the overall column efficiency E_{oc}, which can sometimes equal overall column efficiency E_{oc}, based on mass transfer fundamentals, with conversion to E_{oc} being largely a matter of geometry and hydraulics. It is not uncommon for E_{oc} to be 20% to 40% greater than E_{og} in larger columns. For smaller columns, $E_{oc} \rightarrow E_{og}$.

12.8.2.1 Regimes on Trays

The manner by which liquid and vapor contact each other on a tray determines the vapor-liquid interfacial area for mass transfer. The character of the vapor-liquid dispersion is determined by the relative flow rates and properties of the phases. These dispersions are conveniently described in terms of two-phase flow regimes. The *froth regime* is most commonly found; it is a liquid-continuous mixture containing a variety of bubble sizes that provide the necessary interfacial area. The vapor bubbles circulate rapidly, undergo coalescence and breakup, and have a wide range of nonuniform shapes and sizes. For unusually high flow ratios of liquid to vapor, a free-bubbling or *emulsified regime* occurs, characterized as a simple extension of the froth regime, liquid-continuous bubbling with decreased mixing energy. For unusually high ratios of vapor to liquid, the dispersion is inverted to a vapor-continuous mixture, called the *spray regime*. Here, the liquid entering from the downcomer is atomized by the high energy of the vapor, with coalescence and recirculation feeding the atomization process across the tray.

These regimes appear to be an approximate function of the dimensionless *flow parameter,* introduced earlier in connection with tray and packed column hydraulics:

$$F_{lv} = \left(\frac{L}{G}\right)\left(\frac{\rho_G}{\rho_L}\right)^{1/2} \tag{12.72}$$

This parameter represents a ratio of liquid-to-vapor kinetic energies, and approximate ranges for the regimes are

$F_{lv} < 0.01$ spray (vapor continuous)

$0.01 < F_{lv} < 0.10$ froth (liquid continuous)

$F_{lv} > 0.10$ emulsion or free bubbling

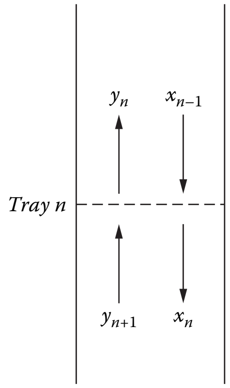
The transition between spray and froth regimes is usually detected by light-scattering techniques. Mass transfer models discussed later are based on the froth regime, the one that normally prevails.

12.8.2.2 Tray Efficiency Definitions

The mass transfer efficiency of contacting trays is often expressed in several ways, but here only two efficiencies will be used: point efficiency and tray efficiency. The former deals with the approach to equilibrium at some point on the tray and cannot be greater than 1.0 (100%). Clearly, the equilibrium can vary across the tray as liquid composition varies; thus, there are a number of different values of point efficiency when the tray liquid is not completely mixed (the normal case).

The overall tray efficiency E_{MV} (often called "Murphree efficiency") takes into account concentration gradients on the tray. It has an arbitrary definition based on the average total vapor composition leaving the froth and the specific liquid composition *leaving* the tray [not the *average* composition on the tray (see Figure 12.58)]. Because of this arbitrariness, the overall tray efficiency value can exceed 1.0. When there are no composition gradients on the tray, $E_{og} = E_{MV}$.

The point efficiency is a fundamental criterion of mass transfer, whereas the overall tray efficiency is the value that can be measured, especially for larger distillation columns. Large-column



$$E_{mv} = \frac{y_n - y_{n+1}}{y^*_n - y_{n+1}} = \frac{y_n - y_{n+1}}{Kx_n - y_{n+1}}$$

Notes: y_n and y_{n+1} are Averaged Over the Cross Section

x_n Is Overflow Composition Only (which can differ from averaged x_n)

FIGURE 12.58 Compositions leading to the definition of overall tray efficiency, E_{MV}.

efficiency must take both of these efficiencies into account, and the analysis can be divided into two parts:

- Understanding basic mechanisms associated with point efficiency
- Determining the concentration gradients across the tray

12.8.2.3 Point Efficiency

The point efficiency of tray n is expressed by

$$E_{OG} = \left(\frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \right)_{point} \tag{12.73}$$

The efficiency concept is based on two-resistance theory and is usually expressed in terms of the molar rate of diffusion:

$$N = k_G a_i (y_i - y) = k_L a_i (x - x_i) \tag{12.74}$$

Assuming phase equilibrium at the interface, the overall mass transfer coefficient can be obtained as the sum of mass transfer resistances:

$$\frac{1}{K_{OG}} = \frac{1}{k_G} + \frac{m}{k_L} \tag{12.75}$$

(overall resistance = vapor resistance + liquid resistance)

For distillations, the vapor resistance dominates, whereas for the stripping or absorption of slightly soluble materials, the liquid resistance dominates. In Equation (12.75), m is related to the VLE ratio K_i [Equation (12.19)], and for the binary distillation of an i-j mixture is defined as the slope of the equilibrium line on a y-x diagram:

$$m = \frac{dy_i}{dx_i} = \frac{\alpha_{ij}}{\left[1 + \left(\alpha_{ij} - 1\right) x_i\right]^2} \tag{12.76}$$

For low values of x_i and high values of α_{ij}, the slope is relatively high and the more important the second term on the right side of Equation (12.75) becomes, meaning that the liquid side resistance becomes more important.

Considering a mass balance across a differential element in the froth of a sieve tray (Figure 12.57), the expressions for the vapor and liquid phase mass transfer units are

$$N_G = k_G a_i' t_G \tag{12.77}$$

and

$$N_L = k_L a_i' t_L \tag{12.78}$$

Volumetric coefficients $k_G a_i'$ and $k_L a_i'$ are used when the interfacial area a_i cannot be determined, and residence times tG and tL depend on the nature and volume of the dispersion as well as the

velocity of the gas. The number of overall transfer units [Equation (12.71)], based on gas concentrations, follows from the individual phase units:

$$\frac{1}{N_{OG}} = \frac{1}{N_G} + \frac{\lambda}{N_L} \tag{12.79}$$

where λ is the ratio of slopes, equilibrium line to operating line:

$$\lambda = \frac{m}{L/V} = \frac{mV}{L} \tag{12.80}$$

Thus, a continuous contacting approach (use of transfer units) is employed. The point efficiency is computed from the value of N_{OG}:

$$E_{OG} = 1 - \exp\left[-N_{OG}\right] \tag{12.81}$$

12.8.2.4 Tray (Murphree) Efficiency

For complete mixing, $E_{MV} = E_{og}$. For the *plug flow* of liquid,

$$E_{MV} = \frac{1}{\lambda}\left(\exp\left[\lambda E_{og} - 1\right]\right) \tag{12.82}$$

The point and overall efficiencies are the same when the phases in the froth are completely mixed. This is more likely for small columns and for very high gas-to-liquid ratios for larger columns. When the liquid is in plug flow, $E_{MV} > E_{og}$. To deduce point efficiency values from measured overall efficiency values, a model involving mixing tendencies must be available, as discussed later.

12.8.2.5 Overall Column Efficiency E_{oc}

This is the efficiency most used and understood [see Equation (12.66)]. At total reflux, E_{OC} and E_{MV} are about equal. Otherwise,

$$E_{oc} = \frac{\ln\left[1 + E_{MV}\left(\lambda - 1\right)\right]}{\ln\lambda} \tag{12.83}$$

or

$$E_{MV} = \frac{\left(\lambda^{E_{oc}} - 1\right)}{\left(\lambda - 1\right)} \tag{12.83a}$$

where λ is defined by Equation (12.80).

The relationships between these efficiencies are shown in Figure 12.59. For design, the sequence is

$$E_{og} \rightarrow E_{MV} \rightarrow E_{oc}$$

with the reverse applying to the analysis of existing columns.

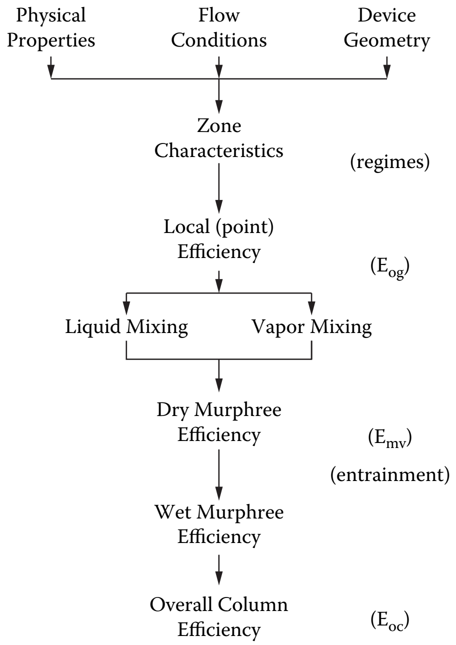


FIGURE 12.59 Relationships between the different efficiencies.

12.8.2.5 Predicting Tray Efficiency

The efficiency of a tray or packed column is a function of the effectiveness of mass transfer between the phases, i.e., *mass transfer efficiency*. This efficiency depends on three sets of design parameters:

- The system: composition and properties
- Flow conditions: rates of throughput
- Geometry/type of contacting device

The column designer has little control over the first set. The system may have inherently low mass transfer capability, e.g., low diffusion coefficients or high liquid viscosities (high Schmidt numbers). Conversely, the system may have such favorable mass transfer characteristics that almost any device chosen will be satisfactory. Clearly, for new designs, one may not know quite what to expect in terms of mass transfer favorability.

Four methods for predicting the efficiency of a commercial fractionator are

- Comparison with performance data for a *very similar* installation
- Use of an empirical or statistical efficiency prediction method
- Direct scaleup from carefully designed laboratory or pilot plant experiments
- Use of theoretical or semitheoretical mass transfer models

Often, more than one approach likely is used. For example, available data from a similar installation may be used for orientation, and a theoretical model then used to extrapolate to the new conditions. Each approach is covered in the material below, with less emphasis on the fourth (modeling) approach.

12.8.2.6 Efficiency from Performance Data

If an existing fractionation system is to be duplicated, careful measurements on the existing system can provide sufficient data for a confident design. For a new system, are the physical properties

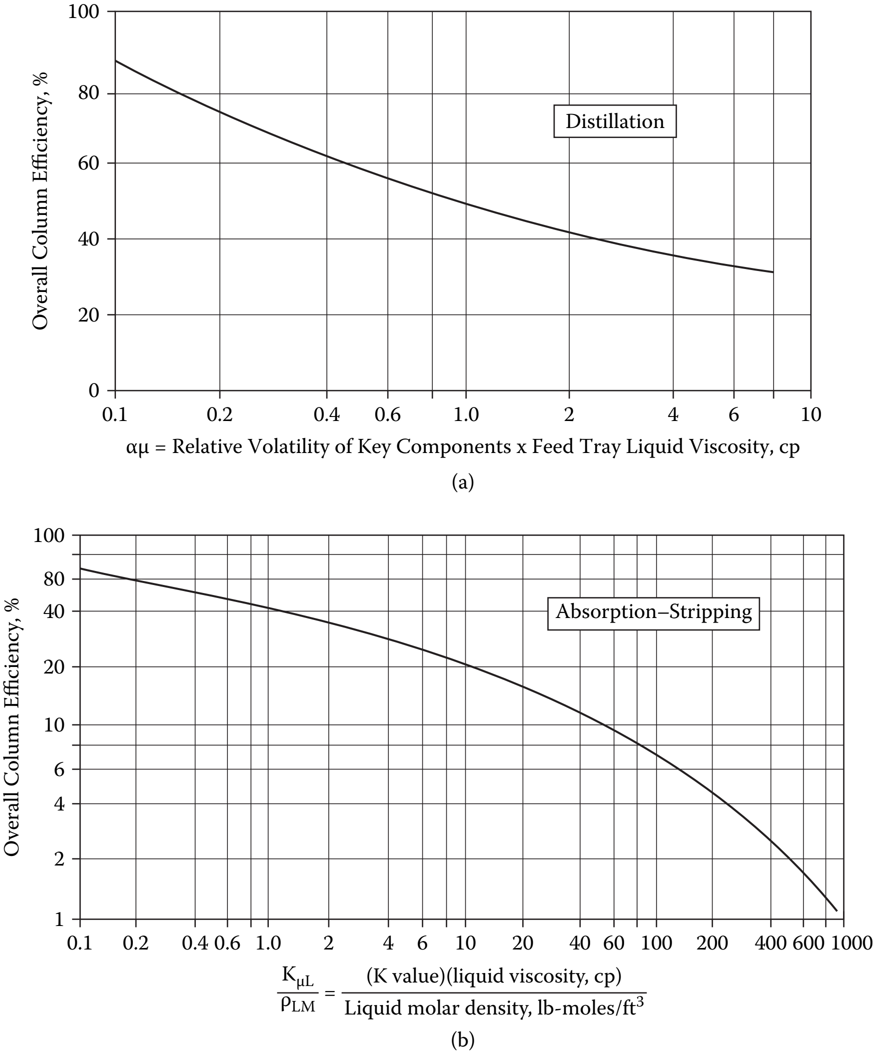

FIGURE 12.60 O'Connell method for estimating overall column efficiencies of distillation columns and absorbers. (H. E. O'Connell, 1946. *Trans AIChE* 42: 741.)

different? Is the loading about the same as for the existing system? Is the same contacting device to be used? Clearly, caution is needed, but it is the best basis to use. Those with access to Fractionation Research, Inc. (FRI) data can benefit from this approach if the system at hand is similar to a system studied by FRI. However, the same questions must be asked.

12.8.2.7 Empirical Efficiency Methods

The best known and most used empirical method is that of O'Connell[68] (Figure 12.60), for distillation columns and absorbers. The curves are based on plant data for several bubble-cap columns plus a few pilot-scale units. Efficiency is related to two properties of the feed mixture: liquid viscosity μ_L and relative volatility α. Higher values of the $\mu_L\alpha$ product indicate larger liquid-side mass transfer resistance and hence a lower efficiency. For a vapor feed or a mixed vapor-liquid feed, the correlating viscosity should be that of the feed tray liquid.

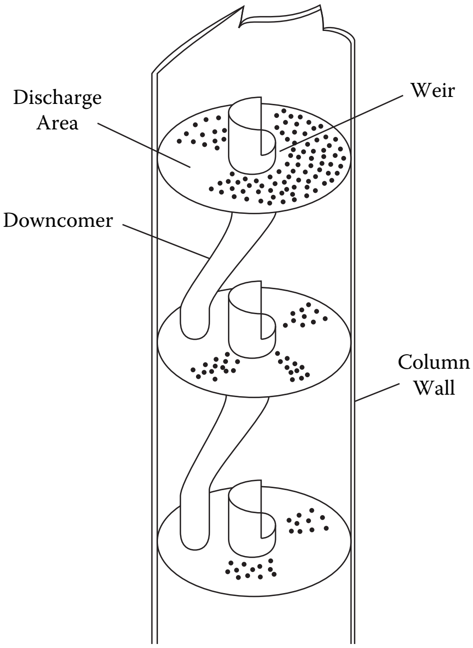

FIGURE 12.61 Diagram of a section of an Oldershaw column.

Such simplified correlations should be used with great discretion but may suffice for preliminary designs, e.g., to support technical feasibility and early economic studies of new or modified processes. In the related areas of absorption or stripping, the liquid phase resistances are higher than for distillation, and the separate correlation of Figure 12.60 for absorbers has been adapted from the O'Connell work. An example is the absorption or stripping of a sparingly soluble gas. The low solubility can result in a high value of the equilibrium ratio K (e.g., in the range of 2400 for toluene in water). The resulting abscissa value for Figure 12.60 gives a very low overall column efficiency.

12.8.2.8 Efficiency from Laboratory Experiments

Large-scale tray column efficiencies can be predicted from measurements in laboratory columns as small as 25 mm (1.0 in) diameter. Comparative studies (laboratory vs. commercial) have shown that the use of a special laboratory sieve tray column, the Oldershaw column, produces equivalent separations.[69] A glass Oldershaw column is shown in Figure 12.61. Each tray has a center downcomer that discharges to one side of the tray below. Comparisons between laboratory and commercial scale efficiencies are shown in Figure 12.62[70] and Table 12.11. The Oldershaw value of overall efficiency E_{oc} is equivalent to the point efficiency E_{og} of the larger column.

The procedure for using this scaleup approach is summarized as follows:

1. Arbitrarily select a number of Oldershaw trays and set up the equipment to operate either at total or at finite reflux, as the situation demands. Oldershaws are generic, off-the-shelf units with varying numbers of trays and can be assembled rapidly.
2. Determine the upper operating limit (flood limit) of the equipment by experiment or by general correlation. Then collect data at some selected approach to flood.
3. Obtain overhead and bottoms samples and determine the degree of separation.
4. If the separation is satisfactory, the commercial column will require the same or fewer trays than the Oldershaw trays used. Comparisons are made at the same approach to flood for both columns.

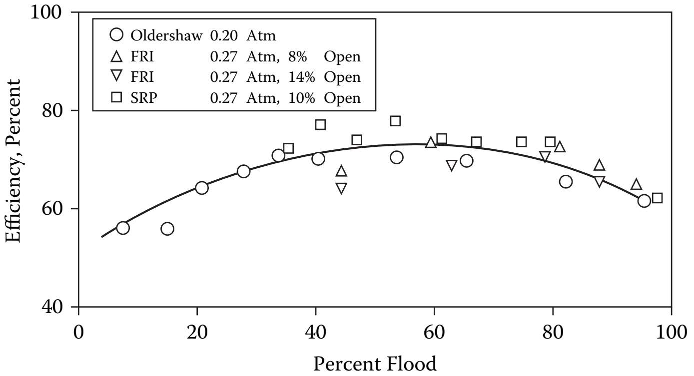

FIGURE 12.62 Comparison of tray point efficiencies for different column sizes. Cyclohexane/*n*-heptane system, 0.20–0.27 atm pressure, total reflux. (Separations Research Program, Univ. of Texas at Austin.)

TABLE 12.11
Conditions for Efficiency Comparisons in Figure 12.62

	Oldershaw[1]	SRP[2]	FRI-1[3]	FRI-2[4]
Head pressure, atm	0.20	0.27	0.27	0.27
Column diameter, m	0.025	0.43	1.2	1.2
Tray spacing, m	0.025	0.46	0.61	0.61
Tray open area, % of active area	10.0	8.7	8.0	14.0
Weir height, mm	51	51	51	
Hole diameter, mm	0.89	4.8	12.7	12.7
Downcomer area, % of total area	8.2	7.2		

Notes: All runs with cyclohexane/n-heptane mixture at total reflux. The SRP column contained a splash baffle. FRI efficiencies are corrected from overall column to point.

12.8.2.9 Efficiency from Mass Transfer Models

The above relationships, coupled with experimental efficiency results, provide a semifundamental approach to modeling tray efficiency. Since the contacting process is not well understood, only an approximation of the efficiency can be expected. However, the application of mass transfer principles can aid the overall process of design by showing relative effects of variables.

The AIChE efficiency model[71] was the first to use a rational approach to mass transfer efficiency. Equations (12.74) through (12.83) are used to predict point efficiency. The values of $k_G a_i'$, $k_L a_i'$, t_G, and t_L are deduced from laboratory measurements with small test trays containing bubble caps. No attempt is made to evaluate interfacial area a_i'. The detailed procedure is in reference 71.

An adaptation of the AIChE model was published by Chan and Fair,[72] is specific to sieve trays, and is based on larger-scale sieve tray measurements. For the vapor phase,

$$k_G\, a_i = \frac{316\, D_G^{0.5}\left(1030\, f - 867\, f^2\right)}{h_L^{0.5}} \tag{12.84}$$

where

D_G = vapor phase diffusion coefficient, m²/s
h_L = liquid holdup, mm [obtain from Equation (12.67)]
f = fractional approach to flood, i.e., $C_{sb}/C_{sb,flood}$ (from Figure 12.30)
$k_G a_i$ = volumetric mass transfer coefficient for the vapor phase, sec^{-1}

The number of vapor phase transfer units is obtained from Equation (12.74), where the residence time t_G is based on the volume of gas flowing through the two-phase mixture on the tray.

The volume of the froth is based on the base (A_a) times the height (Z_f). Estimates of Z_f can be made from Figure 12.63, from which

$$t_G = \frac{\text{vol. of vapor space in froth}}{\text{volumetric flow of vapor}} = \frac{A_a \varepsilon Z_f}{Q_v} = \frac{\varepsilon Z_f}{U_a} \tag{12.85}$$

where

Z_f = height of froth
ε = void fraction of froth = $1 - h_L/Z_f$

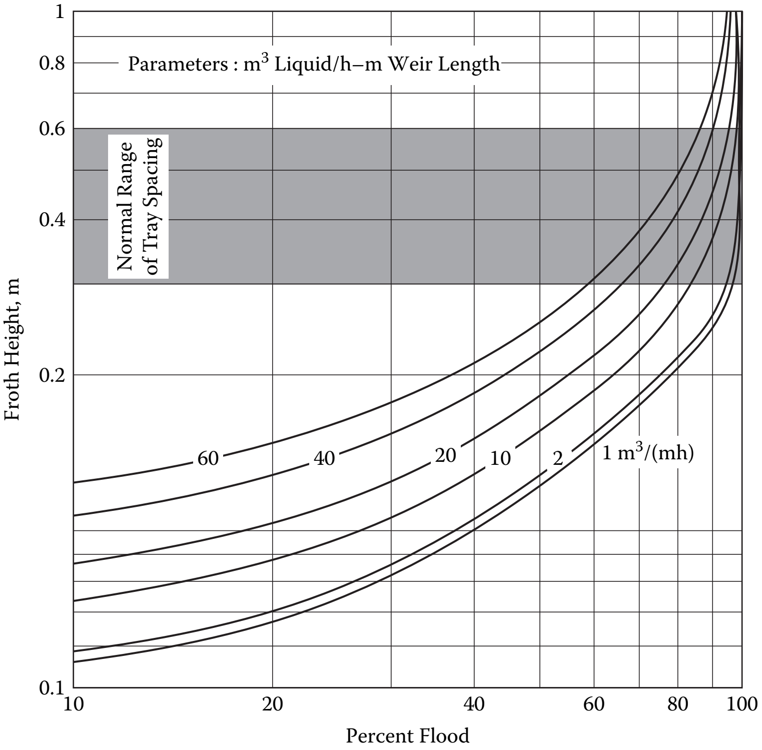

FIGURE 12.63 Estimation of froth height on a tray. (J. Stichlmair, J. R. Fair, 1998. *Distillation—Principles and Practices,* New York: Wiley-VCH.)

However, the volume $A_a Z_f$ is not all effective for mass transfer; its upper zone provides relatively little area for mass transfer. Accordingly, some effective value of Z_f applies. Because this value is not easily determined, an alternative approach to estimating vapor residence time is used:

$$t_G = \frac{(1-\phi_{ef})h_L}{\phi_{fe} U_a} \quad (h_L \text{ in m}) \tag{12.86}$$

where an *effective froth density* ϕ_{fe} [see Equation (12.63)] is used, based on the work of Bennett et al.,[73] who provided the basis for estimating ϕ_{fe}:

$$\phi_{fe} = \exp\left[-12.55\left(C'_{sb}\right)^{0.91}\right] \tag{12.87}$$

with C_{sb}' based on the active area (rather than the net area), in m/s.

The number of liquid phase transfers is obtained from Equation (12.78), with the volumetric coefficient for *sieve trays*:

$$k_L a_i = (3.88 \cdot 10^8 D_L)(0.40 F_{va} + 0.17), \text{ sec}^{-1} \tag{12.88}$$

The residence time t_L is based on the volume of liquid flowing through the two-phase mixture on the tray:

$$t_L = \frac{\text{volume of liquid space in froth}}{\text{volumetric flow of liquid}} = \frac{A_a(1-\varepsilon)Z_f}{q_L} \tag{12.89}$$

which is also modified to eliminate the term Z_f:

$$t_L = \frac{h_L A_a}{q_L} \tag{12.90}$$

which implies that $Z_{f'} = h_L/\phi_{fe}$.

With a more mechanistic model for predicting tray point efficiency, Garcia and Fair[74] showed a better fit to a large database than did the older Chan–Fair model. A parity plot for the Garcia–Fair work is given in Figure 12.64. The newer method is more complex, however, and requires a fairly elaborate computer program.

12.8.2.10 Conversion of Point Efficiency to Tray Efficiency

The assumption of complete mixing on the tray leads to a conservative prediction of tray efficiency, i.e., E_{og} is assumed equal to E_{MV}, as discussed earlier. The other limiting case is where the liquid moves across the tray in pure plug flow and is represented by Equation (12.82). The partial mixing case between these two limits can be handled by available models, and the paper by Bennett and Grimm[75] provides predictive models based on diffusional-type backmixing of the liquid.

12.8.2.11 Entrainment Effects on Efficiency

The performance curve of a crossflow tray shows a lowering of efficiency as vapor velocity approaches a flooding value (Figure 12.27). This lowering results from liquid entrainment. Figure

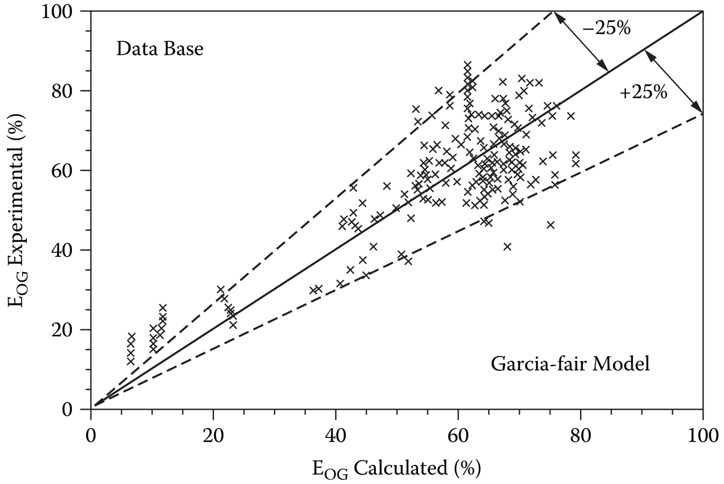

FIGURE 12.64 Parity plot for Garcia–Fair efficiency prediction method. (2002. *Ind. Eng. Chem. Res.* 41: 1632.)

12.33 is used to determine the entrainment ratio ψ. Then, an expression based on early work of Colburn[76] is used to correct the "dry" tray efficiency E_{MV} for entrainment:

$$\frac{E_{MV,wet}}{E_{MV,dry}} = \frac{1}{1 + E_{MV,dry}\left[\psi/(1-\psi)\right]} \tag{12.91}$$

Problem 12.9

Problem 12.6 deals with the dimensioning of a large ethylbenzene/styrene tray-type fractionator. The overall column efficiency for the sieve trays is to be estimated, based on the same conditions given for Problem 12.6. Two methods will be used: (a) the O'Connell (Figure 12.60) approximate method and (b) the Chan/Fair more basic method [Equation (12.84)], corrected for entrainment and liquid crossflow effects.

Solutions

(a) The O'Connell method requires values of relative volatility and liquid viscosity. These values are 1.40 and 0.38 cP, respectively. For the product $\alpha\mu$ = 1.40 (0.38) = 0.53, the efficiency is read from Figure 12.60 as E_{oc} = 0.56 or 56%.

(b) The point efficiency model of Chan and Fair requires values of the phase diffusion coefficients. These are estimated to be:

$D_G = 2.09(10^{-5})\ \text{m}^2/\text{s} = 0.209\ \text{cm}^2/\text{s}$

$D_L = 3.74(10^{-9})\ \text{m}^2/\text{s} = 3.74(10^{-5})\ \text{cm}^2/\text{s}$

Vapor transfer units:

By Equation (12.84),

$$k_G\, a_i = \frac{316\left[2.09(10^{-5})\right]^{0.5}\left[1030(0.8) - 867(0.64)\right]}{(24.4)^{0.5}} = 78.7\ \text{sec}^{-1}$$

For $C_{sb}' = C_{sb}(A_n/A_a) = 0.098(8.40/7.98) = 0.10$ m/s, and by Equation (12.87),

$$\phi_{fe} = \exp[-12.55(0.10)^{0.91}] = 0.21$$

$$t_G = [(1 - 0.21)0.0244]/[(0.21)(4.14)] = 0.022 \text{ sec [Equation (12.86)]}$$

From Equation (12.77), $N_G = 78.7(0.022) = 1.75$ transfer units.

By Equation (12.88), $k_L a_i = 3.88(10^8)(3.74)(10^{-9})[0.40(2.87) + 0.17] = 1.91 \text{ sec}^{-1}$.

By Equation (12.90), $t_L = 0.024(7.98)/0.01162) = 16.5$ sec.

From which $N_L = 1.91(16.5) = 31.5$ transfer units.

The ratio of slopes, equilibrium/operating, will be taken for the rectifying section where slope $m = 1.005$. Then, $\lambda = m/(L/V) = 1.005/(1028/1200) = 1.17$.

Overall transfer units are calculated from Equation (12.79), combining N_G, N_L, and λ; $N_{OG} = 1.64$.

Finally, the point efficiency is calculated from Equation (12.81), $E_{OG} = 0.81$ (81%).

Notes:

- The point efficiency may be enhanced by liquid crossflow effects and/or diminished by entrainment effects.
- The calculated efficiency is significantly greater than the estimate from the O'Connell method.

Commercial ethylbenzene/styrene fractionators show efficiencies in the range of 80 to 90%.

12.8.2.12 Overall Column Efficiency

As indicated by Figure 12.59, the final step is to convert E_{MV} (wet or dry) to the overall column efficiency E_{oc}. This is done using the Lewis[77] relationships:

$$E_{oc} = \frac{\ln\left[1 + E_{MV}(\lambda - 1)\right]}{\ln \lambda} \tag{12.92}$$

$$E_{MV} = \frac{\lambda^{E_{oc}} - 1}{\lambda - 1} \tag{12.93}$$

12.8.2.13 Multicomponent Systems

For binary systems, the efficiency for each component is the same and thus

$$\left(E_{og}\right)_i = \left(E_{og}\right)_j = (E_{og})_{i-j} \tag{12.94}$$

When more than two components are present, the efficiencies of each are not necessarily the same. The rigorous approach to handling multicomponent mixtures, outlined by Taylor and Krishna,[78] uses the Maxwell–Stefan diffusional equations. Chan and Fair[72] used the rigorous approach to compare multicomponent system separations with those predicted by the use of the equivalent pseudobinary systems. They found that if the dominant pair of components present in the mixture is used to determine efficiency for all of the components, the separation determined is quite close to that resulting from rigorous multicomponent procedures.

General rules proposed by Toor and Burchard[79] for multicomponent systems are summarized as follows:

1. When all binary pair efficiencies are high, the multicomponent efficiencies are also high.
2. As the fraction of the total resistance in the liquid phase increases, differences between the component efficiencies diminish.
3. When vapor phase resistance dominates, differences between component efficiencies increase as differences between the binary pair diffusion coefficients increase. If all the vapor diffusion coefficients are equal, indicating minimum liquid-side interaction, all component efficiencies are equal.
4. In a ternary system where there are two similar and one dissimilar species, the dissimilar one will have an efficiency close to the binary value, and the efficiencies of the similar species will differ from each other and from the binary value.
5. The efficiencies of one or more minor components may differ from the binary value (assuming only two major components), but the efficiencies of the major components will approach each other (and the binary value).

12.8.3 Packed Column Efficiency

Packed columns operate in the counterflow mode, and thus it is not really appropriate to utilize stagewise concepts for their analysis and design. Despite this, the HETP approach [Equation (12.69)] is often used. With this approach, the height of packing needed to effect a given separation is simply,

$$Z = (HETP)(N_t) \tag{12.95}$$

Thus, if theoretical stages are computed by one of the methods described earlier, it is only necessary to multiply by some "characteristic value" of the packing, the HETP, to arrive at the required height. This approach is often used in practice, with the packing vendor supplying values of HETP. The problem is that the vendor may not take into account the basic requirements of determining efficiency, as stated earlier for trays:

- The system: composition and properties
- Flow conditions: degree of loading
- Geometry: type and size of packing

A more rigorous—and generally more useful—approach is to utilize transfer units as introduced earlier by Equations (12.69) through (12.71), in which the required height is a product of the height of a transfer unit and the number of transfer units:

$$Z = (H_v)(N_v) = (H_L)(N_L) = (H_{ov})(N_{ov}) \tag{12.96}$$

The transfer unit approach permits consideration of varying vapor and liquid flows, varying properties, and differences in packing geometry. However, computation of transfer units, especially for multicomponent systems, is not straightforward. Instead, a "hybrid" approach can be used:

$$N_{ov} = N_t \left[\frac{\ln \lambda}{(\lambda - 1)} \right] \tag{12.97}$$

where, as before,

$$\lambda = {}^{m}\!/_{L/V}$$

Equation (12.97) is strictly valid when the operating and equilibrium lines are straight. When the lines have equal slope, $N_{ov} = N_t$. The equation may be applied by dividing the column into sections where the equilibrium line can be considered straight.

For distillation,* the height of a transfer unit is defined as

$$H_{og} = \frac{V}{K_{og}a_i} \quad H_v = \frac{V}{k_g a_i} \quad H_L = \frac{L}{k_L a_i} \tag{12.98}$$

These relationships apply when the driving force for mass transfer is expressed as mole fractions. The overall mass transfer coefficient K_{og} is normally used in connection with

$$K_{og} = \frac{1}{\dfrac{1}{k_g} + \dfrac{m}{k_L}} \tag{12.99}$$

In these expressions, k and K have units of kg-moles/(s-m^2-m.f.) or equivalent English units. Usually, the interfacial area a_i is not known and is not segregated from the mass transfer coefficient, giving volumetric coefficients $K_{og}a_i$, $k_g a_i$, and $k_L a_I$. These terms may be substituted in Equation (12.98).

The overall transfer unit height may be broken down into individual phase terms:

$$H_{oG} = \frac{V}{k_G a_i} + \lambda \frac{L}{k_L a_i} \tag{12.100}$$

or

$$H_{oG} = H_G + \lambda H_L \tag{12.100a}$$

from which

$$HETP = H_{OG}\,[\ln \lambda/(\lambda - 1)] \tag{12.100b}$$

12.8.3.1 Random Packings

Several methods have been proposed for predicting values of H_v and H_L as functions of system, flow conditions, and packing type.[80–83] The model of Wagner et al.[82] is directed specifically to the newer, open-style random packings. The Bolles–Fair[83] model has the broadest validation and will be used here and is summarized by the following equations:

$$H_G = \frac{\psi' Sc_G^{0.5} \left(Z_p / 3.05 \right)^{1/3} \left(3.28\, D_c \right)^{n_1}}{3.28 \left(735\, L' \Gamma \right)^{n_1}} \tag{12.101}$$

$$H_L = 0.305\, \phi' C_F \left(Z_p / 3.05 \right)^{0.15} Sc_L^{0.5} \tag{12.102}$$

* For absorption and stripping, the equations are slightly different, in particular if concentrated solutions are being considered. See a mass transfer text, e.g., Hines and Maddox,[67] for a detailed discussion.

where

$$\Gamma = \left(\mu_L / \mu_W\right)^{0.16} \left(\rho_W / \rho_L\right)^{0.16} \left(\sigma_W / \sigma\right)^{0.8} \tag{12.103}$$

and

$$Z_p = \text{bed height, m}$$

Values of exponent n_1 are 1.24 and 1.11 for ring-type and saddle-type packings, respectively. Values of exponent m_1 are 0.6 and 0.5 for ring-type and saddle-type packings. Parameter C_F accounts for enhancement of interfacial area near the flood point; suitable values are

50% flood......1.00
60% flood......0.90
80% flood......0.60

The D_c term (tower diameter) has an upper limit correction *if* there is very good liquid distribution. The upper limit is for D_c = 0.61 m (2.0 ft); for larger diameters, use the correction for 0.61 m. The height correction Z_p applies to each bed in a multibed column and is normalized to a bed height of 3.05 m (10 ft).

For values of parameters ψ' and ϕ', see Figure 12.65. Berl saddle parameters are applicable to ceramic Intalox saddles—but not to metal Intalox saddles, which have a quite different geometry and are of the "through-flow" type covered by Wagner et al.[82]

The smallest size packings in the Bolles–Fair correlation are nominally 13 mm. If the usually required minimum ratio of column diameter to packing diameter of 8 is to be retained (to avoid bypassing at the wall), scaleup studies require a minimum column diameter of about 100 mm. Research in progress may lead to the use of a special, small laboratory packing (e.g., Pro-Pak®, from Scientific Development Co.) for columns as small as 25 mm. *HETP* values of two sizes of Pro-Pak, for cyclohexane/*n*-heptane at 1.0 atm, are shown in Figure 12.66, from reference 84.

12.8.3.2 Structured Packings

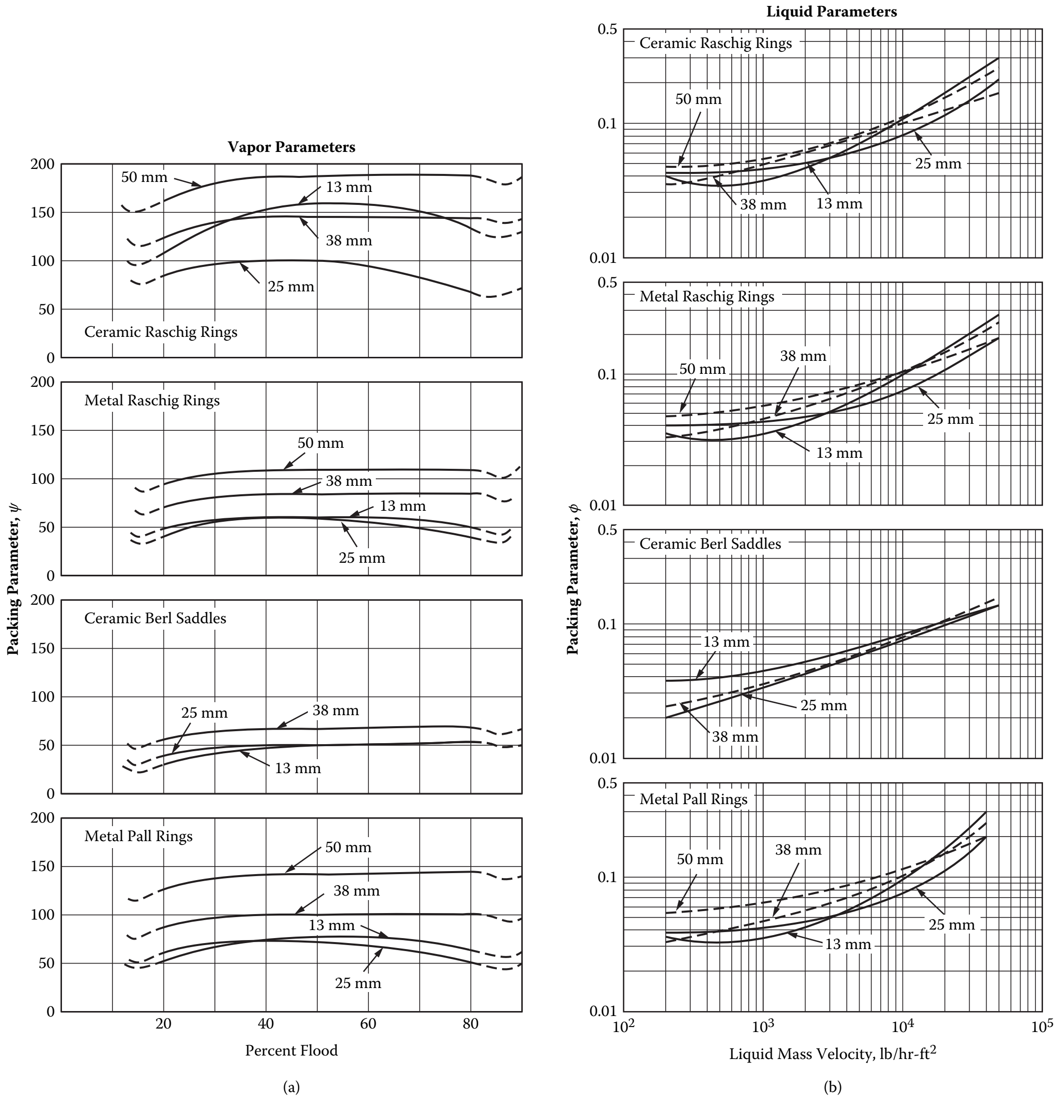
Packings of this type have been described above. Vapor and liquid contact each other in channels that have the general characteristics of wetted wall columns. The design efficiency of these packings may be characterized by *HETP* values obtained experimentally. But the performance data should be based on the same or similar system at the same degree of loading. An approximate method for estimating *HETP* is that of Lockett[85] and derives from a parametric study of a more rigorous model of Bravo and coworkers, to be described later. At total reflux and $\lambda = m/(L/V) = 1.0$,

$$HETP = A_1 + B_1\,(F_{vs,80}) \tag{12.104}$$

where $F_{vs,80} = U_{vs}\rho_g$ = superficial F-factor at 80% of flood.

The constants for Equation (12.107) are

	A_1	B_1	a_p, m²/m³
Flexipac 1	0.018	0.106	443
Flexipac 2	0.023	0.156	223
Flexipac 3	0.061	0.235	111



Note: to Convert from lb/hr-ft^2 to kg/s-m^2, multiply by 0.00136.

FIGURE 12.65 Packing parameters for random packing efficiency. (Bolles, W. L.; Fair, J. R. *Chem. Eng.* 1982, 89 (14) 109.

and *HETP* is in meters. The restriction of $\lambda = 1.0$ is not overly important, since many distillation columns have an average λ close to unity. Packings other than those listed may be used on an equivalent surface basis. Lockett suggests another useful approximation,

$$HETP = \frac{2450 F_{vs,80}}{a_p^{0.5}} \tag{12.105}$$

that allows the use of whatever packing surface is to be specified (Table 12.10). Equations (12.104) and (12.105) require a value of the flooding velocity, obtainable from the vendor or from the generalized methods given earlier.

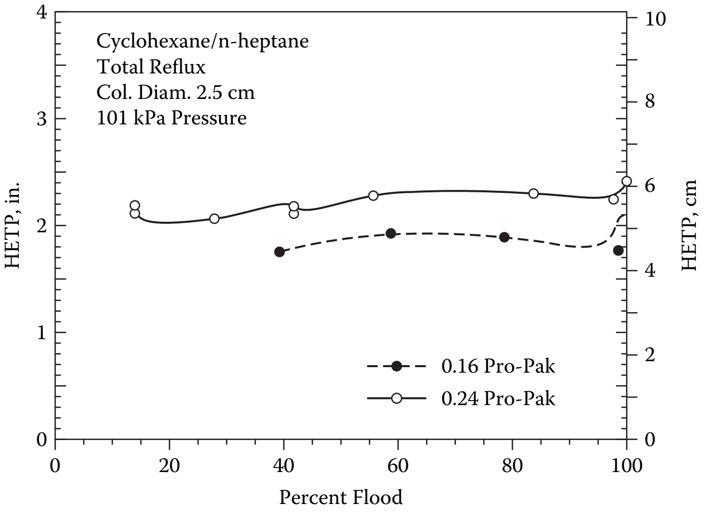


FIGURE 12.66 Efficiency of laboratory random packing, cyclohexane/*n*-heptane system. (Separation Research Program, Univ. of Texas at Austin.)

12.8.3.3 Mechanistic Model for Structured Packings

The first mechanistic and fundamental mass transfer model for structured packings was proposed by Bravo et al.[86] This model is based on a variety of test data obtained for Sulzer BX gauze-type packing. This packing has flow channels triangular in cross section and the total flow path is zigzag as individual elements are passed. Although somewhat oversimplified, because of cross-mixing opportunities, this model forms a reasonable basis for predicting rates of mass transfer between bulk vapor and liquid flowing over the metal surfaces.

Problem 12.10

To continue with the ethylbenzene/styrene separation of the immediately previous problems, now consider the use of a random packing for the fractionator. In Problem 12.8, for 50-mm metal Pall rings, a column diameter of 3.21 m (10.5 ft) would be required to operate at 80% of flood. Now estimate the efficiency of this same packing for the same service. The basic data are given in Problems 12.6 through 12.9. A packed height of 6.0 m will be assumed.

The model of Bolles and Fair [Equations (12.104) through (12.106)] is appropriate. Input data for the model are as follows:

Liquid Schmidt number = 122
Vapor Schmidt number = 0.80 (viscosity of the vapor = 0.008 cP)
Slope of equilibrium line, m = 1.005
Stripping factor $\lambda = m/(L/V) = 1.17$

For 3.2-m column diameter and 13.61 kg/s liquid flow, $L' = 1.69$ kg/s-m^2.

The correction for departure from water properties $\Gamma = (0.37/0.38)(61/52.2)(62/25) = 2.50$.

Finally, the packing parameters for 50-mm Pall rings: $\psi' = 140$, $\phi' = 0.065$ (Figure 12.65).

Substituting in Equation (12.104),

$$H_G = \frac{140(0.80)^{0.5}(6.0/3.05)^{1/3}(3.28(0.61))^{1.24}}{3.28[735(1.69)(2.50)]^{0.6}} = 0.91\,\text{m}$$

For the liquid side [Equation (12.105)],

$$H_L = 0.305(0.065)(0.60)(6.0/3.05)^{0.15}\ (122)^{0.5} = 0.15\ \text{m}$$

The height of an overall transfer unit is obtained from Equation (12.100a):

$$H_{oG} = H_G + \lambda H_L = 0.91 + 1.17(0.15) = 1.09\ \text{m}$$

This value can be converted to HETP for the case of $\lambda = 1.17$, by Equation (12.100b):

$$HETP = H_{OG}\ [\ln 1.17/(1.17 - 1)] = 1.09\ [0.157/0.17] = 1.01\ \text{m (3.30 ft)}$$

Bravo et al. found that earlier data by Gilliland and Sherwood[87] and Johnstone and Pigford,[88] for countercurrent flow in vertical, round wetted-wall columns, agreed well with the results from structured packing experiments. The agreement confirmed that the gauze surface is essentially completely wetted, enabling the interfacial area to be equated to the specific surface area of the packing. The final model for the gas phase mass transfer coefficient is

$$Shv = 0.0338(Re_v)0.8(Sc_v)^{0.333} \tag{12.106}$$

where

Sh_v = Sherwood number = $(k_v d_{eq}/D_v)$ (12.107)
Re_g = Reynolds number = $(d_{eq}\rho_g/\mu_g)(U_{g,eff} + U_{L,eff})$ (12.108)
Sc_g = Schmidt number = $(\mu_g/\rho_v D_v)$ (12.109)

The effective gas and liquid rates, $U_{g,eff}$ and $U_{L,eff}$, take into account the flow angles, void fractions, and film thicknesses that derive from gross flow rates and packing geometry. The equivalent diameter basis is shown in Figure 12.48.

For the liquid phase, a penetration model is used, with the exposure time based on flow across the corrugation side of the packing. Thus,

$$k_L = 2\sqrt{\frac{D_L U_{L,eff}}{\pi S}} \tag{12.110}$$

where S is the length of a side of a corrugation.

Heights of transfer units for the individual phases are obtained from Equation (12.98), and Equation (12.100) provides the height of an overall transfer unit. For the gauze packings, with spreading aided by capillary action, interfacial area $a_i = a_p$ (specific surface area from Table 12.10). For sheet metal packings, which do not promote as much liquid spreading, an empirical correction factor was proposed by Fair and Bravo[89]:

$$a_i = \beta a_p \tag{12.111}$$

where the discount factor β is some function of liquid rate and surface wettability. For poorly wetted surfaces, where rivulet flow dominates, β is quite low—in the range of 0.1 to 0.3, even at high liquid rates. On the other hand, for well wetted surfaces, β can range up to 1.0 or higher, For very approximate estimates, the designer can use the relationship for well wetted metal surfaces:

$$\beta = 0.50 + 0.0058\ (\%\ \text{flood}) \tag{12.112}$$

for flooding percentages in the range of 0 to 85. Above 85% flood, $\beta = 1.0$. Once the value of H_{og} is determined, conversion to *HETP* for a given value of λ is

$$HETP = H_{og}[\ln \lambda/(\lambda - 1)] \tag{12.113}$$

with the same restrictions noted for Equation (12.95). When the operating and equilibrium lines are straight and parallel, $HETP = H_{og}$.

A more rigorous prediction of structured mass transfer efficiency is based on results from the University of Texas' Separations Research Program (SRP) and the Delft University of Technology, in the Netherlands. Models from these sources have been described and compared in a joint publication[90] and are essentially equivalent. The newer SRP model[91] follows that of Bravo et al.,[86] described above, and a brief summary of it follows.

The gas phase mass transfer coefficient is obtained through the Sherwood number, as in Equation (12.107):

$$Sh_v = \frac{k_v S}{D_v} = 0.54\left[\frac{\left(U_{g,eff} + U_{L,eff}\right)\rho_g S}{\mu_v}\right]^{0.8} Sc_v^{1/3} \tag{12.114}$$

The liquid phase mass transfer coefficient k_L is obtained from Equation (12.110). The effective interfacial area a_i is obtained from the rather complex relationship

$$\frac{a_i}{a_p} = F_{SE}\frac{29.12\left(We_L Fr_L\right)^{0.15} S^{0.359}}{\mathrm{Re}_L^{0.2}\,\varepsilon^{0.6}\left(1-0.93\cos\gamma\right)\left(\sin\theta\right)^{0.3}} \tag{12.115}$$

where

S = length of side of corrugation = equivalent diameter, m
F_{SE} = factor to account for surface texturing
θ = corrugation angle, measured from the horizontal, deg
γ = contact angle, liquid/surface, deg, estimated from $\cos\gamma = 5.211 \cdot 10^{-16.835\sigma}$
σ = surface tension, mN/m

The effective velocities of the phases are computed from

$$U_{g,eff} = \frac{U_{gs}}{\varepsilon\left(1-h_t\right)\sin\theta} \tag{12.116}$$

$$U_{L,eff} = \frac{U_{Ls}}{\varepsilon h_t \sin\theta} \tag{12.117}$$

where h_t is total liquid holdup, vol. liquid per vol. packed bed. Values of a_p, F_{SE}, ε, S, and θ for representative structured packings are given in Table 12.12.

12.8.3.4 Scale-Up of Structured Packing Efficiency

As noted earlier, test data from an Oldershaw column as small as 25 mm diameter can often be converted to commercial-scale designs. For random packings, a minimum test column diameter of 100 mm is recommended. For structured packings, a 25-mm column diameter can be used for

TABLE 12.12
Values of Parameters for Equations (12.114) through (12.117)

	a_p (m²/m³)	F_{SE} (–)	ε (–)	S (m)	θ (deg)
Flexipac 2	233	0.350	0.95	0.018	45
Gempak 2A	223	0.344	0.95	45	
Intalox 1T	315	0.415	0.95	0.0152	45
Intalox 2T	213	0.415	0.95	0.0221	45
Jaeger Maxpak	229	0.364	0.95	0.0175	45
Mellapak 250Y	250	0.350	0.95	45	
Mellapak 500Y	500	0.350	0.91	45	
Sulzer BX	492	0.90	0.0090	60	

scale-up studies. Scaled-down versions of some of the packings are available in sizes of about 25 and 50 mm diameter.

Hufton et al.[92] used a 23-mm diameter Sulzer BX laboratory packing and found that the original Bravo et al. model [Equation (12.106)] worked well at the small scale so long as the actual geometric dimensions of the laboratory packing were used.

12.8.3.5 Structured Packing Performance

The most common structured packing has a specific surface area in the range of 225 to 250 m²/m³, has a corrugation angle of 45°, and is fabricated from thin-gauge sheet metal; this is often called a "no. 2 packing." The metal may have a textured surface to promote liquid spreading and may have perforations to equalize pressure (and promote spreading). Performance tests are usually run at total reflux with several standard test mixtures. Figure 12.67 shows how the performance of a no. 2 packing compares with that of two random packings (50-mm Pall rings and no. 40 IMTP) and that of a structured packing with twice the surface and fabricated from metal gauze (Sulzer BX). The structured packings are more efficient (lower HETP values) than the random packings.

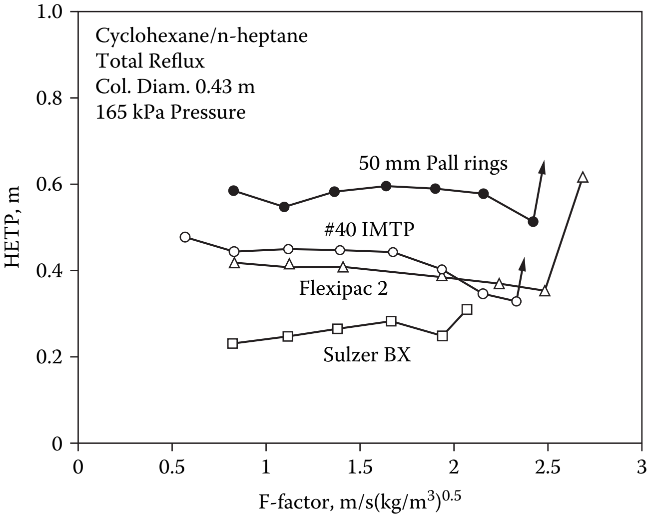

FIGURE 12.67 Efficiency comparison of several packings, cyclohexane/*n*-heptane test mixture. Total reflux, 0.43 m column, 165 kPa. (Z. Olujic et al., 2000. *Chem. Eng. Proc.* 39: 335.)

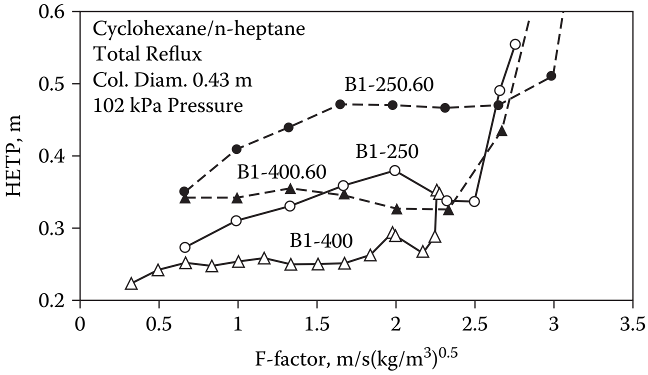

FIGURE 12.68 Efficiency comparison, two structured packings with 45° and 60° corrugation angles. Same conditions as for Figure 12.67. (Z. Olujic et al., 2000. *Chem. Eng. Proc*. 39: 335.)

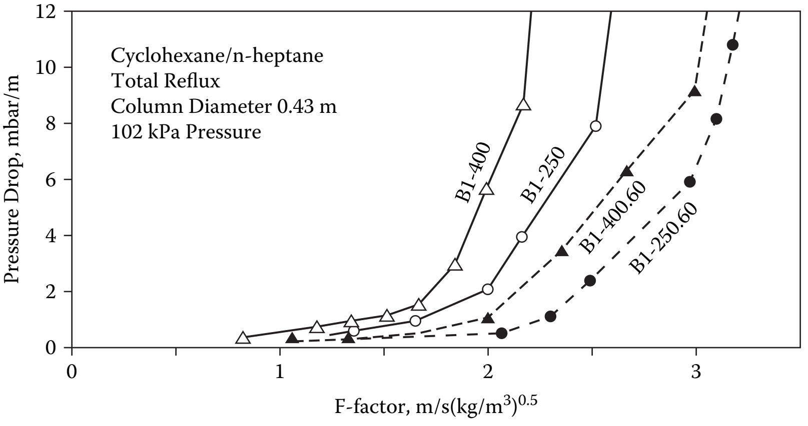

FIGURE 12.69 Pressure drop comparison, two structured packings. Same conditions as for Figure 12.67. (Z. Olujic et al., 2000. *Chem. Eng. Proc*. 39: 335.)

The capacities are about equal for all the packings. The pressure drops (not shown) of the structured packings are lower than those of the random packings. However, the costs of the structured packings are generally considerably greater on a volume basis than those of the random packings.

Figure 12.68 shows a comparison of two structured packings having the same surface texturing but different surface areas and corrugation angles. The packing with the higher area, Montzpak B1-400, has a better efficiency but a lower capacity. The higher-angle packing, 60° from the horizontal, has a lower efficiency but a higher capacity. Figure 12.69 gives a companion to Figure 12.67, showing comparative pressure drops. The higher-angle packing has a lower pressure drop and a higher capacity but lower efficiency. Obviously, several variables must be adjusted when optimizing the design of a bed of structured packing.

12.8.4 Packings versus Crossflow Trays

Choices between packing types and between packings and trays are listed in Table 12.13. In general, trays are cheaper, especially when the cost of expensive distributors and redistributors is added to the packing cost. But packings give higher efficiency and thus can permit lower reflux flows for the same separations. There are also capacity considerations, as indicated qualitatively in Figure 12.70. Packings have capacity advantages over trays at low flow parameter values, typically

TABLE 12.13
Advantages-Crossflow Trays versus High-Efficiency (Random or Structured) Packings

Vapor capacity	Packings – lower pressure
	Trays – higher pressure
Liquid capacity	Trays – higher pressure
	Standoff – lower pressure
Pressure drop	Packings
Efficiency	Packings
Efficiency modeling	Packings
Foaming	Packings
Fouling	Trays
Chemical reactions	Trays
Control	Trays
Ultra-pure products	Trays
Designer comfort	Trays – hydraulics
	Packings – efficiency
Scaleup	Trays
Cost	Depends on situation

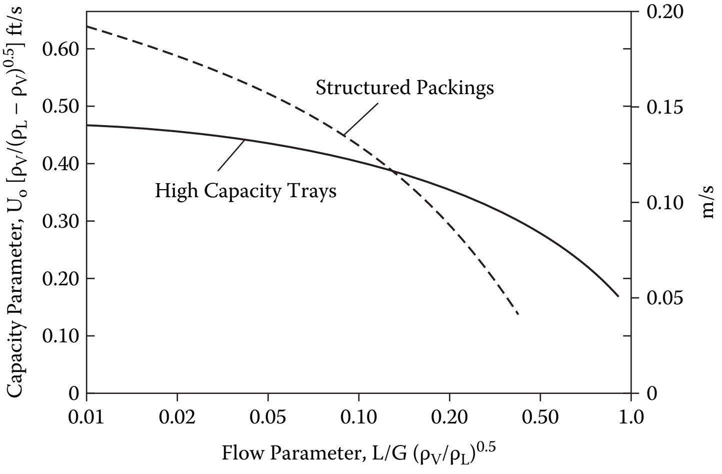

FIGURE 12.70 Generalized comparison of capacities, structured packings vs. high-capacity trays. [J. L. Bravo, 1998. *Chem. Eng.* 105 (2): 77.]

encountered in vacuum distillations; at high parameters, typical of high-pressure distillations, trays can handle the larger liquid flows.

Problem 12.11

Structured packing is now considered for the ethylbenzene/styrene separation. In Problem 12.10, 50-mm Pall rings were used in a 3.20-m column to give an HETP of 1.01 m. For the present case, a 3.05-m column will be used (i.e., rated) along with Mellapak 250Y (see Table 12.12). This is a sheet metal structured packing with about 250 m^2/m^3 surface and a corrugation angle of 45°. with the horizontal. For pressure drop and efficiency, the method of Rocha et al. [Equations (12.114)–(117)] is used.

Results: From a computer program, the results are shown:

Flooding Calculations	
Superficial vapor velocities	
At the flood point	6.113 m/s
At design conditions	4.519 m/s
Column diameter	3.050 m
Flooding factor (%)	73.9
Pressure Drop Calculations	
Friction factor	0.190
Fractional liquid holdup	0.047
Dry pressure drop	0.0023 bar/m
Wet pressure drop	0.0036 bar/m
Flood pressure drop	0.0103 bar/m
Mass Transfer Calculations	
Stripping factor	1.173
Effective interfacial area	148.0 1/m
Ae/ap	0.592
Mass transfer coefficient, liquid	1.372E–04 m/s
Mass transfer coefficient, vapor	7.443E–02 m/s
Height of a transfer unit, liquid	0.110 m
Height of a transfer unit, vapor	0.410 m
Overall height of a vapor transfer unit	0.539
Number of transfer units	11.135
HETP, plug flow	0.497

The HETP is 0.50 m, compared with 1.01 m for 50-mm Pall rings. A 3.05-m column diameter shows 74% flooding, a pressure drop of 0.0036 bar/m. The 6-m packed section can achieve 11.1 transfer units. At this loading, 59% of the total packing surface is wetted.

From the previous problems we can now show a comparison of devices:

	Sieve Tray	50 mm Pall Rings	Structured Packing
Col. Diam., m	3.36	3.21	3.05
HETP, m	1.33	1.01	0.50
ΔP, mm liq/m	72	66	44
Stages/P	0.012	0.015	0.045

12.8.4.1 Counterflow Trays

A model for predicting the efficiency of dualflow-type trays has been reported[47] and is mechanistic in character. A large efficiency database, provided by Fractionation Research, Inc. (FRI), was used in constructing the model. Efficiency data for counterflow baffle tray columns are sparse, and the only model available[51] is based largely on a heat transfer database, using the appropriate analogies.

12.9 TROUBLESHOOTING

Troubles with the performance of operating distillation columns generally fall into one of four categories: capacity for vapor or liquid flows falls short of design, pressure drop is higher than predicted, the separation is not as expected, or the column does not operate in a stable fashion.

Each of these will be discussed in further detail below. Other troubleshooting areas, not discussed, include mechanical failures, damages from fire and explosion, and problems with auxiliaries.

Kister[93], Lieberman,[94] and Saletan[95] provide details on troubleshooting.

12.9.1 Inadequate Vapor Capacity

The criterion here is usually a capacity correlation such as given in Figures 12.29, 12.41, 12.43, and 12.53, depending on the type of contacting device. If the capacity falls short of prediction, there are several possibilities: the correlation was not used properly, too much was expected of the correlation, there is unexpected foaming, or the column internals are not arranged according to specification or are disarranged as a result of an internal vapor surge.

A gamma-ray scan of the column can generally pinpoint problem areas or zones. The rays penetrate the column metal, and their absorption depends on the amount of fluids or solids in their paths. Several commercial organizations specialize in scanning, and they are capable of traversing the entire column, with rays emitted in several different directions.

12.9.2 Liquid Flow Capacity

For tray columns, liquid flow constrictions are normally found in the tray downcomers. Example causes are lack of adequate froth collapse time, excessive pressure drop for flow under the downcomer baffle, and foreign materials being left in the downcomer by construction people. For packed columns, clogged support plates, broken packings, or growth of fouling deposits can cause liquid flow restrictions.

12.9.3 Pressure Drop

The usual problem is excessive pressure drop. It can be caused by flow constrictions/plugging, a bad predictive model, faulty internals, flow rates higher than design, entrainment, and weeping.

12.9.4 Separation Efficiency

Possible explanations for this shortcoming are faulty equilibrium data (relative volatility different from design), use of an improper stage model, wrong material balance (e.g., trace impurities), an erroneous scaleup model, or column internals being less efficient than anticipated.

In the previous sections, the comment was made that the process engineer should make certain that all possible components of the feed are identified. The comment should be extended to a concern about whether "hidden" azeotropes might be present.

12.9.5 Stability

Unstable operation often results from control system problems, improper design of the reboiler, or very low flow rates of liquid (leading to pulsing). Some devices, such as dualflow trays (with no downcomers), tend toward oscillating flows. The most common cause of stability is the control system.

12.10 NOMENCLATURE

a_i = interfacial area for mass transfer, m^2/m^3
a_i' = effective interfacial area for mass transfer, m^2/m^3
a_p = total surface area of packing, m^2/m^3
A = areas of trays, m^2
A_a = active area of tray
A_d = downcomer area
A_{da} = area under downcomer baffle
A_h = hole area
A_n = net area

A_t	= total (superficial) area
A,B,C	= constants in Antoine equation [Equation (12.13)]
A_{ij},A_{ji}	= constants in Van Laar relationship [Equation (12.20)]
A_1,B_1	= constants in Lockett equation [Equation (12.104)]
A_n	= absorption factor [Equation (12.43)]
C_F	= correction factor for approach to flood [Equation (12.102)]
C_{ov}	= discharge coefficient for sieve trays
C_s	= capacity factor for packings, m/s (Figure 12.53)
C_{sb}	= Souders–Brown capacity coefficient for trays, m/s
d_b	= bubble diameter, mm or m
d_h	= hole diameter, mm or m
D_c	= column diameter, m
D_e	= eddy diffusion coefficient, m^2/s
D_G	= molecular diffusion coefficient for gas or vapor, m^2/s.
D_L	= molecular diffusion coefficient for liquid, m^2/s
E	= mass transfer efficiency, fractional
E_{oc}	= overall column efficiency
E_{og}	= point (local) efficiency, vapor basis
E_{mv}	= Murphree tray efficiency, vapor basis
f	= fractional approach to flooding condition [Equation (12.84)]
F	= feed rate, kg-moles/s
F_p	= packing factor (Figure 12.53)
FP, F_{lv}	= flow parameter (Figure 12.29)
Fr	= Froude number
F_{SE}	= surface texturing factor [Equation (12.115)]
F-factor	= vapor flow factor = $U\rho_v^{0.5}$
F_{va}	= active area F-factor for vapor, $U_a\ \rho_v^{0.5}$
F_{vs}	= superficial (total) area F-factor, $U_s\ \rho_v^{0.5}$
GM	= molar vapor rate, lb-moles/hr-ft2
h	= pressure head, mm or m of liquid
h_d	= head loss through holes
h_{ad}	= head loss under downcomer baffle
h_{dc}	= head of clear liquid in downcomer
h_{dc}'	= head of aerated liquid in downcomer
h_L	= head loss through liquid ~ liquid holdup
h_L'	= residual loss on dualflow trays
h_σ	= head loss in bubble formation
h_t	= total head loss across tray
h_{ow}	= clear liquid over weir
hw	= weir height, mm or m
h,H	= enthalpy of liquid, vapor, J/kg
H	= height of a transfer unit, m
H_L	= liquid
H_v	= vapor or gas
H_{og}	= overall, vapor or gas basis
HETP	= height equivalent to a theoretical plate, m
k	= mass transfer coefficient, kg-moles/(s-m^2-mole fraction)
k_v	= vapor (gas)
k_L	= liquid
K_{ov}	= overall, vapor basis
K_c,K_o	= discharge coefficients for valve trays [Equations (12.71) and (12.72)]

K = vapor-liquid equilibrium ratio ("K value")
L = molar liquid rate, lb-moles/hr-ft^2
l_w = weir length, in
L, L_M = liquid molar flow rate, kg-moles/s
L' = liquid flow rate, kg-/s-m^2
L/G = liquid to vapor mass flow rate ratio
L_w = liquid flow rate over the tray weir, ft^3/s-m
m = slope of equilibrium curve
m_1 = exponent in Equation (12.101)
M_L = molecular weight of liquid
n_1 = exponent in Equation (12.101)
N = number of trays or stages
N_a = actual stages or trays
N_m = minimum stages
N_t = total trays
N = number of transfer units (also NTU)
N_L = number of liquid phase transfer units
N_{ov} = number of overall transfer units, liquid basis
N_v = number of vapor phase transfer units
N_A = molar flux, species A
p = partial pressure, atm or bar
p^{sat} = vapor pressure, atm or bar
P = total pressure, atm or bar
q = liquid flow rate, m^3/s
Q = vapor flow rate, m^3/s
R = reflux ratio
R_m = minimum reflux ratio
Re = Reynolds number, dimensionless [Equation (12.108)]
S = length of a side of corrugation, structured packing, m
Sc = Schmidt number, dimensionless [Equation (12.109)]
Sh = Sherwood number, dimensionless [Equation (12.109)]
t = residence time, s
T = absolute temperature
u_a = liquid velocity to active area of tray (q/A_a), m/s
u_{Lh} = liquid velocity through distributor holes, m/s
U = vapor or gas velocity, m/s
U_a = vapor velocity through active area of tray (Qv/Aa), m/s
U_g = actual vapor velocity in structured packing, m/s
U_L = actual liquid velocity on structured packing surface (film flow), m/s
v = vapor or gas flow for an individual component, m/s
V = vapor or gas flow rate, kg-moles/s
V' = vapor sidestream flow, kg-moles/s
W = length of flow travel on tray, m
x = liquid mole fraction x^* = equilibrium value
y = vapor mole fraction y^* = equilibrium value
z = mole fraction in feed
Z = height of packing, m
Z_f = height of froth on tray, m

Symbols

α	= relative volatility (α_{ij} for i-j binary)
β	= froth aeration factor [Equation (12.60)]
β	= fractional liquid coverage of packing surface [Equation (12.111)]
γ	= activity coefficient
γ	= liquid-solid contact angle, deg [Equation (12.115)]
Γ	= physical property correction factor [Equation (12.103)]
ε	= void fraction of packed bed
θ	= corrugation angle for structured packing (from horizontal), deg
λ	= ratio of slopes, equilibrium/operating lines
μ	= viscosity, Pa-s
ν	= kinematic viscosity, cSt
ρ	= density, kg/m^3
σ	= surface tension, mN/m (dynes/cm)
ϕ'	= packing parameter [Equation (12.102)]
ϕ_f	= froth or spray relative density [Equation (12.63)]
ψ	= packing parameter, Eq 101)
ψ	= entrainment ratio, moles/mole gross downflow liquid

Subscripts

A	= species A
B	= bottoms
D	= distillate
eff	= effective
F	= feed
G	= gas phase
i,j,k,m	= components i,j,k,m
L	= liquid phase
M	= molar
n,*n*–1,*n*+1	= stages *n*, *n*–1, *n*+1
org	= organics
V	= vapor
W	= water

Superscripts

L	= liquid phase
V	= vapor phase
F	= feed
∞	= infinite dilution

13.1 INTRODUCTION

13.1.1 Functions of Absorption and Stripping

Absorption and stripping are counterpart processes used in the process industries for separating gas or liquid mixtures. Their functions are generally of two types: *recovering* one or more components from the mixture or *purifying* the mixture to meet specifications or standards. In absorption, a gas mixture is contacted with a suitable liquid *solvent* to remove preferentially one or more mixture components from the gas phase. Conversely, in stripping, a liquid mixture is contacted by a suitable *stripping gas* to remove preferentially one or more components from the liquid phase. In practice, absorption and stripping are often coupled processes, as shown later. Both processes involve gas-liquid contacting, generally in vertical, cylindrical towers called *absorbers* or *strippers*.

Processes of this type are distinguished between physical and chemical absorption or stripping. For physical processes, transfer of the solute between phases is by physical mechanisms without any chemical reactions. For chemical processes, the solute reacts with a component of the solvent, resulting in an increased capacity of the solvent for the solute. Conversely, stripping sometimes breaks the chemical bonds between solute and solvent.

13.1.2 Commercial Applications

Absorption is often used to purify a gas stream; an alternate name of the operation is *scrubbing*. Contaminated air, for example, can be purified by scrubbing out the contaminants with a selective solvent. Another example is removing sulfur and carbon dioxide from natural gas using solvents such as alkanolamines. As the solutes are being removed from the gas, the solvent becomes richer in these materials. To purify the solvent for reuse, stripping is needed. The contaminants are removed from the liquid by the action of a stripping gas. The general flow diagram for this coupled operation is shown in Figure 13.1. Such a process is useful for reducing the level of gaseous pollutants. Representative commercial applications of physical and chemical absorption are shown in Table 13.1.

Not all absorptions and strippings are as straightforward as indicated in Figure 13.1. Absorption may be used to produce a product—for example, the absorption of nitrogen oxides in water to form nitric acid. Or absorption may be used to recover valuable products, such as propanes and butanes from natural gas. And stripping may be a once-through operation such as the removal of volatile organic compounds (VOCs) from groundwater using atmospheric air for the stripping medium.

Flow diagrams for representative absorption and stripping processes are shown in Figures 13.2 and 13.3. In Figure 13.2, acetone is scrubbed from air to meet an exit air specification. The acetone transfers to the water phase, and the rich solvent flows to a distillation column wherein the acetone is recovered in high purity and the water is recycled to the absorber. In Figure 13.3, trichloroethylene (TCE) is stripped from groundwater by air, with the discharge from the stripper flowing through a carbon bed in which the TCE is adsorbed.

Obviously, a solvent must be found that has an affinity for the constituent(s) to be absorbed, and the stripping medium must be such that the physical or chemical bond between solute and solvent can be easily broken. This affinity, or solubility, is a critical consideration in the design of absorption/stripping systems, as discussed next.

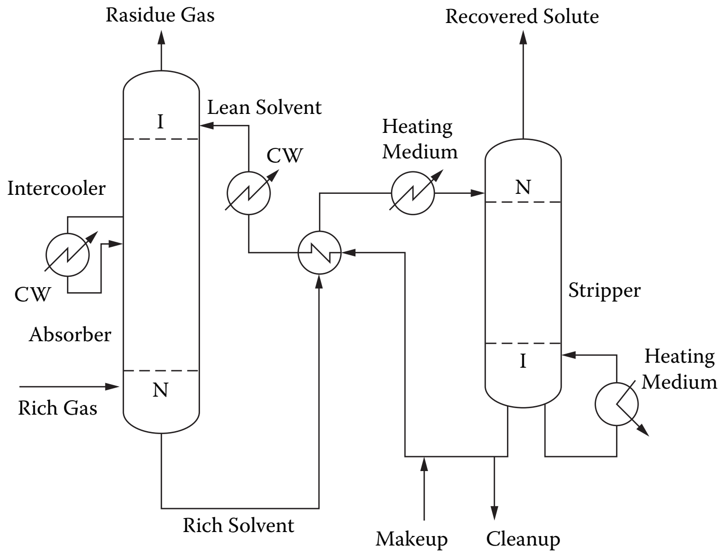

FIGURE 13.1 Typical flow diagram for a coupled absorption-stripping unit. Because the solvent flows in a closed circuit, allowance is made for losses ("makeup") as well as removal of accumulated impurities ("cleanup"). An intercooler is shown to suggest the need to remove heat of solution in the absorber.

TABLE 13.1
Representative Commercial Applications of Absorption

Solute	Solvent	Type of Absorption
Acetone	Water	Physical
Ammonia	Water	Physical
Formaldehyde	Water	Physical
Hydrochloric acid	Water	Physical
Sulfur trioxide	Water	Physical
Benzene and toluene	Hydrocarbon oil	Physical
Butanes and propane	Hydrocarbon oil	Physical
Carbon dioxide	Aq. NaOH	Irreversible chemical
Hydrochloric acid	Aq. NaOH	Irreversible chemical
Chlorine	Water	Reversible chemical
Carbon monoxide	Aq. cuprous ammonium salts	Reversible chemical
Carbon dioxide	Aq. ethanolamines	Reversible chemical
Hydrogen sulfide	Aq. ethanolamines	Reversible chemical
Nitrogen oxides	Water	Reversible chemical

13.1.3 Solubility and Phase Equilibria

If an absorber is to be designed for efficient and economical service, the solvent chosen must have a special affinity for the one or more components of the gas mixture that are to be selectively removed. In other words, a degree of *solubility* is needed. Solubility data, which relate the solute, the solvent, the concentrations, and the temperature-pressure conditions, may be found in various compendia and journal articles. In the past, it was common to report solubility as a *Bunsen solubility coefficient*:

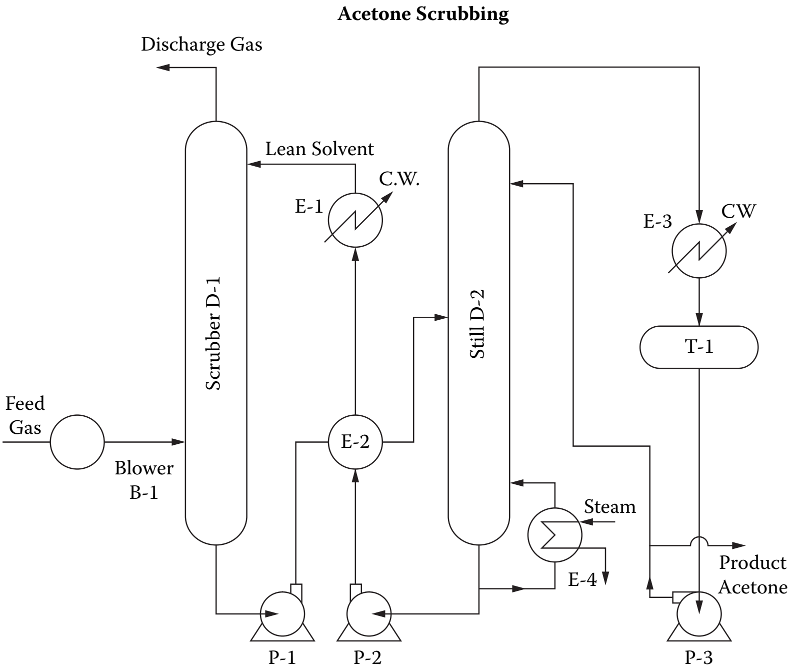

FIGURE 13.2 System for scrubbing acetone from air using a circulating solvent. Water or a non-volatile organic liquid can be used as the solvent.

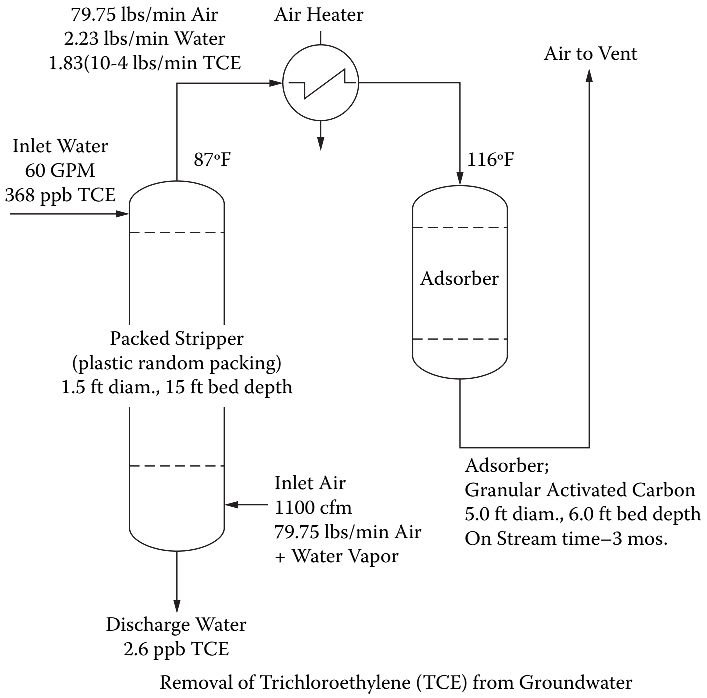

FIGURE 13.3 System for removing volatile organic compounds (VOCs) from groundwater, by stripping with atmospheric air. The exit gas contains the stripped VOCs and must be purified by flow through a bed of activated carbon.

$$\alpha'_i = \frac{vol\, i\, dissolved\left[0^o, 1.0\, atm\right]}{(vol.solvent)(partial\ pressure\ of\ i\ in\ gas, atm)},\ \text{atm}^{-1} \tag{13.1}$$

(An older variation of this term is the *Ostwald coefficient*, which uses the gas volume at actual conditions instead of at standard conditions.) In general use today is the *Henry's law coefficient, H_i*:

$$H_i = \frac{partial\ pressure\ of\ i\ in\ gas, atm}{mole\ fraction\ of\ i\ in\ solvent} = \frac{p_i}{x_i} \tag{13.2}$$

A related term, widely used in distillation and absorption calculations, is the equilibrium ratio, K_i:

$$K_i = \frac{mole\ fraction\ of\ i\ in\ gas}{mole\ fraction\ i\ in\ liquid} = \frac{y_i^*}{x_i} \tag{13.3}$$

where the asterisk indicates an equilibrium condition. For certain absorption/stripping calculations, a modified K value will be used:

$$K'_i = \frac{moles\ i\ per\ mole\ solute\ free\ gas}{moles\ i\ per\ mole\ solute\ free\ solvent} = \frac{Y_i^*}{X_i} \tag{13.4}$$

The solute-free gas is sometimes called the "carrier gas."

For the nonideal solutions usually encountered in absorption/stripping problems, the K_i value can be expressed as follows:

$$K_i = \frac{\gamma_i\, p^{sat}}{P} \tag{13.5}$$

where γ_i is the liquid phase activity coefficient for i in the solvent, p^{sat} is the vapor pressure of i, and P is the total pressure. In many cases, especially those dealing with dilute solutions, the value of γ_i approaches the thermodynamically important infinite dilution coefficient γ_i^∞.

Most importantly, Equations (13.1) through (13.3) are based on thermodynamic equilibrium. A further discussion of the equilibrium ratio and its basis is found in Chapter 12, "Distillation," of this handbook. Note that the simple relationship

$$H_i = K_i P \tag{13.6}$$

where P is total pressure, can be useful in solubility studies because of the vast amount of work and reference data on the K value. One must be careful with units, particularly in utilizing data from various sources. In the following sections, the K value will be used, in some cases with molar ratios [Equation (13.4)].

13.1.3.1 Sources of Solubility Data

For solubility of various elements and compounds in water, there are many references, but only a few are mentioned here. Hwang et al.[1] have provided data for 404 common organic pollutants at 1.0 atm and temperatures of 25 and 100°C, the latter values being useful for steam stripping. Their

data are for low-concentration conditions, the usual case for sparingly soluble organic compounds. For cases where experimental data do not exist, the predictive model UNIFAC,[2] discussed in Chapter 12 is recommended.

Problem 13.1

Acetone is to be scrubbed from dry air into water at 30°C and 1.0 atm. The acetone concentration is 2.60 vol-%. For the condition of thermodynamic equilibrium, calculate the following:

(a) The Henry's law coefficient
(b) The equilibrium ratio, K
(c) The liquid phase activity coefficient
(d) The Bunsen coefficient.

Data: molecular weights: acetone = 58, air = 29, water = 18
Vapor pressures at 30°C: acetone = 283 mm Hg, water = 31.8 mm Hg
According to the measurements of Othmer et al.,[17] for a partial pressure of acetone = 760(0.025) = 19.0 mm Hg, the equilibrium acetone composition in the liquid is 0.010 mole-%. Thus,

(a) H_i = 19/0.01 = 1900 mm Hg/m.f. = 2.5 atm/m.f.
(b) K value = 0.025/0.010 = 2.50 [$H_i = K_i P$ = 2.50(760) = 1900 mm/m.f.]
(c) Since $K_i = \gamma_i\ p^{sat}/P$, then γ_i = 2.5(760)/284 = 6.72
(d) Bunsen coefficient [Equation (13.1)]. Basis 1.0 mole equil. liquid. Moles acetone = 0.025. Vol. acetone at STP = 22,400(0.025) = 560 cm^3. Vol. water = 18 (0.0975) = 1.755/1.00 = 1.755. Hence α_i = 560/(1.755 x 19/760) = 12,760 mm^{-1} or 16.8 atm^{-1}

Yaws and coworkers[3] have presented many compilations and correlations of solubility data, for example, hydrocarbons in water. Methods are available for estimating the solubility of gases in organic liquids.[4–6] And special compendia include those in the Solubility Data Series,[7] Seidell and coworkers,[8–10] and Dack.[11] Extensive reviews have been provided by Markham and Kobe,[12] Long and McDevit,[13] Battino and Clever,[14] Wilhelm and Battino,[15] and Wilhelm et al.,[16] among others. Often data usually associated with vapor-liquid equilibrium in distillation can be used. Finally, various handbooks contain some useful solubility data.

13.1.3.2 Multicomponent Solubilities

The simplest case of absorption and stripping is the removal of a single component from the second component in a binary mixture. This means, however, that the solubility of the other component must also be considered. In Problem 13.1, the tacit assumption was made that air (the second component) is insoluble in water. For many situations, there is a mixture of varying solubilities to be removed in absorption, or varying effective vapor pressure to be stripped. Thus, *relative solubility* must be considered.

For dilute mixtures where the majority component is not being absorbed or stripped, the mixture components usually can be considered to behave as individual entities subject to their individual solubilities. Thus, for a mixture of 1000 ppm-vol trichloroethylene and 500 ppm-vol perchloroethylene, the solubility for each can be determined as if the other is absent. In general, for several components of varying solubility, the relative solubility is

$$\alpha'_{i \ldots n} = K_i / K_{j \ldots n} \tag{13.7}$$

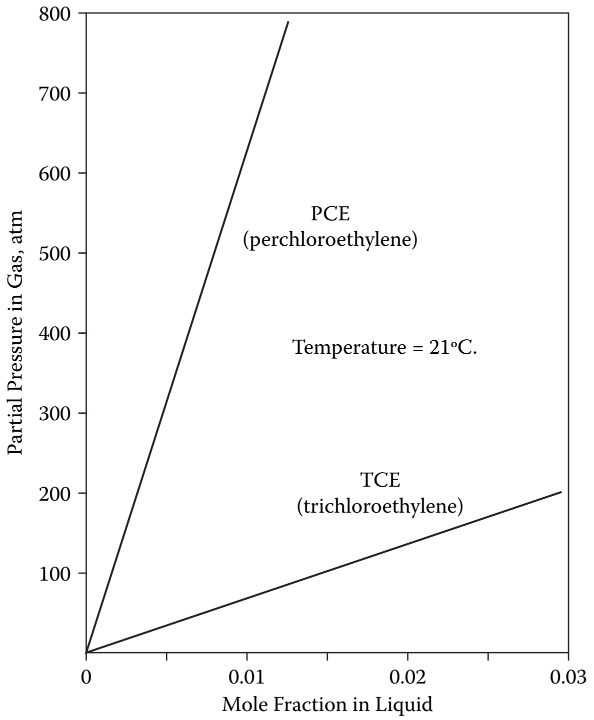

FIGURE 13.4 Solubility of trichloroethylene (TCE) and perchloroethylene (PCE) in water at 21°C. The PCE is much less soluble, requiring a relatively high partial pressure to achieve a given mole fraction liquid concentration.

13.1.3.3 Graphical Representation of Solubility

The equilibrium composition of a component in the gas is often plotted versus the equilibrium concentration of the same component in the liquid, at constant temperature. Figure 13.4 is a plot of solubilities of trichloroethylene (TCE) and perchloroethylene (PCE) in water at 21°C. The H_i values are H_{TCE} = 6753 and H_{PCE} = 61,790. The higher value means that PCE is less soluble than TCE. At 1.0 atm total pressure, the numerical values of K and H are the same.

Graphs, such as Figure 13.4, are useful for determining separation requirements in terms of stages or transfer units. An alternate form of plotting, useful for stage calculations, is the Y-X diagram, where Y represents the ratio of moles solute per mole of solute-free gas, and X represents the ratio of moles solute per mole of solute-free solvent. For mass transfer calculations, the simple mole fraction plot, y*-x, is convenient, as discussed later. For concentrated gas cases, particularly where heat effects can be significant, plots showing temperature effects (such as Figure 13.5) may be needed.

13.1.4 Solvent Selection

As discussed immediately above, an important criterion for solvent selection is solubility. The solvent must accommodate a reasonable amount of the species to be removed from the gas while still maintaining selectivity between the solute(s) and carrier gas. When the carrier is air or an inert gas, it is easy to designate solute vs. carrier; in other cases, it is a matter of relative solubility.

Other criteria for solvent selection include the following:

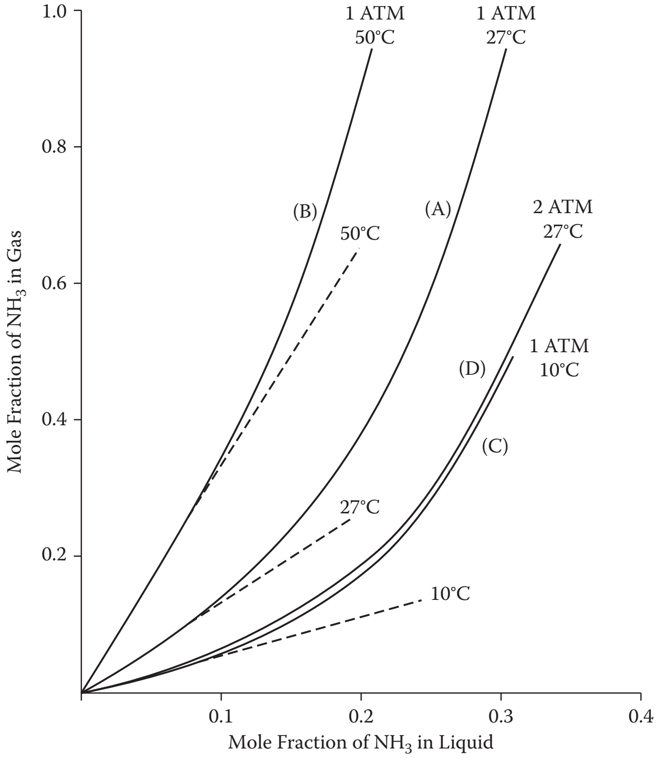

FIGURE 13.5 Solubility of ammonia in water from ammonia-air mixtures. The dashed lines indicate the slope of the lines near the origin. [Perry, R. H. (ed.), 1985. *Chemical Engineer's Handbook*, 5th ed., New York: McGraw-Hill.]

1. Availability and cost
2. Volatility (higher volatility can contaminate the absorber exit gas)
3. Stability, especially for recirculating systems
4. Corrosiveness
5. Ease of stripping
6. Convenience of disposal
7. Degree of hazard to humans and the environment

13.1.5 Theoretical Stages/Transfer Units

In designing an absorber or stripper, one must ascertain some index of "difficulty of separation." As in the case of distillation separations, this index is either the required *number of theoretical stages* or the required *number of transfer units.* These parameters are interchangeable, with stages often used for plate columns and transfer units for packed columns. Background on the parameters is provided in Chapter 12. For convenience in handling the associated hydraulics and mass transfer calculations, the remainder of this chapter is divided into three parts: "Plate Columns," "Packed Columns," and "Special Devices."

13.2 PLATE COLUMNS

Plate columns are vertical vessels, usually circular in cross section, that contain a multiplicity of plates that bring gas and liquid into intimate contact. These columns are the same as those used

for distillation. Most plates are connected by downcomers, where the downflowing liquid transfers from a plate to the next plate below. Typically, the plates have openings through which the upflowing gas passes and above which the gas and liquid make contact. If the gas leaving the plate is in thermodynamic equilibrium with the liquid leaving the plate, then a *theoretical stage* is provided.* To account for the failure to achieve equilibrium, *plate efficiency* is used. The computational approach is to determine the theoretical stages and then correct to actual stages (plates) by means of *plate efficiency*, in the same fashion as for distillation columns.

13.2.1 Absorption Stages

The number of stages required for a specified amount of absorption may be calculated from the Kremser–Brown equation[18] with stages numbered down from the top of the column:

$$E_{ai} = \frac{Y_{N+1} - Y_1}{Y_{N+1} - Y_o^*} = \frac{A_i^{N+1} - A_i}{A_i^{N+!} - 1} \tag{13.8}$$

where

E_{ai} = absorption efficiency of component i
Y_{N+1} = moles i per mole of solute-free gas, entering (bottom) condition
Y_1 = moles i per mole of solute-free gas, exit (top) condition
Y_o* = moles i per mole of solute-free gas, determined as in equilibrium with i in the entering solvent
N = required theoretical stages
A_i = absorption factor for component $i = L'/(V'K_i)$
L' = moles of total liquid
V' = moles of total gas

For some studies, a rearrangement of Equation (13.8), to give explicit number of stages, is convenient:

$$N = \frac{\ln\left(\dfrac{E_{ai} - A_i}{E_{ai} - 1}\right)}{\ln A_i} - 1 \tag{13.9}$$

Different solutes require different numbers of stages; the "key solute," for which the separation is specified, prevails. Thus, the required stages for that solute are calculated, and then Equation (13.8) determines the degree of absorption for the other solutes (if any). There are other aspects of Equations (13.8) and (13.9) that should be noted. The value of the absorption factor can change with changes in the *L/V* ratio; for the very lean gas feeds, the value of *L/V* varies very little because the material balance changes very little. Also, the value of the absorption factor can change with changes in *K*. Again, this may not be important for the dilute case, which is essentially isothermal, but may present problems for the more concentrated cases. The net effect of these limitations is the problem of assigning some average value of A_i in Equations (13.8) and (13.9).

For varying *L/V*, an analytical approach utilizing the modified molar concentrations [see Equation (13.4)] may be used:

* The theoretical stage concept is discussed in detail in the section on distillation as well as in unit operations textbooks.

$$\text{Gas: } Y_i = \frac{y_i}{1-y_i} = \frac{\textit{moles solute}}{\textit{mole solute free gas}} = \frac{\textit{moles solute}}{\textit{mole "carrier gas"}} \tag{13.10}$$

$$\text{Liquid: } X_i = \frac{x_i}{1-x_i} = \frac{\textit{moles solute}}{\textit{mole solute free solvent}} = \frac{\textit{moles solute}}{\textit{mole solvent}} \tag{13.11}$$

Clearly, at very low concentrations, $y \sim Y$ and $x \sim X$, but as will be shown later, the modified relationships can be used for concentrated cases. When there is more than one solute, the denominators in Equations (13.10) and (13.11) do not change.

Consider a general-type absorber as diagrammed in Figure 13.6. Gas and liquid flow countercurrently through real or imagined stages. The usual specifications include (a) fraction of absorption of solute in the feed gas, (b) maximum allowable concentration of solute in the exit gas, and (c) optimal ratio of solvent to feed gas. Based on mass balances,

$$\text{Total: } G_{N+1} + L_o = G_1 + L_N \tag{13.12}$$

$$\text{Solute } i\text{: } G_{N+1}Y_{N+1} + L_oX_o + = G_1Y_1 + L_{N+1}X_{N+1} \tag{13.13}$$

By definition, $G_{N+1} = G_1 = G$, and $L_o = L_{N+1} = L$

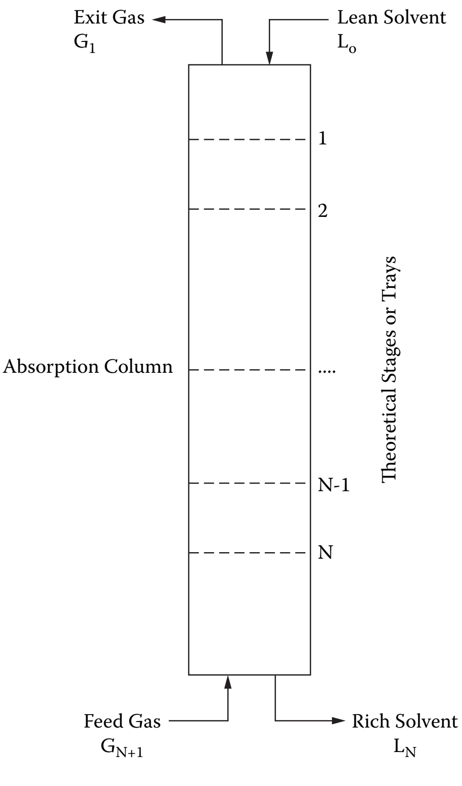

FIGURE 13.6 Arrangement and nomenclature for a plate-type absorber. Note that stages or trays are numbered from the top.

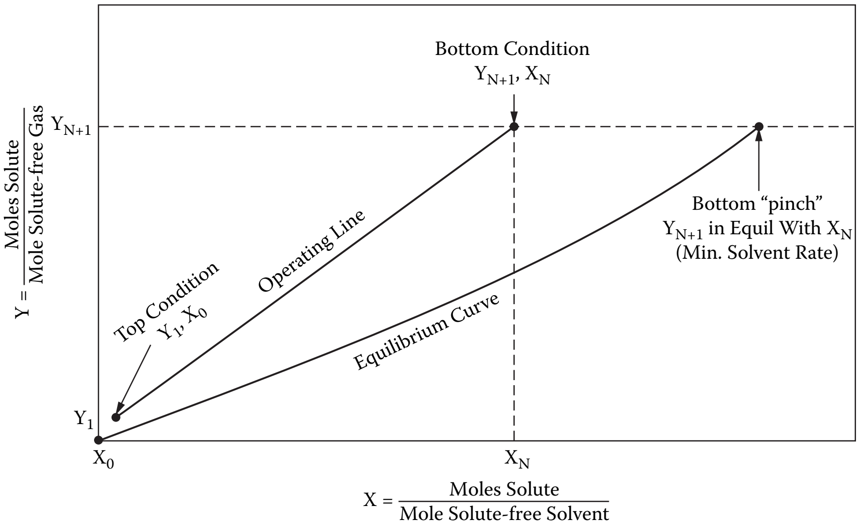

FIGURE 13.7 General layout for graphical determination of theoretical stages in an absorber. Note the bottom pinch point, which determines the minimum solvent rate.

$$\text{So that } Y_{N+1} = (L/G)\, X_N + Y_1 - L_o X_o / Y_{N+1} \tag{13.14}$$

Equation (13.14) is linear in a plot of Y vs. X. The slope is L/G, and the intercept is $Y_1 - L_o X_0 / Y_{N+1}$; and for the often-encountered case of no solute in the entering solvent (once-through solvent or fully stripped solvent in a recirculating system), the intercept is simply Y_1. In Equations (13.8) and (13.9), the absorption factor is based on the slope as defined in Equation (13.14), i.e., on a solute-free basis. Figure 13.7 shows these concepts and can be generalized to apply to any stage n in the column. Note that while the operating line is always straight, the equilibrium curve may not be straight.

Problem 13.2

Acetone is to be absorbed from its mixture with air into a nonvolatile oil. The entering gas contains 30 mole-% acetone and 70% dry air. Removal of acetone from the air is to be 97%. Calculate the following:

(a) Minimum solvent rate, in terms of L_o/G_{N+1}
(b) Theoretical stages at a solvent rate 1.4 times the minimum
(c) Theoretical stages if the solvent contains 0.5 mole-% acetone (solvent incompletely stripped) and the exit gas concentration from part (b) is to be maintained

Data: The molar concentration of acetone in the liquid is linear with a molar concentration of acetone in the air: $y^* = 1.80\, x$.

Solution

(a) The minimum solvent ratio is based on a "pinch" at the bottom of the column. When the feed gas composition is in equilibrium with the rich solvent exit composition, an infinite number of stages would be required. On the basis of $y^* = 1.80\, x$, $x = 0.30/1.80 = 0.167$. Then $L_{o,min} = 29.1/0.167 = 173.6$ moles.

(b) If the solvent rate is 1.4 times the minimum, the bottoms composition is $0.167/1.4 = 0.119$. A molar balance across the column becomes (basis 100 total moles of feed gas)

	Feed gas	Rich oil	Off gas	Entering solvent
Acetone	30	29.1	0.90	0
Air	70	0	70	0
Oil	0	244.4	0	244.4
	100	273.5	70.9	244.4

Y_{N+1} = 30/70 = 0.428 X_N = 29.1/244.4 = 0.119 Y_1 = 0.9/70 = 0.0129 X_o = 0

The effective absorption efficiency is (0.428 – 0.0129)/(0.428 – 0) = 0.970.

For the modified coordinates, the K value is not constant at 1.8. The equilibrium line has a slight curvature, and its slope varies from 1.80 to 1.98. Use an average = 1.90. Then, the absorption factor is 244.4/(70 × 1.90) = 1.84.

Number of theoretical stages required [Equation (13.9)]:

$$N_t = \frac{\ln\left(\dfrac{0.97-1.84}{0.97-1}\right)}{\ln 1.84} - 1 = 4.52$$

The material balance for this case is

	Feed gas	Rich oil	Off gas	Entering solvent
Acetone	30	30.3	0.9	1.2
Air	70	0	70	0
Oil	0	244.4	0	244.4
	100	274.7	70.9	245.6

Y_{N+1} = 30/70 = 0.428 X_N = 30.3/244.4 = 0.124 Y_1 = 0.9/70 = 0.0129 X_o = 1.2/244.4 = 0.005

Now the effective absorption efficiency is (0.428 – 0.0129)/(0.428 – 0.005) = 0.981.

The number of theoretical stages by Equation (13.9) = 5.04. The acetone in the entering oil increases the stage requirement from 4.52 to 5.04. The graphical treatment of case (c) is shown in Figure 13.8.

13.2.1.1 Multiple Solutes

Equation (13.8) can be used for multiple solute cases, since it can accommodate absorption factors A_i, A_j, A_k, …, each giving a different value of E_a. The liquid/gas ratio does not change, since it is based on overall flows. Thus, Equation (13.9) can give different values of N (theoretical stages). It is here that the key component enters into the picture. The required stages for that component are calculated, and then the same value of N is substituted back in Equation (13.8) to determine the relative absorption effectiveness of the other components.

The graphical counterpart of Equations (13.8) and (13.9) is shown in Figure 13.9 for the example of absorbing ethane, propane, butane, and pentane into absorption oil. Pentane is the key component, and its value of Y is reduced from 0.04 to essentially zero. The other components are restricted by the same operating line slope as required for pentane. Thus, butane is reduced from Y = 0.08 to Y = 0.02, propane is reduced from Y = 0.08 to 0.063, and ethane is reduced very little. The requirement for butane is about four stages. Ethane and propane fall into a "pinch" composition after one or two stages and then for the remaining stages have no change in composition. The absorption effectiveness values indicated in Figure 13.9 would also result from the use of Equations (13.8) and (13.9).

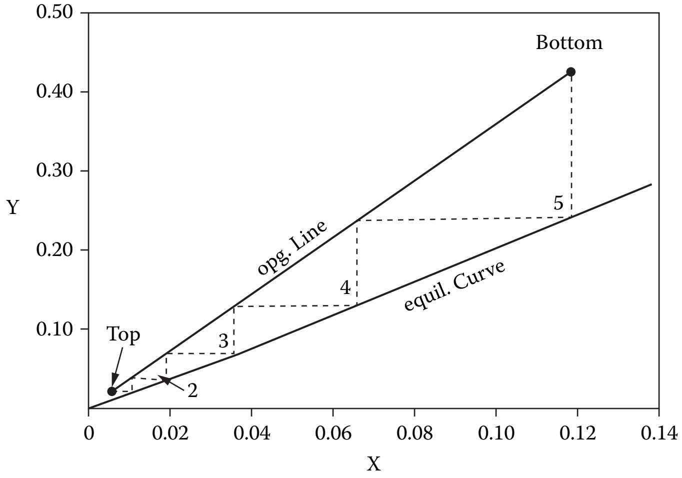

FIGURE 13.8 Graphical determination of equilibrium stages for Problem 13.2.

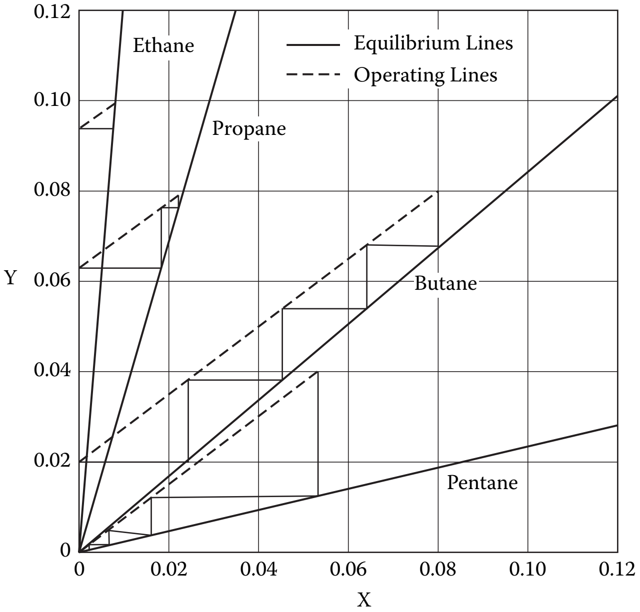

FIGURE 13.9 Equilibrium stage graph for a multiple solute system. Note that the operating lines are straight and parallel. If pentane is the key absorbing component, then the exit gas has significant amounts of butane, propane, and ethane.

13.2.1.2 Concentrated Feeds

Equations (13.8) and (13.9) apply to whatever concentration range can result in minor variations of the absorption factor, i.e., for essentially linear equilibrium lines. When this is not the case, a variant of Equation (13.8), due to Edmister,[19] may be used:

$$E_{ai} = \frac{Y_{N+1} - Y_1}{Y_{N+1}} = \left[1 - \frac{L_o X_o}{A' V_{N+1} Y_{N+1}}\right]\left[\frac{A_e^{N+1} - A_e}{A_e^{N+1} - 1}\right] \tag{13.15}$$

with the nomenclature the same as for Equation (13.8) (Figure 13.6) with the following additions:

$$A' = \frac{A_N(A_1+1)}{A_N+1} \tag{13.16}$$

$$A_e = \sqrt{A_N(A_1+1)+0.25} - 0.50 \tag{13.17}$$

$$A_N = \frac{L_N}{V_N K_N} \tag{13.18}$$

$$A_1 = \frac{L_1}{V_1 K_1} \tag{13.19}$$

$$V_N = V_{N+1}\left(\frac{V_1}{V_{N-1}}\right)^{1/N} \tag{13.20}$$

The Edmister approach makes corrections such that an average value A_e can be used in the Kremser-Brown relationship. The effect of solute in the entering solvent is accounted for by the first term on the right in Equation (13.15). For the same form to be used for stripping, tray numbering and other terms are amplified in Figure 13.10. The stripping equations will be given later.

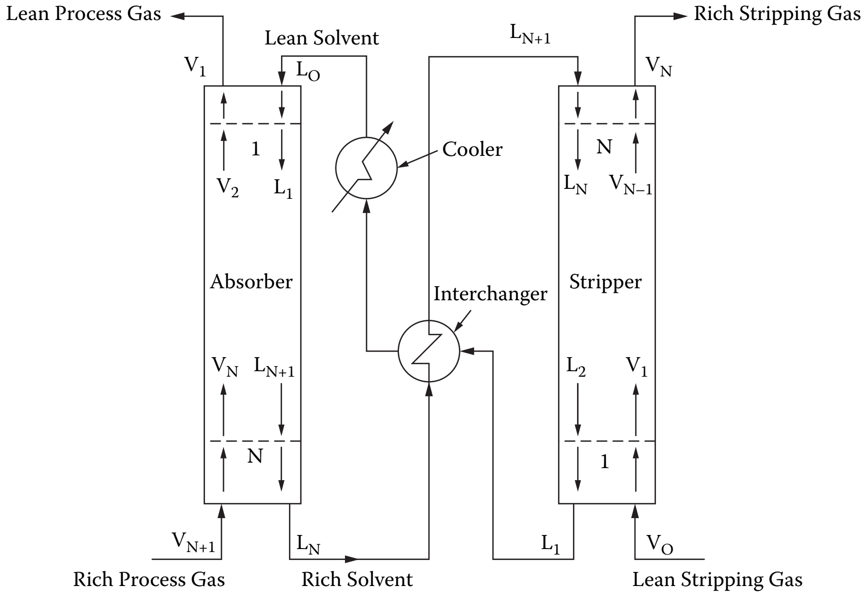

FIGURE 13.10 Nomenclature for use of the Edmister method for determining stages in absorbers and strippers. In order to maintain similarity of equations for absorption and stripping, the stages are numbered up from the bottom of the stripper.

13.2.1.3 Minimum Solvent Rate

As noted in the solution to Problem 13.2, when the solvent rate is lowered to a value at which the entering gas composition approaches equilibrium with the exit solvent, the required stages approach infinity. Recognize that this is not based on Equation (13.8), where it might appear that when $A = 1$, $N \rightarrow \infty$; in fact, when $A = 1$, $E_{ai} = N/(N + 1)$ by L'Hospital's rule. Rather, it is based on a "pinch" at the bottom of the column where the gas leaving the bottom stage is the same as the gas entering that stage (i.e., feed gas). In Figure 13.8, if an operating line is drawn from the bottom pinch condition to the desired top condition, an infinite number of steps would be required at the bottom condition.

The bottom pinch is the most common type but, under certain conditions, the pinch can occur at the top, wherein the off gas composition is in equilibrium with the entering solvent composition.

Many studies have indicated that an optimum solvent-to-feed ratio is about 40% greater than the minimum. The optimum represents a trade-off between additional capital cost (more stages at lower solvent/feed ratios) and increased operating costs owing to the circulation of more solvent. It is recommended that the minimum rate be determined first and, as a starting value, a design solvent rate be 1.4 times the minimum.

13.2.1.4 Heat Effects

With lean gas feeds, only relatively small amounts of feed components pass into the liquid. Hence, the heats of solution of these components are relatively small, and the absorption column operates approximately *isothermally.* For significant amounts of absorption, the exothermic heats of solution become important. In the latter case, the temperature of the liquid phase can increase measurably, resulting in lower solubility of solutes and more solvent required. For this adiabatic case, the exit solvent temperature can be calculated from heats of absorption and the heat capacity of the solvent. As the solvent temperature rises, two approaches can be used:

(1) Allow for decreased solubility in the design, and adjust the location of the equilibrium curve (or the value of K) accordingly. For example, Equation (13.8) can be used for segments of the column where the temperatures are different because of solution effects.
(2) Install intercooling capacity in the column to maintain a pseudo-isothermal condition. The cooling can be done with coils on each tray (as in nitric acid columns) or with external heat exchangers processing the total liquid downflow.

Figure 13.5 compares the slopes of the equilibrium curves at a low concentration of ammonia in the liquid and at a higher concentration. If the concentration of ammonia is less than about 0.1 mole fraction, the equilibrium line is fairly straight. However, heat effects associated with the absorption of ammonia can move the equilibrium curve to a higher slope. Problem 13.3[20] shows how even a low concentration case may require correction.

13.2.2 Stripping Stages

Stripping is in many ways the reverse of absorption, and most of the same design equations apply. Figures 13.1 and 13.2 show examples of stripping coupled with absorption, while Figure 13.3 shows a once-through stripping operation. In this process, an inert gas is used to remove components from a liquid feed mixture, and the same solubility considerations presented earlier for absorption apply to stripping. To maintain the same form of the equations, stripping stages are numbered from the bottom to the top (Figure 13.10). The stripping gas is G_o (the counterpart of solvent L_o in absorption), the feed mixture is $L_{N+!}$, and so on.

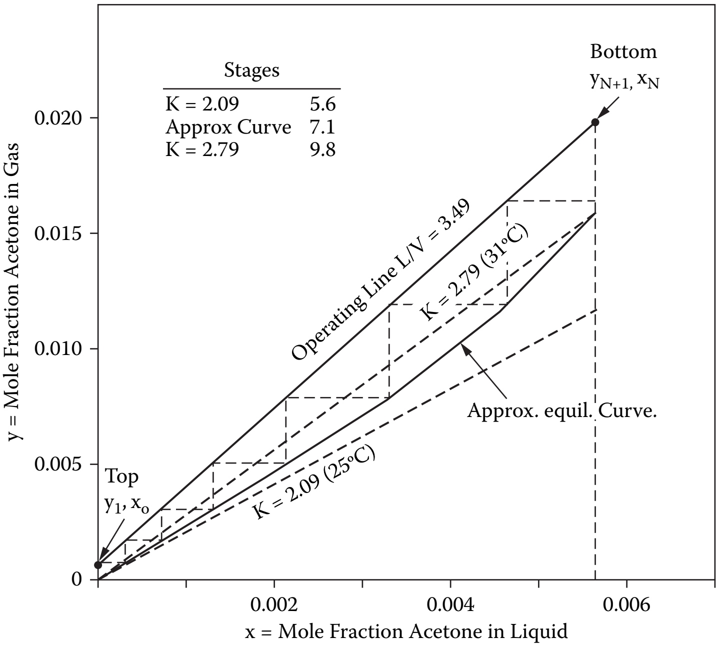

FIGURE 13.11 Diagram for Problem 13.3, showing effect of heat of absorption on required stages. Only the steps for the temperature-corrected equilibrium curve are shown.

Problem 13.3

Acetone is to be absorbed from wet air into pure water in a plate column. The laden air enters at 35°C, and the water solvent enters at 25°C. Pressure is atmospheric. The air contains 2.0 mole-% acetone and is 70% saturated with water vapor (4 vol-% water). The concentration of acetone in the air is to be reduced to 0.05 mole-% (E_{ai} = 0.975). The solvent rate is chosen such that the operating line has a slope of 3.49 on a mole fraction-plotting basis. How many stages are needed?

Solution

Based on an overall heat balance, with the exit air temperature closely approaching the inlet water temperature, the adiabatic temperature rise of the liquid is 6°C, giving an exit liquid temperature of 31°C. Isothermal K values (= y/x) are 2.09 at 25°C and 2.79 at 31°C. The exit water contains 0.57 mole-% acetone.

Figure 13.11 shows a y-x diagram with the isothermal equilibrium lines at 25 and 31°C. Also shown is the approximate actual equilibrium curve location, taking into account heat effects in the column. For the linear equilibrium line, stages are determined by Equation (13.9) or by stepping graphically. For the curved (approximate actual) line, stages are stepped off as shown in Figure 13.11:

1. For the straight line at 25°C: stages = 5.6
2. For the straight line at 31°C: stages = 9.8
3. For the actual curve: stages = 7.1

Clearly, the equilibrium line based on the outlet temperature (31°C) requires excessive stages—but neglecting heat effects is too optimistic. The design of 7.1 stages would be used.

The Kremser–Brown relationship [Equation (13.8)] can be modified for stripping:

$$E_{si} = \frac{X_{N+1} - X_1}{X_{N+1} - X_o^*} = \frac{S_i^{N+1} - S_i}{S_i^{N+!} - 1} \tag{13.21}$$

where

E_{si} = stripping efficiency of component i
X_{N+1} = moles i per mole of solute-free liquid, entering (top) condition
X_1 = moles i per mole of solute-free liquid, exiting (bottom) condition
X_o* = moles i per mole of solute-free liquid, determined as in equilibrium with i in the entering stripping gas
N = required theoretical stages
S_i = stripping factor for component $i = (V K_i)/L' = 1/A_i$
V/L' = vapor/liquid molar ratio

The gas and liquid concentrations in capitals are the same as those defined by Equations (13.10) and (13.11).

The stages needed to achieve a given degree of stripping are obtained from a counterpart of Equation (13.9):

$$N = \frac{\ln\left(\dfrac{E_{si} - S_i}{E_{si} - 1}\right)}{\ln S_i} - 1 \tag{13.22}$$

The most prevalent stripping gases are steam and air (or nitrogen). Thousands of air strippers are used to purify contaminated groundwaters, and many steam strippers are used to purify contaminated process aqueous wastes as well as groundwaters.

For the more concentrated feed liquids, such as those found in petroleum refinery stripping operations, the Edmister method [Equations (13.15) through (13.20)] are modified as follows (see Figure 13.10):

$$E_{si} = \frac{X_{N+1} - X_1}{X_{N+1}} = \left[1 - \frac{V_o Y_o}{S' L_{N+1} X_{N+1}}\right]\left[\frac{S_e^{N+1} - S_e}{S_e^{N+1} - 1}\right] \tag{13.23}$$

$$S' = \frac{S_N (S_1 + 1)}{S_N + 1} \tag{13.24}$$

$$S_e = \sqrt{S_N (S_1 + 1) + 0.25} - 0.50 \tag{13.25}$$

$$S_N = \frac{V_N K_N}{L_N} \tag{13.26}$$

$$S_1 = \frac{V_1 K_1}{L_1} \tag{13.27}$$

$$V_N = V_{N-1}\left(\frac{V_N}{V_o}\right)^{1/N} \tag{13.28}$$

13.2.2.1 Minimum Stripping Gas Rate

An infinite number of stages will be required if the exit gas and the entering liquid approach equilibrium, i.e., $Y_N \sim K X_{N+1}$. It is recommended that a stripping gas rate of about twice the minimum be considered first. However, for once-through air strippers, where the stripping gas has no cost other than the energy needed to move it through the stripper, an optimum *V/L* ratio may depend on some trade-off of blower horsepower and height of contactor.

Equipment Design

Plate columns for absorption and stripping are fairly standard in design, with the plates perforated to allow gas to pass upward and provisions for conveying liquid from a plate to the next plate below. Figure 13.12 shows an absorber of this type, which utilizes simple sieve trays for contacting. Only the rudiments of designing such a contactor will be given here; see Chapter 12 for more details. Predicting the performance of a plate absorber or stripper involves the following key elements:

(a) Capacity. This dictates the diameter of the needed column and is a function of the plate geometry, the vertical spacing of the plates, and the flow rates of liquid and gas.
(b) Pressure drop. This is a function of flow rates and plate geometry and is particularly important for large gas flows where blower horsepower may be an important element in the economics of system design.
(c) Efficiency. The foregoing discussions of absorption and stripping stages have led to a determination of theoretical stages or plates. For a practical design, a plate efficiency is needed to determine the number of *actual* plates needed in the column. The discussion on plate efficiency will follow.
(d) Liquid holdup. The amount of liquid present on the trays has implications for control system design; the more the holdup, the less responsive the column is to changes in control variables. It may be particularly important for chemical absorbers where a degree of residence time of the liquid is needed to complete the absorption/reaction. This is discussed further in a separate section on "Chemical Absorption/Stripping."

Problem 13.4

A contaminated groundwater stream contains 5 mg/L trichloroethylene (TCE) and 1.5 mg/L perchloroethylene (PCE) at 21°C. The stream is fed to the top of a tray column, where it is stripped with a countercurrent flow of air, also at 21°C.

(a) Calculate the minimum air rate needed (using infinite stages).
(b) For a molar feed-air ratio of 10.0, how many stages are needed to remove 99.8% of the TCE?
(c) What percentage of the PCE will be removed in the process?

Solubility data for PCE and PCE are given in Figure 13.4. Use $K = 6753$ for TCE and 61,790 for PCE.

Solution

The inlet composition of TCE may be converted to a mole fraction of $6.85(10^{-7})$. The equilibrium exit gas concentration is $6753(6.85)(10^{-7}) = 0.00463$ moles TCE per mole of air + TCE, or a

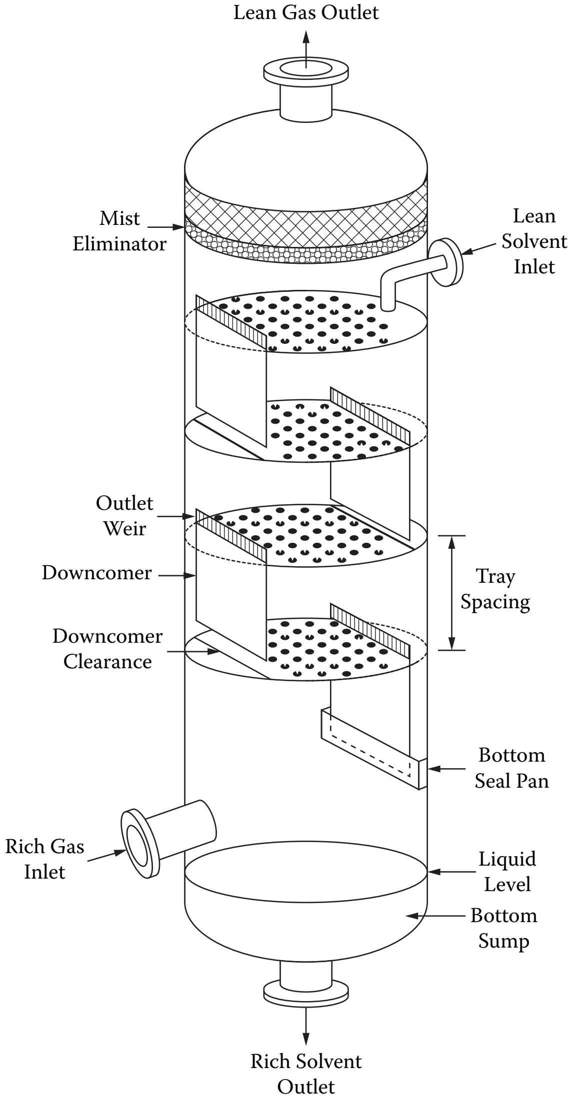

FIGURE 13.12 Plate-type absorber.

minimum air rate of 0.1465 moles/1000 moles feed. The design ratio of 100 is far greater than the minimum, and is based on field experience of optimum operation.

The stripping factor at the bottom is VK/L = (6753)/100 = 67.53. Because of the very dilute feed, the stripping factor changes very little across the column. By Equation (13.22),

$$N = \frac{\ln\left(\dfrac{0.998 - 67.53}{0.998 - 1.000}\right)}{\ln 67.53} - 1 = 1.47 \text{ stages}$$

For PCE, S_{avg} = 67.53(61790/6753) = 618. By Equation (13.22), 100% of the PCE is stripped.

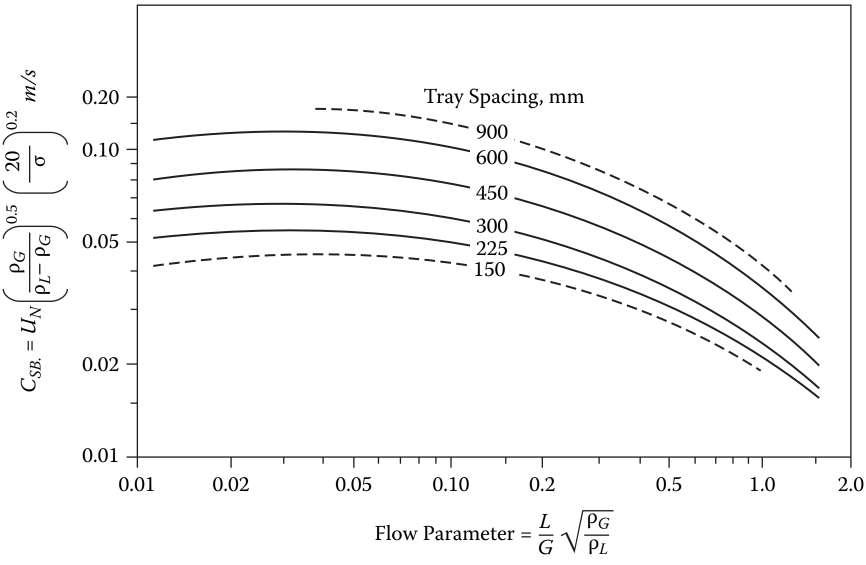

FIGURE 13.13 Capacity of plate-type absorbers and strippers. Curves denote the incipient flooding condition, and for design must be discounted. [Fair, J. R., 1961. *Petro/Chem. Engineer* 33 (9): 57.]

13.2.2.2 Capacity and Column Diameter

The maximum allowable capacity of a plate absorber or stripper is represented by an incipient flooding condition. The prudent operating capacity is based on about 85% of the predicted flooding condition. The first step is to calculate the dimensionless *flow parameter* for the point in the column being investigated:

$$FP = \frac{L}{G}\sqrt{\frac{\rho_G}{\rho_L}} \tag{13.29}$$

where L/G is the mass ratio of liquid to gas. This parameter is a high number for the typical high L/G ratios encountered in absorbers and strippers, but there are notable exceptions (e.g., the use of glycols to scrub water out of natural gas) where the L/G is extremely low. The allowable gas velocity for a given flow parameter is obtained from Figure 13.13,[21] making use of the geometrical relationships shown in Figure 13.14.

The value of FP is obtained directly from the overall material balance. For a selected tray spacing (usually 18 in (457 mm) of 24 in (610 mm) and FP as the abscissa, a value of the ordinate is obtained. This is the capacity parameter C_{sbf} at the maximum (flood) capacity. The ordinate value is

$$C_{sbf} = U_N\left[\frac{\rho_G}{\rho_L-\rho_G}\right]^{0.5}\left[\frac{20}{\sigma}\right]^{0.2} \tag{13.30}$$

where U_N = linear gas velocity through the net area of the tray, i.e., through the cross section open to flow, considering the space blocked off by the downcomer(s), and σ = the surface tension of liquid in mN/m.

Since $U_N = U_s\,(A_T/A_N)$, the superficial gas velocity is calculated as

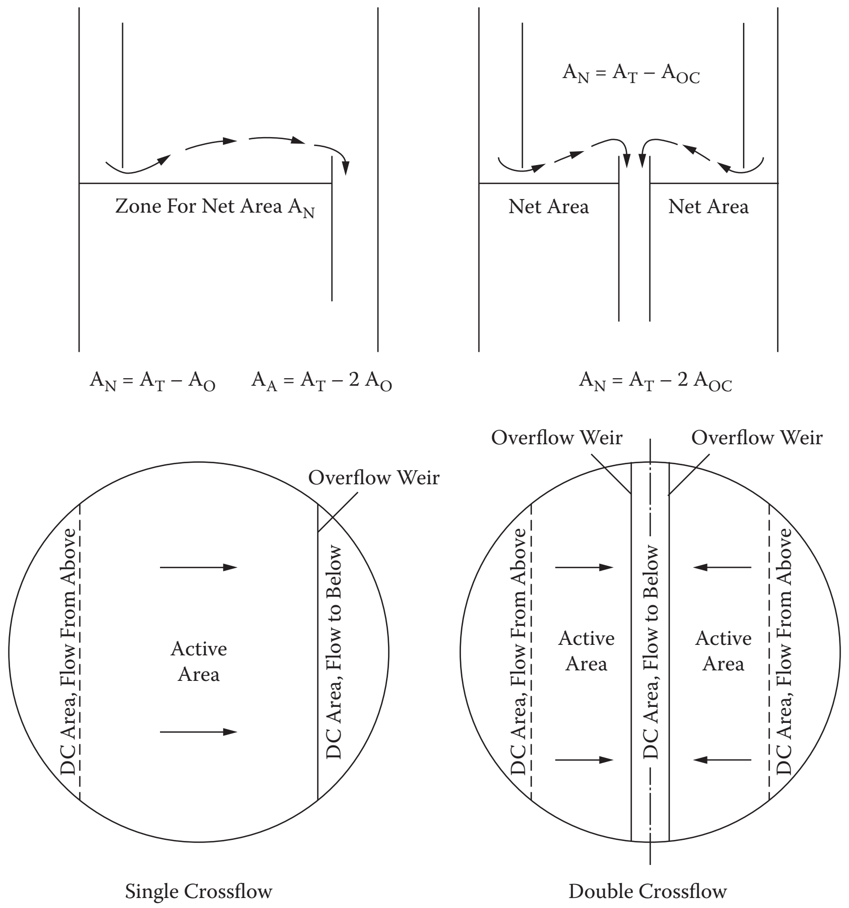

FIGURE 13.14 Geometrical relationships for plate-type absorbers and strippers. Liquid flows across the plates.

$$U_s = \frac{0.85\, C_{sbf}}{\dfrac{A_T}{A_N}\sqrt{\dfrac{\rho_G}{\rho_L - \rho_G}}\left[\dfrac{20}{\sigma}\right]^{0.2}} \tag{13.31}$$

so that

$$col.\ diam. = \sqrt{\frac{vol.\ flow\ of\ gas}{0.785\, U_s}} \tag{13.32}$$

Multiple pass trays are handled in the same fashion (see Figure 13.14); one should recognize that geometric variables are different for successive trays.

13.2.2.3 Pressure Drop

The total pressure drop through the column, in terms of liquid head, is

$$h_{total} = N_{act}(h_t) \tag{13.33}$$

where

h_{total} = drop through all the plates, in height of the flowing solvent
N_{act} = number of actual plates
h_t = pressure drop across a single plate

Equation (13.29) does not cover losses such as gas entrance, drop through a demister at the top of the column, and so on.

The pressure drop across the plate comprises two resistances in series, one for friction through the perforations and the other for head loss in flowing through the aerated liquid on the tray:

$$h_t = h_d + h_L, \text{ mm liquid} \tag{13.34}$$

For the perforations, the orifice equation applies:

$$h_d = \frac{50.8}{C_v^2}\frac{\rho_G}{\rho_L}U_h^2 \tag{13.35}$$

where

C_v = orifice coefficient, dimensionless
U_h = gas velocity through the holes

Typically, the area of the holes is 6 to 8% of the total cross-sectional area. The orifice coefficient is about 0.8, but for more precise work, consult Chapter 12, "Distillation." The drop through the aerated liquid depends on the loading of the plate, and Figure 13.15 enables an estimate of the height of the two-phase mixture (i.e., froth). This mixture is typically 80% gas by volume, so the froth height times 0.2 will give the equivalent height of clear liquid for use in Equation (13.30).

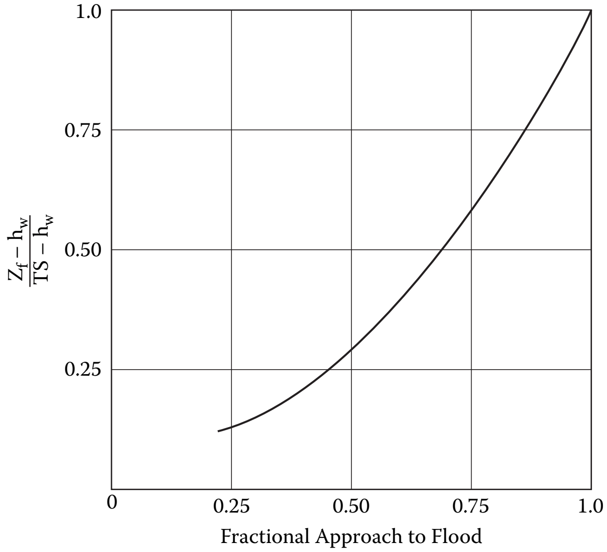

FIGURE 13.15 Chart for estimating the height of froth on a crossflow plate.

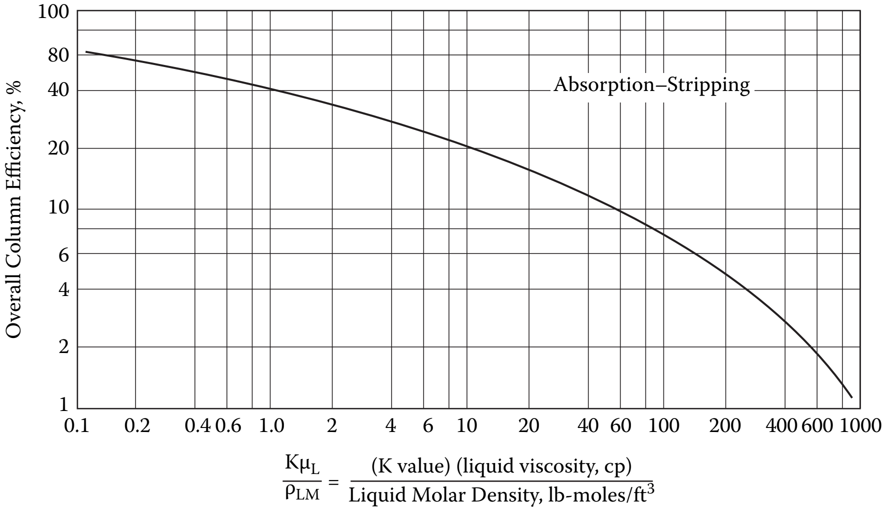

FIGURE 13.16 Chart for estimating efficiency of plate-type absorbers and strippers. [H. E. O'Connell, 1946. *Trans. AIChE* 42: 741.]

13.2.3 Stage Efficiency

In Sections 13.1 and 13.2, methods are given for the estimation of the number of theoretical stages required for a specified separation. The number of actual stages, or plates, is computed from an average plate efficiency for the overall column:

$$E_{oc} = \frac{theoretical\ stages}{actual\ plates} \times 100 \tag{13.36}$$

This efficiency term actually comprises a number of component efficiencies, and for meticulous work, it may be necessary to take them into account. Methods given in Chapter 12 can be used for this purpose, since the mass transfer mechanisms for absorption and stripping are the same as those for distillation.

Figure 13.16, from O'Connell,[22] may be used for preliminary designs—and often for final designs. It relates overall column efficiency to the equilibrium ratio K, the solvent phase viscosity, and the molar density of the solvent phase.

Problem 13.5

In Problem 13.3, 7.1 actual stages were required to remove a certain amount of acetone from wet air. What are the column diameter, pressure drop, and actual number of stages if the airflow rate is 35,300 actual ft^3/min (1000 actual m^3/min)? A tray spacing of 24 in (610 mm) will be used. Weir height = 50 mm.

Data: Liquid density = 1000 kg/m^3; gas density = 1.15 kg/m^3; liquid viscosity = 1.0 cp; surface tension = 70 mN/m.

Solution

Use bottom conditions, since in that zone both liquid and gas flows are greatest. The temperature is taken as an average of the entering gas and the exit liquid = 33°C. The operating line has a slope of 3.49 in molar units, or 3.49 (18/29) = 2.17 in mass units. The flow parameter FP = $2.17[1.15/1000]^{0.5}$ = 0.074.

Diameter. From Figure 13.13, C_{sbf} = 0.13 m/s. At 85% of flood, C_{sb} = 0.85(0.13) = 0.11 m/s. Use downcomer area = 10% of the total cross section so that A_T/A_N = 1.11. From Equation (13.31),

$$U_s = \frac{0.11}{1.11\sqrt{\dfrac{1.15}{1000-1.15}}\left[\dfrac{20}{70}\right]^{0.2}} = 3.75\,\text{m/s}$$

From Equation (13.32), diameter = $[1000/(60 \times 0.785 \times 3.75)]^{0.5}$ = 2.38 m = 7.80 ft.

Efficiency. For Figure 13.16, the abscissa group at the bottom of the column is $(K\mu_L)/\rho_{LM}$, or (2.8 × 1.0)/(62.4/18) = 0.81, for which E_{oc} = 40%. Thus, 7.1/0.40 = 17.8—say 18 actual plates.

Pressure drop. For an open area (A_H/A_A) = 0.14 and 10% downcomers, the active area is $0.785(2.38)^2(0.80) = 3.56\ \text{m}^2$ and hole area = 0.498 m². From Equation (13.35) and for one tray,

$$h_d = \frac{50.8(1.15)\left[\dfrac{1000}{60(0.498)}\right]^2}{(0.80)^2(1000)} = 102.2\ \text{mm liquid} = 4.02\,\text{in liquid}$$

For pressure drop through the liquid at 85% flood, from Figure 13.15,

$$\text{Froth height} = Z_f = 0.75(610 - 50) + 50 = 470\ \text{mm}$$

At 20% liquid in froth, liquid head = 0.2(470) = 94 mm.

Total drop/tray = 102.2 + 94 = 196 mm liquid. For 18 plates, 3528 mm = 3.528 m = 5.0 lb/in².

13.3 PACKED COLUMNS

As in distillation columns, a packed column contains small packing elements dumped into the column in a random fashion, and these elements can provide the needed intimate contacting of the descending liquid and the rising gas or vapor. Packings of an ordered, or structured, form are rarely if ever used for absorption or stripping.

13.3.1 Transfer Units

Instead of stages or plates, *transfer units* are introduced to represent the separation requirement of a continuous, countercurrent contactor such as a packed column. As will be shown later, theoretical stages can be converted to transfer units for design purposes. Thus, only a summary of transfer unit theory will be given here, since it is usual practice to determine the required stages, as discussed in the previous section, and then convert them to transfer units. The conversion is in order because the mass transfer characteristics of packings are usually correlated in terms of heights of a transfer unit. Thus,

$$\text{Packed height} = Z = N_{og}H_{og} \tag{13.37}$$

where N_{og} = number of overall (both phases considered) transfer units and H_{og} = height of an overall transfer unit.

Overall transfer units may be expressed in terms of individual phase transfer units:

$$H_{og} = H_g + \lambda H_L \tag{13.38}$$

$$\frac{1}{N_{og}} = \frac{1}{N_g} + \frac{\lambda}{N_L} \tag{13.39}$$

where λ is the ratio of slopes, equilibrium line to operating line, for the transferring component *i*:

$$\lambda_i = \frac{dy_i^* / x_i}{(L/V)_{total,molar}} = \frac{m_i}{L/V} \tag{13.40}$$

The λ term is equivalent to the stripping factor defined earlier. When the equilibrium line is essentially straight (e.g., as in Figure 13.9) and for dilute cases, λ is constant.

13.3.2 Number of Transfer Units

According to basic relationships, not included here,* the overall number of gas-phase transfer units is defined as

$$N_{og,i} = \int_{y_{i2}}^{y_{i1}} \frac{dy_i}{y_i - y_i^*} \tag{13.41}$$

where y_i is the mole fraction of *i* in the gas and y_i* is the mole fraction of *i* in the gas that would be in equilibrium with bulk liquid composition x_i. Note that y_i* is not a real composition but rather a calculated term from the equilibrium expression $y_i^* = K_i x_i$. The subscripts 1 and 2 for the gas composition refer to the inlet and outlet conditions. If a stage model is being used to compute the separation, theoretical stages can be converted to transfer units by the relationship

$$N_{og} = N_{theo}\left(\frac{\ln\lambda}{(\lambda-1)}\right) \tag{13.42}$$

Note that when λ = 1.0, $N_{og} = N_{theo}$.

As in the case of absorption factors with stages, each component can have its individual number of transfer units.

13.3.3 Heights of Transfer Units

For systems with significant mass transfer resistance in both phases, Equation (13.38) is used. Values of H_g and H_L are usually obtained from generalized correlations supported by experimental work but can be expressed in terms of more fundamental relationships:

$$\text{Gas: } H_{gi} = \frac{G_m}{k_{gi}\, a_e\, P(1-y_i)} \tag{13.43}$$

* Detailed development of relationships for packed columns is included in mass transfer texts such as that of Hines and Maddox.[22a]

where

G_m = total gas flow, kg-moles/s–m^2
k_{gi} = mass transfer coefficient, kg-moles/(s-m^2-atm)
a_e = effective interfacial area, m^2/m^3
P = total pressure, atm

$$\text{Liquid: } H_{Li} = \frac{L_m}{k_{Li}\, a_e\, \rho_L \left(1 - x_i\right)} \tag{13.44}$$

where

L_m = total liquid flow, kg-moles/s-m^2
k_{Li} = mass transfer coefficient, kg-moles/(s-m^2-kg/m^3)
ρ_L = average liquid density, kg/m^3

In Equations (13.43) and (13.44), the units shown are representative; other consistent sets may be used.

13.3.4 Heights of Theoretical Stages

There are instances when it is preferable to convert from heights of transfer units to theoretical stages. The term *height equivalent to a theoretical plate (HETP)* is used. This is the height of a packed bed in which one theoretical stage of separation is achieved. The conversion is related to Equation (13.42):

$$HETP = H_{og}\left(\frac{\ln\lambda}{\left(\lambda - 1\right)}\right) \tag{13.45}$$

Thus, when $\lambda = 1.0$, $HETP = H_{og}$.

13.3.5 Equipment Design

Packed columns for absorption and stripping are simple in design, if not in analysis. A vertical column is fitted with a packing support plate, filled with random packing, and equipped at the top with a suitable device to distribute the liquid to the bed. A screen or hold-down grid is usually placed on top of the bed to prevent movement of the packing, especially if the packing material has a low density (e.g., plastic) and the momentum of the gas is high. In a few cases, a special device at the bottom of the bed is used to ensure uniform gas distribution up through the bed. A representative packed absorber is illustrated in Figure 13.17; the liquid distributor is of the perforated pipe type, but other types, less subject to liquid fouling, can be used. See Chapter 12.

Problem 13.6

In Problem 13.3, theoretical stages were determined for a scrubber to remove acetone from air with a water solvent. For the same conditions, determine the required number of overall gas phase transfer units. The graphical work for the previous problem is shown in Figure 13.11.

Solution

Since this is a lean gas case, simplified expressions can be used. The number of gas phase transfer units can be obtained by integrating Equation (13.41), or from theoretical stages by Equation

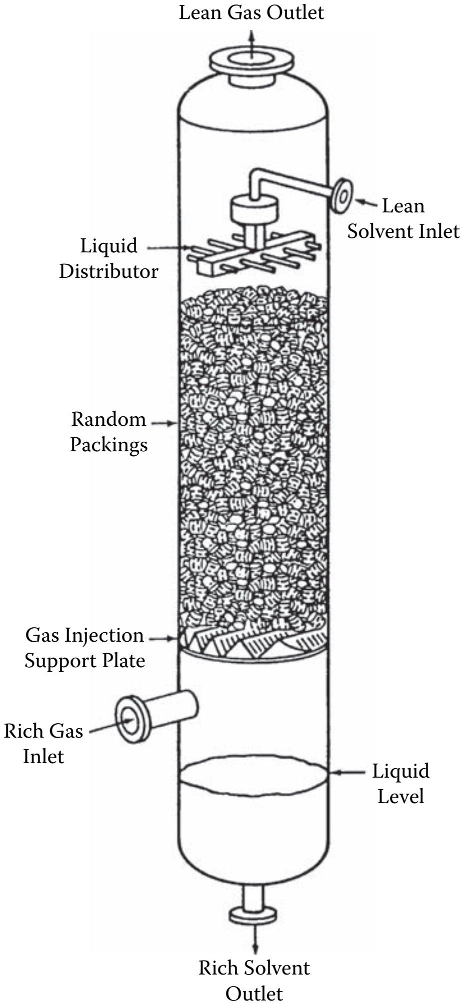

FIGURE 13.17 Packed-type absorber.

(13.42). Since the theoretical stage requirement is available from Problem 13.3, the stage conversion approach will be used first.

For the lower equilibrium line (K = 2.09), the value of λ is calculated as follows:

$$\lambda = \frac{m}{L/V} = \frac{2.09}{3.49} = 0.599$$

From Equation (13.42),

$$N_{og} = 5.6\left(\frac{\ln 0.599}{0.599-1}\right) = 7.16 \text{ transfer units}$$

Similarly, for K = 2.79, N_{og} = 11.4 transfer units.

For the intermediate case, where there is significant curvature of the equilibrium line, Equation (13.41) can be integrated over the range of y values from 0.005 (top condition) to 0.020 (bottom

condition). This can be done numerically or graphically. For the latter approach, values of $1/(y - y^*)$ are plotted on the Y scale against value of y on the X scale. The area under the plotted curve equals 8.2 (or 8.2 transfer units).

Since there is definite curvature of the equilibrium line, the value $N_{og} = 8.2$ should be used. It can be combined with a value of H_{og} for the packing device selected to provide the total packed height needed.

As in the case of tray absorbers and strippers, only the rudiments of design will be given here; more details are available in Chapter 12. Predicting the performance of a packed column involves four key criteria: capacity (column diameter), pressure drop (column diameter), efficiency (bed height), and liquid holdup (pressure drop and residence, as for chemical reactions). Each of these criteria depends strongly on the type and size of packing element selected. Thus, the first step is to choose a packing.

13.3.6 Packing and Packed Bed Characteristics

Representative random packings are shown in Figure 12.25. Properties of important packings for absorption/stripping are given in Table 13.2. The first three packings listed are the "through-flow" type, in which the phases can flow freely through the elements with reduced form drag. The others listed are of the "around flow" type, with increased form drag and therefore higher pressure drop.

Random packings are fabricated from a wide variety of materials. Originally, most were made of ceramic and were popular for corrosive services despite their friability. Today, polypropylene is widely used to provide a bed that offers light weight, reasonable resistance to corrosion by many fluids, and low cost. Plastic random packings are often suitable where dissolved volatile organic compounds (VOCs) are to be removed from groundwaters.

Normally, liquid and gas flow countercurrently through the bed. At low gas rates, there is little disturbance of the downflowing liquid, but at higher gas rates the liquid is dragged by the vapor into a "loading" situation, and, if the gas flow is further increased, the packed bed begins to flood. Loading/flooding phenomena are shown schematically in Figure 12.51. While it may be optimum to operate a packed column in the loading zone, it is important not to operate too close to flooding. Thus, as a first consideration in design (or analysis of an operating column), the flood point is located as a function of gas and liquid flow rates, packing element geometry, and properties of the phases.

13.3.7 Maximum Gas/Liquid Capacity

The hydraulic flood point, as illustrated in Figure 12.51, is reached at a combination of countercurrent gas and liquid rates such that the pressure drop exhibits a relatively large increase with a small increase in flow rate of either phase. Methods for estimating maximum hydraulic capacity for a packing provide a basis for design (optimum approach to flood). Although there are several approaches to predicting flooding, the most popular also provides a pressure drop estimating capability, most recently published by Strigle[23] as the diagram in Figure 12.53.

From Figure 12.53, both limiting capacity and pressure drop may be predicted. The abscissa term is the flow parameter [Equation (13.29)], used also for plate columns. The ordinate term is a capacity parameter CP, modified from the capacity parameter for plate columns [Equation (13.30)]:

$$CP = U_S \sqrt{\frac{\rho_G}{\rho_L - \rho_G}} F_p \, \upsilon^{0.05} = C_{sb} \, F_p \, \upsilon^{0.05} \tag{13.46}$$

where U_S = superficial gas velocity, m/s; ν = kinematic viscosity, cs; and F_p = packing factor, characteristic of the packing type and size. Packing factors are given in Table 13.2.

For flooding, an estimate can be made from Figure 12.53, although manufacturers often like to omit the flood line from the chart. Maximum throughput is assumed to occur at the top curve (125 mm H_2O/m), although slightly more capacity is sometimes available. The presumption that flooding occurs at a constant value of pressure drop is not necessarily correct, since the more open-type packings flood at lower pressure drops. Also, flooding occurs at lower pressure drops under high liquid loadings and gas densities for a given packing.

13.3.8 Pressure Drop

Prediction of pressure drop is handled by Figure 12.53 for all but the most critical designs. A more fundamental, and more complicated, method has been developed by Stichlmair and coworkers.[24,25] Diagrams of the Strigle type are available for individual packings (thus eliminating the need for the packing factor) in Kister[26]. Finally, estimates of pressure drop can be obtained from graphs developed by the vendors of the packings. Figure 13.18 shows data for a particular packing, including liquid holdup and a mass transfer coefficient. The bases for information such as in Figure 13.18 should be understood. The basic tests were made with air-water in a column with a diameter of about 1 m. Holdup was measured by abruptly shutting off air and water flow and then collecting the water that drained from the bed. The mass transfer coefficient is on an overall (including gas and liquid resistances) basis, using carbon dioxide absorption in dilute aqueous sodium hydroxide. Since many absorption and stripping applications involve gases and liquids with properties not far different from those of air and water, the vendor charts can be quite useful.

13.3.9 Liquid Distribution and Redistribution

This topic is discussed in detail in Chapter 12, and only a brief summary is included here. Good initial liquid distribution to the packed bed is essential for good performance. This is done by introducing the liquid through a distributor device that provides a multiplicity of small, uniform streams to the bed. A minimum of 100 separate streams per sq. m. is needed. If a random packing without through-flow characteristics is needed, fewer streams can be accommodated, since the packing itself tends to provide uniform distribution.

Once the liquid has been introduced to the top of the bed, it is possible for the uniformity of the liquid to deteriorate—for example, to migrate toward the wall of the column. For beds greater than 10 m high, it may be necessary to collect the liquid and redistribute it for further flow down the bed. If redistribution is not used, then the loss of mass transfer efficiency must be taken into account. In some cases, the optimum design does not call for redistribution, even for bed heights much greater than 10 m.

13.3.10 Mass Transfer

Several methods have been proposed for predicting values of H_g and H_L as functions of system, flow conditions, and packing type. While the Bolles/Fair[27] random packing method has a broad validation, most of the supporting data are from distillation tests. It is described in Chapter 12. A better model for absorption is based on the work of Onda et al.,[28] as modified by Bravo and Fair,[29] and is detailed below. For the gas mass transfer coefficient,

$$k_g = \frac{5.23\ a_p D_g}{RT}\left(\frac{G}{a_p \mu_g}\right)^{0.7}\left(\frac{\mu}{\rho D}\right)_g^{1/3} \tag{13.47}$$

This equation represents the usual functional relationship between the dimensionless groups (Sherwood, Reynolds, and Schmidt numbers) plus the assumption that the effective packing element

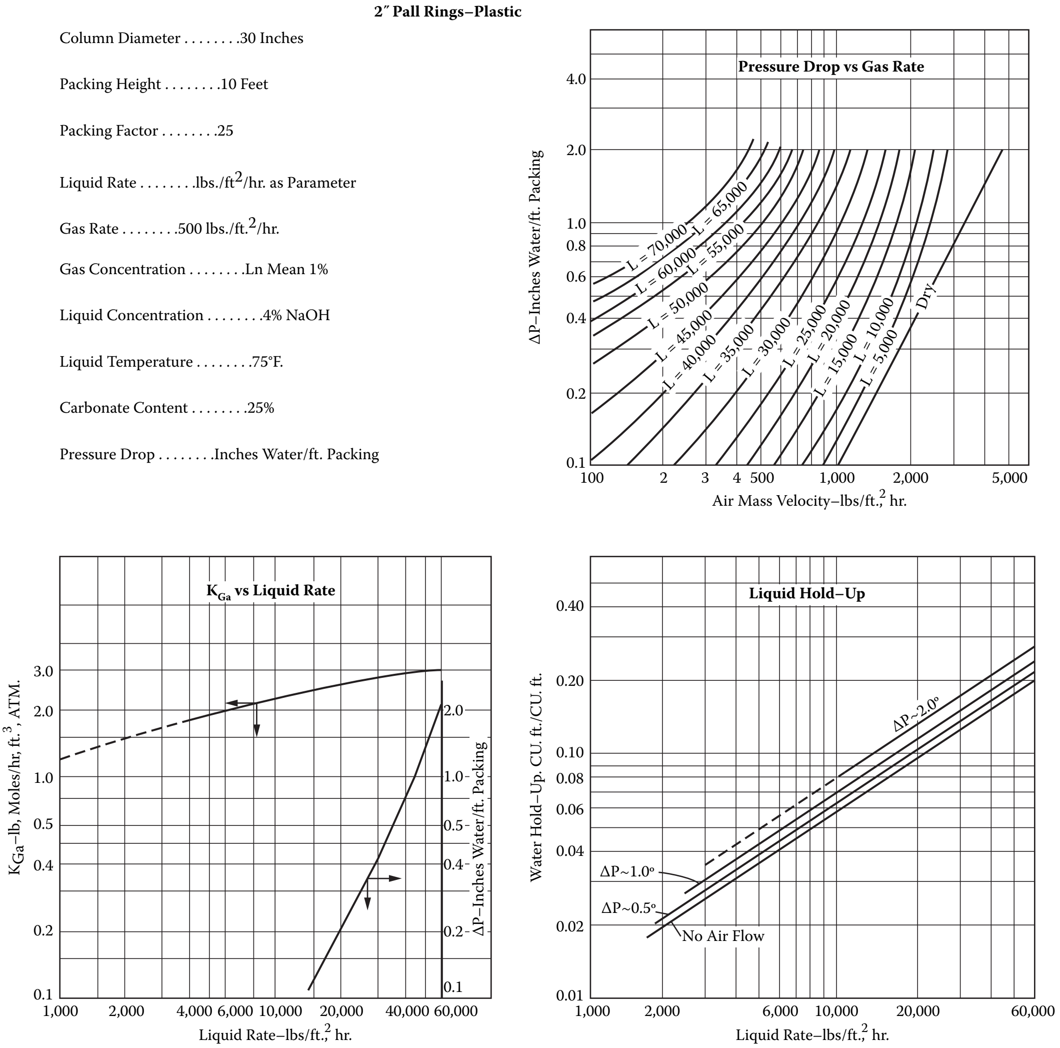

FIGURE 13.18 Representative vendor information on the characteristics of a random packing. Two-inch plastic Pall rings.

diameter can be expressed as the diameter of a sphere with the same surface area, i.e., $d_p = 6/a_p$. Values of packing surface area a_p may be obtained from Table 13.2 or equivalent listings.

For the liquid coefficient, Onda et al. departed from more usual formulations to obtain

$$k_L = 0.010\left(\frac{g\mu_L}{\rho_L}\right)^{1/3}\left(\frac{L}{a_e\mu_L}\right)^{2/3}\left(\frac{\rho D}{\mu}\right)_L^{1/2} \tag{13.48}$$

where a_e is an effective interfacial area.

For absorption and stripping, Bravo and Fair[29,30] found the effective area to be

$$a_e = 9.79\, a_p\left(\frac{\sigma^{0.5}}{Z^{0.4}}\right)\left(Ca_L \mathrm{Re}_G\right)^{0.1603} \tag{13.49}$$

* Through-flow packing.

where

σ = surface tension, kg/s (0.001 • dynes/cm)

Z = bed height (or height between distributor and redistributor), m

Ca_L = dimensionless capillary number for liquid = $\dfrac{\mu_L L}{\rho_L \sigma}$

Re_G = dimensionless Reynolds number for gas = $6G/(a_p \mu_G)$

The units of the liquid mass transfer coefficient k_L are m/s; of the gas coefficient k_g, kg-moles/(s-m²-atm). Note that in Equation (13.47), the specific packing area a_p is used, whereas in Equation (13.48), the effective area a_e is used. The two terms are related by Equation (13.49).

The procedure for using the Onda–Bravo approach is as follows:

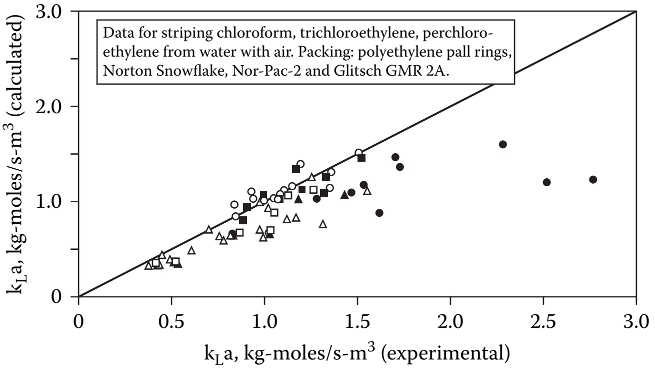

FIGURE 13.19 Parity plot for calculated vs. measured mass transfer coefficients, air-stripping of volatile organic compounds from water with air.

1. For the flow rates and properties, compute the effective area by Equation (13.49).
2. Calculate mass transfer coefficients k_G and k_L by Equations (13.47) and (13.48).
3. Compute heights of transfer units H_G and H_L by Equations (13.43) and (13.44), using volumetric mass transfer coefficients $k_g a_e$ and $k_L a_e$.
4. Compute overall H_{og} by Equation (13.38).
5. Multiply H_{og} by N_{og} to obtain required packed height, or
6. Convert H_{og} to HETP by Equation (13.45) and multiply by theoretical stages to obtain required packed height.

Problem 13.7 illustrates the procedure.

This model has been applied successfully to random packings of the ring and saddle type, in ceramic, steel, or plastic materials. A parity plot for tests of air-stripping of VOCs from water with air is shown in Figure 13.19, taken from reference 30. Several plastic packings were used. For details of the experiments, as well as use of the original Onda equations, see reference 31.

The Onda–Bravo approach has been found especially reliable for absorbers and strippers operating with lean mixtures, as is usually the case. For more concentrated cases (inlet gas > 5 vol-% solute for absorbers and inlet liquid > 5 vol-% solute for strippers), the Bolles/Fair[27] model is more appropriate.

13.4 OTHER DEVICES

While tray columns and packed columns are invariably the devices used for stripping, other devices are occasionally used for absorption or scrubbing. These are often proprietary, and the vendor does the design based on the specifications provided by the user and/or process designer. While the foregoing material is based on countercurrent contacting of gas and liquid, there may be some instances when cocurrent operation has advantages:

1. Throughput capacity is great, since flooding does not occur in the usual sense.
2. Pressure drop is lower than countercurrent.
3. Removal of solid particulates from the gas is favorable.

Problem 13.7

For Problem 13.4, a contaminated groundwater stream is used to illustrate the computation of theoretical stages. Now a stripping column is to be dimensioned based on the same removal of

trichloroethylene (TCE) and perchloroethylene (PCE) at ambient pressure (1.0 atm) and temperature (21°C). A higher gas/liquid ratio will be used to reduce the number of stages. The packing is to be 50-mm polypropylene Pall rings. Properties are given in Table 13.3. The material balance is to be as follows:

	Flows in kg/s:			
	Feed liquid	**Feed air**	**Exit liquid**	**Exit air**
Air	—	5.09	—	5.09
TCE	1.579E–04	—	1.579E–06	1.563E–04
PCE	4.737E–04	—	0	4.737E–04
Water	31.57	—	31.40	0.17

For 50-mm plastic Pall rings, a_p = 130 m^2/m^3 and F_p = 131 m^{-1} (Table 13.3).

(a) Column diameter

$$\text{Flow parameter} = \frac{L}{G}\sqrt{\frac{\rho_g}{\rho_L}} = \frac{31.57}{5.09}\sqrt{\frac{1.234}{1000}} = 0.218$$

From Figure 12.53, for ΔP = 85 mm H_2O/m (1.02 " H_2O/ft) and FP = 0.218, $C_{sb}F_p\nu^{0.05}$ = 0.65 (metric)

From which, $C_{sb} = 0.65/[(131)^{0.5}\ (1.0)] = 0.057$

Superficial velocity of gas = $0.057[1000/1.234]^{0.5}$ = 1.63 m/s

For the design air rate of 5.09 kg/s = 4.12 m^3/s, the cross section is 2.40 m^2, and rounding,

Column diameter = 1.75 m, Column cross section = 2.54 m^2

(b) Effective area

Assume a packed height of 10 ft (3.05 m)

For A_t = 2.54 m^2, L = 31.57/2.54 = 12.43 $kg/s\text{-}m^2$, G = 5.09/2.54 = 2.00 $kg/s\text{-}m^2$.

From Equation (13.49), $a_e/a_p = 9.79[0.070^{0.5}/3.05^{0.4}][(14.6E{-}06 \bullet 12.43)(2637 \bullet 2.00)]^{0.1603} = 1.65$.

Thus, a_e = 1.65 (130) = 215 m^{-1}.

(c) Transfer coefficients

[Equation (13.48)]

$$k_L = 0.0306\left(\frac{9.81(1.02(10^{-3}))}{1000}\right)^{1/3}\left(\frac{31.57}{2.54(130)(1.02)(10^{-3})}\right)^{2/3}\left(\frac{1}{1150}\right)^{1/2} = 1.30(10^{-3})\ \text{m/s}$$

[Equation (13.47)]

$$k_G = \frac{0.145(130)(8.2)(10^{-6})}{(0.082)(294)}\left(\frac{2.00(10^5)}{(130)(1.75)}\right)^{0.7}(1.73)^{1/3} = 8.84(10^{-4})\frac{kg\,moles}{s-m^2-atm}$$

[Equation (13.43)]

$$H_g = \frac{2.00}{(29)(8.84E-04)(215)(1.0)(1.0)} = 0.363\ m$$

[Equation (13.44)]

$$H_L = \frac{12.43}{18(1.30)(10^{-3})(215)(1000)(1.0)} = 2.47(10^{-3})m \quad \lambda = \frac{m}{L_m/V_m} = \frac{6753}{0.691/0.0690} = 675$$

$$H_{og} = H_g + \lambda\, H_L = 0.363 + 675(2.47(10^{-3})) = 0.363 + 1.667 = 2.03\ \text{m}$$

The stripping factor is 675 (same as λ). By Equation (13.22), 0.71 theoretical stages are needed.

By Equation (13.42), this translates to N_{og} = 0.0066, and $Z = N_{og}H_{og}$ = 0.013 m. Thus, for the relatively high gas/liquid ratio used, and for, say, 3.05 m bed height, the removal of TCE is far greater than 99%. In fact, it is greater than 99.999%. It is not unusual for a feed of, say, 20 parts per million to be purified to less than one part per billion by air stripping.

Figure 13.20 shows how a cocurrent absorber may be analyzed. Note the equilibrium limitation, which limits the degree of recovery of solute. Basic models for estimating hydraulics and mass transfer are based on countercurrent flow, which is normally more efficient, and must be adjusted if the gas flow direction is reversed.

Other contacting devices are shown in Figure 13.21 and discussed below.

13.4.1 Spray Chamber

This is the ultimate low-pressure drop device, since the energy for dispersion and contacting is pumped into the entering liquid. Spray contactors suffer from departure from countercurrent flow, due to the high degree of backmixing or circulation in the gas. Drop coalescence and migration of drops to the vessel wall compromise the effective area for mass transfer. The mass transfer rate is highest in the close vicinity of the spray nozzles. As shown in the figure, it is economical to use more than one level of spray nozzles, and for large diameter units, each level comprises a bank of nozzles. Heights of transfer units for commercial-scale spray chambers have been reported by Pigford and Pyle.[32] More than two or three transfer units usually cannot be achieved in a spray contactor, but those units are achieved at very low pressure drop.

Spray chambers are frequently used for scrubbing sulfur dioxide and solid particulates from stack gases. The nozzles can be designed to handle slurries, e.g., lime slurry fed to the stack gas scrubber.

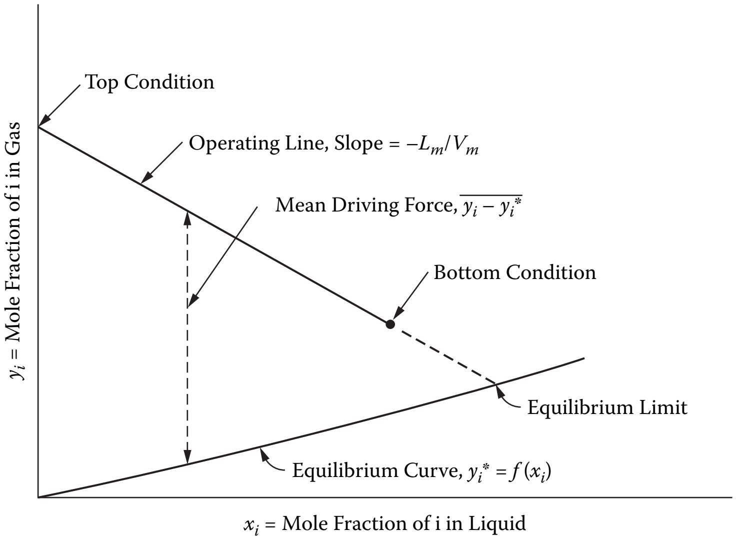

FIGURE 13.20 Calculation diagram for a cocurrent absorber.

13.4.2 Crossflow Scrubber

The gas flows horizontally, contacting by downflowing liquid. The effective driving force for mass transfer is between that for counter- and cocurrent contactors. Crossflow scrubbers have low pressure drop and usually require a lower liquid/gas ratio than either counter- or cocurrent scrubbers. The time of contact between gas and liquid is relatively low, and crossflow units are not recommended for most chemical absorptions. Design procedures follow a finite-element approach; the scrubber volume is divided into cubes, each of which is assumed to reach equilibrium.

13.4.3 Venturi Scrubber

This is a cocurrent scrubber with pressure drop advantages (venturi effect) and a high degree of turbulence at the point of contact. The equilibrium limitation as indicated in Figure 13.20 prevails. Venturi units have found applications for rapid reactions and for particulate removal. As shown in Figure 13.21, elaborate means for separating the effluent gas and liquid may be necessary.

13.5 STEAM STRIPPING

Steam stripping is used widely and differs from stripping with an inert gas (e.g., air) in that the vent gas can be condensed and the stripped liquids recovered by decantation or distillation. Thus, steam stripping can be used for removing VOCs and differs from air stripping in two important respects: steam is condensable, and the operating temperate is high, which reduces the solubility of the solute(s) in the feed liquid. Invariably, the feed is an aqueous solution, and the operating pressure can be varied over a wide range. An overall heat balance shows that there is a minimum rate of steam to prevent complete condensation (and thus no stripping) in the unit. A typical flow diagram for a steam stripper is shown in Figure 13.22. The steam can be extraneous (live steam) or generated in a reboiler as shown.

Steam stripping is often performed in plate columns since, in the past, few studies of mass transfer in packed columns have been made. A detailed study of stripping toluene from water in a 1.2-m diameter sieve tray column has been reported by Kunesh et al.[33] Earlier, Rush and Stirba[34] reported stripping methylisobutyl ketone (MIBK) from water in a 0.46-m sieve tray column.

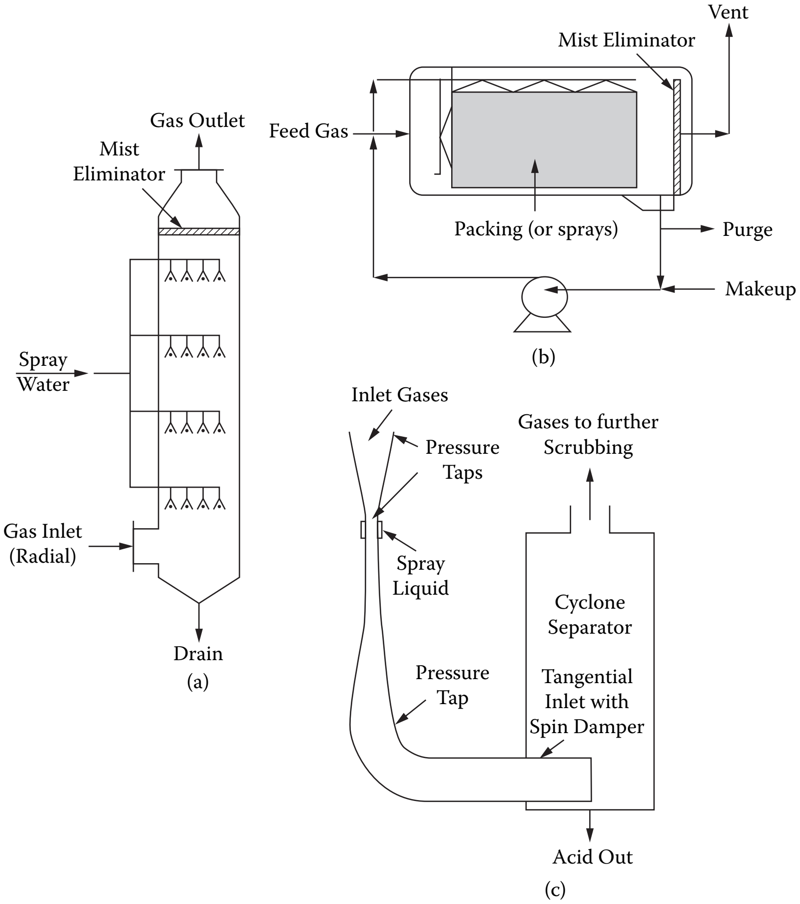

FIGURE 13.21 Representative vendor information on the characteristics of a random packing. Two-inch plastic Pall rings. [Courtesy of NorPro-Ste.Gobain Co., Akron, Ohio.]

Representative results from these studies are shown in Figure 13.23. The efficiencies tend to be low, and the liquid phase resistance dominates. Fair and Harvey[35] found that a slight modification of the Chan–Fair model[36] could be used for steam stripping (Figure 13.24).

While packed steam strippers are not widely used, there is no reason why they should not be. Performance data for such strippers are limited, however. Because of the temperature levels, metal pickings would normally be specified. Kolev et al.[37] studied chloroform stripping in a 0.40-m column using metal structured packing. Ortiz–Del Castillo et al.[38] studied toluene stripping in a 0.25-m column using metal structured and random packings. The latter group developed models for mass transfer based on air stripping experiences. The use of packing for commercial-scale steam stripping apparently has not been investigated.

The economics of vacuum steam stripping of volatile organic compounds have been reported by Rasquin et al.[39] The U.S. Environmental Protection Agency has favored steam stripping over air stripping, because the closed system prevents the stripped components from moving into the atmosphere.

Problem 13.8

A refinery aqueous stream flows at 600 gal/min and contains 15 lb/hr benzene. The benzene is to be removed at a stripping efficiency of 99.95%. A tray column is to be used. Consider two operating pressures, 2.0 psia and 14.7 psia. With no attempt at optimization, evaluate the parameters that should be considered for design. In keeping with refinery practice, use conventional English units.

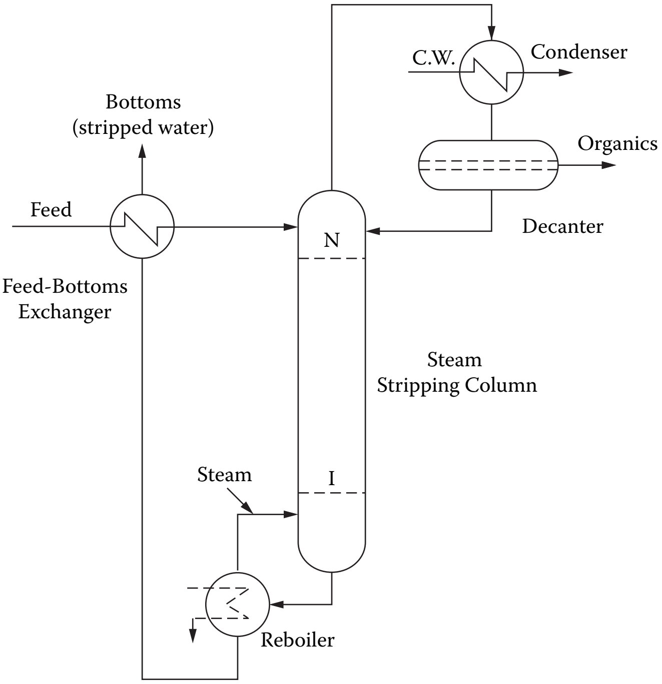

FIGURE 13.22 Typical flow diagram for a steam stripper.

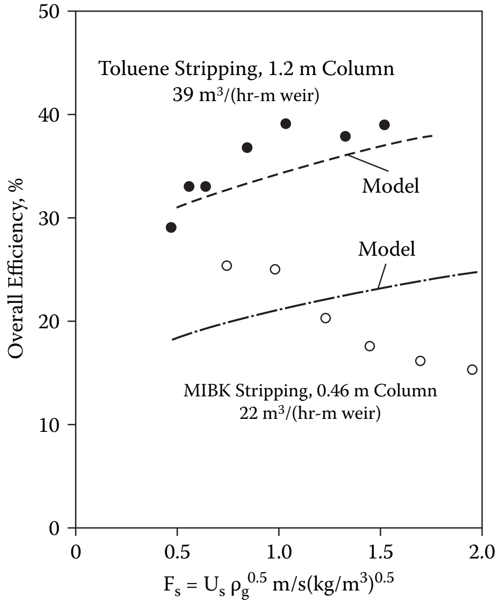

FIGURE 13.23 Overall tray efficiencies for steam stripping using sieve trays.

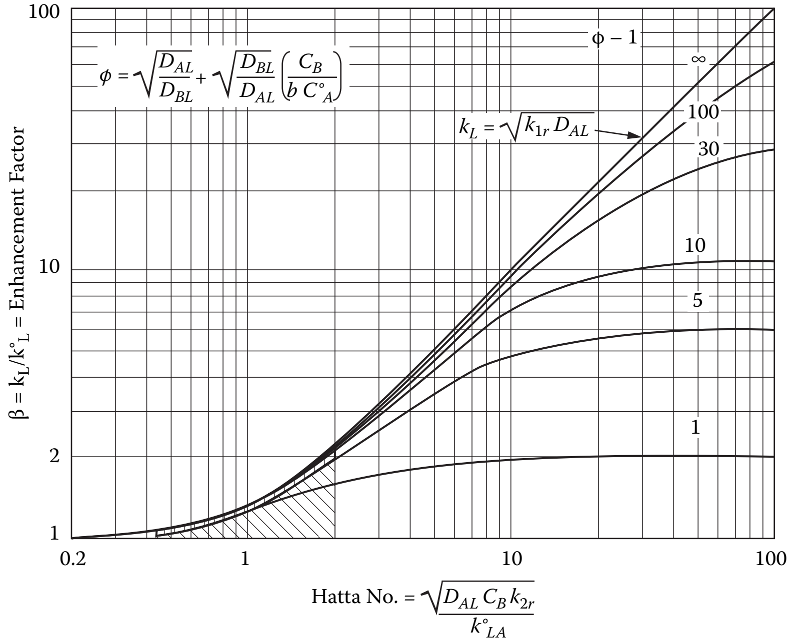

FIGURE 13.24 Enhancement factor as a function of Hatta number. Chemical absorption, irreversible reactions.

Properties:	**2.0 psia**	**14.7 psia**
Temperature, °F	126	212
Liquid density, lb/ft^3	61.6	59.8
Vapor density, lb/ft^3	0.0058	0.0373
Liquid viscosity, cp	0.56	0.27
K value	300	4300
Column feed flow rate, lb/hr	295,800	287,400
Column feed flow rate, lb-moles/hr	16,430	15,970
Entering benzene conc., ppmw	50.8	52.2
Entering benzene conc., ppmm	11.7	12.0

For the first try, use 2.0 psia and assume S = K/(L/V) = 100. Required stages [Equation (13.22)]:

$$N = \frac{\ln\left(\dfrac{E_s - S}{E_s - 1}\right)}{\ln S} - 1 = \frac{\ln\left(\dfrac{0.9995 - 100}{0.9995 - 1}\right)}{\ln 100} - 1 = 1.65 \quad \text{theo.stages}$$

The stage efficiency is obtained from Figure 13.16; the X-scale parameter is

$$K\mu_L/\rho_{LM} = \frac{(900)(0.56)}{(61.6/18)} = 147 \text{ from which, } E_{oc} = 0.060 = 6.0\%$$

Actual plates required in column = 1.65/0.060 = 28

A sample of other calculations follows:

P, psia	°*F*	S	L/V	N_{theo}	Eff, %	N_{act}	lb/hr steam	Vapor, acfs	Col. diam,ft*
2.0	126	75	12.0	1.76	6.0	30	24,600	1178	8.2
2.0	126	100	9.0	1.56	6.0	28	32,800	1570	9.1
14.7	212	75	57.3	1.76	3.2	55	5,200	39	4.6
14.7	212	100	43.0	1.65	3.2	52	6,900	51	4.5
14.7	212	200	21.5	1.76	3.2	45	13,700	102	5.1

* Using Figure 13.13 with 24-in tray spacing, 12% downcomer area, 80% approach to flood.

Interpretation. The examples used are far from optimum. An intermediate pressure may give the best combination of column height and column diameter. Refinery strippers usually have 20 to 30 plates, but such a heuristic depends on the stream being stripped, the cost of steam, and so on.

13.6 CHEMICAL ABSORPTION

Many commercial absorptions involve a chemical reaction between the solute (diffusing species) and the solvent. A common example is the removal of carbon dioxide from air or an inert gas by scrubbing with aqueous sodium hydroxide:

$$CO_2 + 2NaOH = Na_2CO_3 + H_2O \tag{13.50}$$

or for the removal of carbon dioxide by an amine solution:

$$2R\text{–}NH_2 + CO_2 = R\text{–}NHCOONH_3\text{–}R \tag{13.51}$$

where, for monoethanolamine, R = $HOCH_2CH_2$.

These are examples of commercially important chemical absorptions where simple physical mass transfer rate equations need modifications. Usually, the presence of a reaction speeds up mass transfer. For a rigorous design, information must be available on the rate of reaction as a function of concentrations, temperature, pressure, and degree of ionization in the liquid.

13.6.1 Computational Approach

The following development applies to almost all chemical absorptions. Solute molecules in the gas diffuse to and across the interface, then diffuse in the liquid until meeting a reactant. If the reaction is very fast, the nonreactive mass transfer relations, previously discussed, apply—but very conservatively; the effective rate is higher. The flux equation for liquid phase transfer of component i is modified as follows:

$$N_i = \beta\, k_{Li}^{o}\left(C_i^{*} - C_i\right) \tag{13.52}$$

where N_i is the transport flux, kg moles/s-m^2 effective interfacial area, and k_{Li}^{o} is the physical mass transfer coefficient discussed previously. (The superscript is added to avoid confusion with the overall rate $k_{Li} = \beta\, k_{Li}^{o}$.) The coefficient β is called an "enhancement factor," which allows for chemical reaction. There are models available for estimating β from reaction rate data, but they are discussed only briefly here. For details, consult References 40 through 42.

Equation (13.52) may be made more general to include gas resistance and a reaction rate constant:

$$\frac{p_i}{N_i} = \frac{1}{k_{gi}\, a_e} + \frac{H_i}{k_{Li}\, a_e} + \frac{H_i}{k_r\, a_e} \tag{13.53}$$

In other words, the total resistance to mass transfer is the sum of resistances of gas, liquid, and reaction:

$$R_t = R_g + R_L + R_r \tag{13.54}$$

where H_i is the Henry's law constant = $p_i{}^*/C_i$, and k_r is the specific velocity constant for the reaction. When the reaction is very rapid and complete, k_r is very high, and R_r drops out. If there is negligible gas resistance, R_g drops out, and

$$\frac{p_i}{N_i} = \frac{H_i}{k_L\, a_e}$$

or the equivalent of Equation (13.52), with $C_i \sim 0$. Usually, a bimolecular reaction is of interest, involving species A from the gas and B from the liquid,

$$A + bB \rightarrow C$$

We can define a dimensionless Hatta number,

$$Ha = \frac{\sqrt{D_{AL}\, C_B\, k_{2r}}}{k_{LA}^o} = \frac{\textit{effective rate}}{\textit{rate for diffusional transport only}} \tag{13.55}$$

where

D_{AL} = liquid diffusivity for A, m^2/s
C_B = bulk liquid concentration of B, kg-moles/m^3
k_{2r} = reaction velocity constant (second-order), m^3/(s-kg mole)
k_{La}^o = physical liquid phase mass transfer coefficient, kg mole/(s-m^2-kg mole/m^3) = m/s

When the Hatta number (Ha) is evaluated, the value of the enhancement factor may be determined from Figure 13.24, based on reference 43.

The parameters in Figure 13.24 are $\phi - 1$, where

$$\phi = \sqrt{\frac{D_{AL}}{D_{BL}}} + \sqrt{\frac{D_{BL}}{D_{AL}}}\left(\frac{C_B}{b\,C_A^*}\right) \tag{13.56}$$

The top curve in Figure 13.24 applies to first-order and pseudo-first-order irreversible reactions, and for Ha > 3,

$$k_L = \sqrt{k_{1r}\, D_{AL}} \tag{13.57}$$

The above treatment has dealt only with irreversible bimolecular reactions and, as a special case, first-order irreversible reactions. Although these cases predominate, others are certainly possible. The references cited are sources for additional situations.

Problem 13.9

Eckert et al.[44] report test data for carbon dioxide absorption from air in a packed column. Conditions for a particular test are as follows:

Total pressure	1.0 atm	—
CO_2 partial pressure	0.01 atm	—
Temperature	24°C	75°F
Packing	25 mm ceramic Raschig rings	—
Gas rate	0.678 kg/s-m^2	500 lb/hr-ft^2
Liquid rate	6.78 kg/s-m^2	5000 lb/hr-ft^2
Column diameter	0.76 m	2.50 ft
Packed height	3.05 m	10.0 ft
Solvent	1.0 N NaOH, 25% conversion to carbonate	

Solution

For the degree of conversion, and taking into account the ionized liquid, the Henry's law coefficient is H_i = 2535 atm/m.f. = 45.63 atm/(kg moles/m^3). Also, for the flow conditions given, the physical mass transfer coefficients, based on the method of Bolles and Fair,[27] are

$$(k_L a_e)^\circ = 16.7\text{E–}03 \text{ sec}^{-1}$$

$$k_g a_e = 5.69\text{E–}02 \text{ kg-moles/(s-m}^3\text{-atm)}$$

$$\frac{1}{K_{og}\,a_e} = \frac{1}{k_g\,a_e} + \frac{H}{\left(k_L\,a_e\right)^o} = \frac{1}{5.69E-02} + \frac{45.63}{16.7E-03} \quad k_g a_e$$

For purely physical absorption, with component $i = CO_2$,

$$\frac{1}{K_{og}\,a_e} = \frac{1}{k_g\,a_e} + \frac{H_i}{\left(k_L\,a_e\right)^o} = \frac{1}{5.69E-02} + \frac{45.63}{16.7E-03}$$

from which $K_{og}a_e$ = 3.64E–04 kg moles/(s-m^3-atm).

Now, determine the effect of the chemical reaction between CO_2 (comp. A) and NaOH (comp. B).

- Bimolecular reaction velocity constant, k_{2r} = 11,000 m^3/(kg mole-s) (reference 40)
- Conc. of NaOH = C_{OH^-} = 0.375 kg-ions/m^3
- Diffusivity of CO_2 in ionized liquid = D_{AL} = 1.92E–09 m^2/s
- Effective interfacial area: assume $a_e = a_p$ = 190 m^2/m^3 (Table 13.2)
- Physical mass transfer coefficient $k_L^\circ = (k_L a_e)^\circ / a_e$ = 16.7E–03/190 = 8.79E–05 m/s

$$\phi = 1 + 1.0\left(\frac{0.375}{1.0\left(2.191E-04\right)}\right) = 1.0 + 1711 = 1712$$

To evaluate the ϕ parameter for Figure 13.27, calculate the dimensionless Hatta number:

$C_A^* = p_{CO2}/H_{CO2}$ = 0.01/45.63 = 2.191E–04 kg moles/m^3 assume $D_{AL} \sim D_{BL}$ (reference 40)

From Figure 13.24, for Hatta No. = 32.0 and ϕ = 1171, enhancement factor β = 32.

This converts to $K_{og}a_e$ = 2.18 lb moles/(hr-ft^3-atm), very close to the value of 2.20 measured by Eckert et al.[44] The absorption with reaction is about 32 times faster than for physical absorption alone.

13.7 SUMMARY

Absorption and stripping are counterpart processes, and the same general equations apply to both. Most applications of the processes deal with dilute mixtures, namely, absorbing small amounts of material from a large volume of gas or stripping small amounts of material from a large volume of liquid. When the dilute conditions prevail, the methodology for determining theoretical stages or transfer units is relatively simple. For concentrated mixtures, rigorous solutions normally are obtained from special computer programs. Approximate approaches to handling concentrated mixtures are given in this section.

Absorptions and strippings may be performed in conventional plate-type columns or countercurrent packed columns. In a few cases, specialized equipment is used. The traditional approaches to plate and packed column design, used in distillation, apply also to absorption and stripping. Thus, readers of this chapter should also refer to Chapter 12 particularly for dimensioning the contacting equipment.

A significant number of commercial absorption processes involve a chemical reaction in the liquid phase. The effect of the reaction is to speed up the rate of mass transfer and, to some extent, make the determination of transfer units or stages simpler.

As for all separation processes, basic thermodynamic and physical property data must be available. For absorption and stripping, key data relate to solubility, and fortunately there are large databases available to support predictive methods.

13.8 NOMENCLATURE

a_e = effective interfacial area, m^2/m^3
a_p = specific surface area of packing, m^2/m^3
A = area, m^2
A = absorption factor, dimensionless [Equation (13.8)]
A_T = total cross sectional area of column, m^2
A_N = net area cross section, m^2
A' = average absorption factor, dimensionless [Equation (13.16)]
C = concentration, kg moles/m^3
C_v = orifice coefficient, dimensionless
C_{sbf} = capacity parameter, m/s [Equation (13.30)]
Ca = dimensionless capillary number [Equation (13.49)]
CP = capacity parameter [Equation (13.46)]
D = diffusion coefficient (diffusivity), m^2/s
E_a = absorption efficiency, fractional
E_{oc} = overall column efficiency, fractional
E_s = stripping efficiency, fractional
F_p = pacing factor, 1/m (Table 13.1)
F_S = gas F-factor = $U_s\,\rho_G^{0.5}$, m/s(kg/m^3)$^{0.5}$
g = gravitational constant, m/s^2
G = gas flow, kg/s-m^2
G_m = gas flow, kg moles/s-m^2
h = pressure head, mm liquid
h_d = head loss for flow through holes, mm liquid

h_L = head loss for flow through froth on plate, mm liquid
h_w = weir height, mm
H_g = height of a gas phase transfer unit, m
H_i = Henry's law coefficient for component i, atm/mole fraction
H_L = height of a liquid phase transfer unit, m
H_{og} = height of a liquid phase transfer unit, m
Ha = dimensionless Hatta number [Equation (13.55)]
$HETP$ = height of packing equivalent to theoretical plate, m
k_g = mass transfer coefficient for gas, kg moles/(s-m^2-atm)
k_L = mass transfer coefficient for liquid, m/s [kg moles/(s-m^2-kg/m^3)]
k°_L = mass transfer coefficient for liquid, physical basis only, m/s
k_r = reaction velocity constant (units dependent on reaction order)
K = gas-liquid equilibrium ratio= y^*/x
K_{og} = overall mass transfer coefficient, gas concentration basis, kg moles/(s-m^2-atm)
L = liquid flow, kg/s-m^2
L_m = liquid flow, kg moles/s
m = slope of equilibrium line
N_{theo} = number of theoretical stages
N_g = number of gas phase transfer units
N_i = molar flux of component i, kg moles/s-m^2
N_L = number of liquid phase transfer units
N_{og} = number of overall transfer units, gas concentration basis
p = partial pressure, atm
p^{sat} = vapor pressure, atm
P = total pressure, atm
R = universal gas constant
Re = dimensionless Reynolds number
S = stripping factor, dimensionless [Equation (13.21)]
S' = average stripping factor, dimensionless [Equation (13.24)]
S_e = effective stripping factor, dimensionless [Equation (13.25)]
T = absolute temperature, Kelvin
TS = tray spacing, m or mm
U = gas velocity, m/s
U_h = gas velocity through holes, m/s
U_N = gas velocity through net area of tray, m/s
U_s = superficial velocity through column, m/s
V = vapor or gas flow, kg/s-m^2
V_m = vapor or gas flow, kg moles/s
x = mole fraction in liquid
X = ratio, moles/mole solute free liquid
y = mole fraction in gas or vapor
y^* = mole fraction in gas or vapor, equilibrium condition
Y = ratio, moles/mole solute free gas
Z = height, m
Z_f = froth height, m or mm

13.8.1 Greek Letters

α_c = relative volatility
α_i' = Bunsen solubility coefficient, 1/atm [Equation (13.1)]
α = relative solubility

β = enhancement factor for chemical absorption [Equation (13.52)]
γ = activity coefficient
λ = ratio of slopes, equilibrium line/operating line
μ = absolute viscosity, mPa-s (cp)
ν = kinematic viscosity, cs
ρ = density, kg/m^3
ρ_{LM} = liquid molar density, kg moles/m^3
σ = surface tension, mN/m (dynes/cm)
ϕ = parameter for Figure 13.24

13.8.2 Subscripts

1 = top plate in column for absorbers, bottom plate in column for strippers
A,B = components A or B
g = gas phase
i = component i
L = liquid phase
N = bottom plate in column for absorbers, top plate in column for strippers

14.1 INTRODUCTION

Adsorption is the phenomenon that selectively segregates atoms or molecules between a fluid and a solid. In some ways, it is like *ab*sorption, except the liquid-phase *ab*sorbent is replaced with a solid-phase *ad*sorbent. Sometimes solids could be said to *ab*sorb or *ad*sorb fluids, i.e., the distinction is blurred.* In this chapter, the focus is on selective uptake (and release) by porous solids, especially for process applications. Another subtle distinction occurs when vapor is adsorbed from a gas; it is like condensation, except that the driving force is subtle molecular forces rather than a temperature gradient.

When applied as a unit operation, adsorption can be used to split mixtures containing significant percentages of adsorbable components or purify streams containing trace amounts of contaminants. These separations, whether for gases or liquids, are accomplished by allowing the fluid and solid phases to interact under controlled conditions. Molecules that are selectively taken up are called *adsorbates*, and the solid surface that attracts the adsorbate is called the *adsorbent*. Jargon used in connection with adsorbents and adsorption, as well as some prominent definitions, are listed in Table 14.1. Fundamental causes and effects of adsorption are discussed in Section 14.3.

This chapter presents different facets of adsorption. Unfortunately, there is not sufficient space to provide case studies for any of the hundreds of unique applications of adsorption. On the other hand, most of the topics discussed here are the subject of dozens of technical papers each year, many of which appear in specialized journals, including (alphabetically) Adsorption, Carbon, Langmuir, Microporous and Mesoporous Materials (formerly Zeolites), Reactive Polymers, and other more general titles. Some subjects are also treated in much greater detail in books, many of which are listed in the bibliography that follows.

It is an understatement to say that adsorption is a diverse field. It impacts separation processes, materials science, catalysis, soil science, pharmaceutical products, environmental applications, and other widely different fields. A brief overview of those subjects, mainly oriented toward applications, is presented here.

Adsorption can perform many separations that are impossible or impractical by conventional techniques, such as distillation, absorption (gas–liquid), and even membrane-based systems. Adsorption has found recent applications in solving environmental problems and meeting stringent quality requirements. Important applications of adsorption fall in the category of purification, as cited by Yang (1987), but they represent only a small fraction of the uses of adsorption. The largest single application of adsorption is for water treatment. It employs nearly 100 million pounds of activated carbon annually in the U.S. alone, to remove compounds that could be toxic or merely pose problems of taste or odor. It was first used for municipal water treatment in powdered form in the late 1930s, and as granules in the 1960s. In addition, activated carbon has been used to decolorize sugar since the 1920s. Another widespread purification application is the pressure-swing air dryer found on heavy trucks and buses for their air-brake systems. Those would probably go unnoticed were it not for the abrupt, audible "blowdown" of these adsorbers, which sounds like a tire blowing out or a hydraulic system failure. A third, very widespread application is in the seal between thermopane windows. They employ 3A zeolite (as a powder mixed with caulk or as

* When a solid behaves like a sponge (i.e., by capturing a fluid via surface tension or by nonselective penetration), it could be called *ab*sorbent (e.g., granules used to pick up oil that has spilled on a floor). When a solid exhibits selective uptake, it should be called an *ad*sorbent(e.g., granules contained in a column through which oil-laden water passed, selectively removing the oil).

TABLE 14.1
Definitions of Terms Used Commonly in Adsorption

Adsorbate	Component (usually dilute) taken up by the adsorbent; also called *adsorptive*. The remaining fluid (solvent or carrier) is viewed as nonadsorbing. Some prefer this be strictly the component in the adsorbed state.
Adsorbent	Porous solid with "active" sites that take up specific constituents such that the composition on the surface differs from that in the surrounding fluid. Some pores may act as a sieve. Examples: activated carbon, alumina, silica gel, and zeolite.
Adsorption	Enrichment (or depletion) of one or more constituents in an interfacial layer [IUPAC, 1972]. The net effect of chemical and/or physical forces exerted by the adsorbent or co-adsorbed species.
Adsorption potential	The free energy change associated with the desorption of a molecule (or mole). Employed by Polanyi and Dubinin and coworkers to fit isotherm data. See Equation (14.7).
Breakthrough	An observation in a fixed-bed adsorber as the effluent composition rises toward the feed composition. It can refer to a criterion, e.g., 5% of the feed concentration of a component, or to the shape of the composition vs. time profile. The profile can change sharply or gradually, depending on equilibrium properties and mass transfer rates. Classifications (see Figure 14.9 for illustrations): Constant pattern or self-sharpening front—usually a sharp, symmetric transition observed during uptake under favorable (Type I) equilibrium. The physical limit (without mass transfer effects) is called a *shock wave*. Proportional pattern or disperse front—usually a gradual and asymmetric transition during regeneration or uptake under unfavorable (Type II) equilibrium. The physical limit (without mass transfer effects) is a *simple wave*.
CTC index	Carbon tetrachloride index for activated carbon; weight percent of carbon tetrachloride adsorbed at a partial pressure of 0.1505 atm (114 torr) and a carbon temperature of 25°C; obsolescent.
Chemisorption	Chemical bonding via electron transfer: specific; slow (activation barrier); forms monolayer, $\Delta H_{ads} > 3\,\Delta H_{vap}$.
Co-adsorption	Uptake of two or more constituents, each potentially affecting the adsorbability of the other.
Constant pattern front	An axial composition profile for a component having a shape that does not depend on axial position. This occurs during uptake of a component that exhibits a favorable isotherm and no dispersion. Mathematically, this occurs when $C_A / C_{A_F} = \bar{n}_A / n_A^*(C_{A_F})$.
Favorable isotherm	Concave downward (also Type I; see Figure 14.4 and Section 14.3.2).
Heats of adsorption	1. Isosteric heat of adsorption: $\Delta H_{ADS_i} = q_{st_i} = -R \left.\dfrac{d \ln p_i}{d 1/T}\right\|_{q_i} > 0$ Similar to Clapeyron equation; can be used to interpolate or extrapolate data to other temperatures; and $\Delta H_{ADS_i} = f(q_i^*)$ 2. Differential heat of adsorption: $\Delta H_{Diff_i} = q_{st_i} - RT$ 3. Equilibrium heat of adsorption: $$\Delta H_{Equil_i} = \left[\int_0^{q_i} \Delta H_{ADS_i} dq_i - \pi_t A \right] \Big/ q_i$$ where the spreading pressure, π_i, is (for ideal gases): $$\frac{\pi_i A}{RT} \doteq \int_0^{q_i} \frac{d \ln p_i}{d \ln q_i} dq_i$$ 4. Integral heat of adsorption: $\Delta E_{Int_i} = \dfrac{1}{q_i} \int_0^{q_i} \Delta H_{Diff_i} dq_i$

Continued

TABLE 14.1 ***(Continued)***
Definitions of Terms Used Commonly in Adsorption

Hysteresis	Divergence of uptake and release isotherm data due to the difference in mechanisms of pore filling vs. emptying, or other irreversible phenomena of uptake and release.
Iodine number	Amount of iodine adsorbed from an iodine/potassium iodide solution (0.02 N) per mass of activated carbon (mg/g). A measure of capacity of activated carbon for small molecules.
Ion exchange	Sorption using "fixed" acidic or basic functional groups, such as $–SO_3^-$, $–NH^+$, etc. Rates of uptake or release may be affected by reaction and/or diffusion.
Isobar	Plot of equilibrium data as amount adsorbed vs. temperature, holding partial pressure constant.
Isotherm	Set of equilibrium data: amount adsorbed (n^*_i) vs. concentration (c_i) or partial pressure (p_i), at constant temperature. See Figure 14.4 for classifications. Constraints: (1) $\lim_{c_i \to 0} \frac{dn_i^*}{dc_i} < \infty$ (2) $\frac{dn_i^*}{dc_i} \geq 0$ Typical units: $n_i^* [=] \frac{\text{moles }(i)}{\text{mass (adsorbent)}}$ or $\frac{\text{mass }(i)}{\text{mass (adsorbent)}}$ or $\frac{\text{std. vol. }(i)}{\text{vol. (adsorbent)}}$
Macropores	$d_p > 500$Å. (pigments, bacteria)
Mesopores	$d_p \in (20, 500)$Å (colloidal silica, viruses)
Micropores	$d_p < 20$Å (common molecules)
Mass transfer zone	Region of the axial composition profile in which the composition varies from that of the feed (toward the feed end) to that of the initially present fluid (toward the product end). Despite its name, the shape of this zone can depend on mass transfer resistances, dispersion, or equilibrium effects. For uptake with a favorable isotherm, the width remains essentially constant beyond a certain axial position, leading to the term *constant pattern front.* In that case, the effects are exclusively due to intraparticle- and/or film-diffusion resistances.
Methylene blue factor	Volume (cm^3) of 0.15% methylene blue solution decolorized by 100 g of adsorbent in 5 min.
Molasses number	Quantitative measure of decolorizing capacity based on the change in color of molasses; relates to adsorption of large molecules from a liquid.
Physisorption	Based on weak physical attraction: sensitive to temperature, nonspecific, rapid (no activation barrier), possibly multilayer $\Delta H_{ADS} < 3\Delta H_{VAP}$.
Proportional pattern	An axial composition profile (or breakthrough curve) having a shape that "relaxes" gradually as the front moves along the axis. This is characteristic of desorption for a system that has a favorable isotherm. Axial dispersion exhibits a similar effect but may affect uptake and release.
Sorption	Adsorption or desorption.
Structure	Described by densities, void fractions, porosity, pore-size distribution.
Unfavorable isotherm	Concave upward (also Type II; see Figure 14.4 and Section 14.3.2).
Working capacity	The effective change of loading of an adsorbent between the regenerated and exhausted states. May reflect either operating data or a theoretical limit based on isotherm data.

particles within an aluminum frame) to adsorb moisture in the air space, preventing it from fogging the internal glass surface.

Two types of *cyclic* adsorption technologies [pressure swing adsorption (PSA) and temperature swing adsorption (TSA)], developed since the mid-1960s, are widely used for industrial separations. Examples of PSA include air dryers (as mentioned previously), hydrogen from refinery off-gases (commercialized in the 1960s), oxygen from air (early 1970s), and nitrogen from air (late 1970s). Many TSA systems remove or recover VOCs from solvent-laden air, e.g., at polymer processing, painting, and pharmaceutical production sites. Those use steam, hot gases, or even electrical resistance heating for regeneration. In addition, simulated moving-bed (SMB) systems split xylene isomers, sugars, and pharmaceutical products.

Moving-bed systems are *continuous* and include vapor-phase recovery systems that employ staged fluidized beds in which the adsorbent circulates through a thermal regenerator. Generally, it is possible for the fluid phase and adsorbent to be contacted in a countercurrent flow pattern. An early version,

called the hypersorption process, was patented in 1922 but was not fully commercialized until the late 1940s. It performed well but suffered from high attrition rates of the adsorbent. A later version, called the Purasiv^{SM} process, employed small, glassy activated carbon beads that resisted attrition. Other moving-bed systems have mostly been used for solvent recovery from contaminated air. Among them are the PolyAd^{SM} system of Chematur and the Blizzard^{SM} system of On-Demand Environmental Systems, which used polymeric adsorbents because of their inherent toughness.

SMB systems were created to exploit some of the countercurrent features of moving-bed systems, but employing fixed beds to avoid attrition. Liquid-phase SMB adsorption systems, such as UOP's Sorbex^{SM} processes, have been commercialized since the early 1960s. Among the Sorbex^{SM} family, the Molex^{SM} process separates normal paraffins from branched and cyclic isomers; the Olex^{SM} process splits olefins from paraffins; the Parex^{SM} process isolates *p*-xylens from *m*-, *o*-xylene, and ethyl benzene mixtures; and the Sarex^{SM} process splits fructose from corn syrup. These are discussed further in Section 14.6.

All of the various applications require special adsorbent characteristics. The broadest and generally the most significant are the inherent adsorption *capacity* and *selectivity*. In many cases, the adsorption and desorption rates or *kinetics* and pressure drop are also important; hence, particle size is important. In addition, nearly every different application has a different set of additional priorities. For example, the main prerequisite for municipal water purification and many other large-scale applications is *low cost*. Other adverse conditions can complicate adsorbent specifications. For example, properties such as density, color, fluid compatibility, and durability (e.g., attrition resistance, crush strength, and hardness) all may be important. Adsorbents that have the ideal combination of essential characteristics for a specific application may or may not exist. That implies that compromises are frequently necessary.

Going hand in hand with advances in process technology and adsorbent materials, engineers and scientists have developed a better understanding of the mechanisms of adsorption. The mechanisms are complicated, because adsorption is always transient vs. steady state (implying that partial differential equations are common), and various mass transfer resistances may be important (implying that a significant amount of data, as well as constitutive rate equations, are needed). For example, it is highly important to know the time, t, when the adsorbent at a particular location, z, achieves a certain level of saturation, $n^*(C,z,t)$; it is, hence, necessary to know the fluid phase concentration, $C(z,t)$. For most design purposes, four different technical aspects must be addressed: adsorbent properties, adsorbate characteristics, equipment performance, and operating conditions. These are intricately coupled, and they control feasibility, safety, and profitability. Of course, the ease and flexibility of numerical simulations in particular have been augmented by faster, more accessible computers.

14.2 ADSORBENTS

Specific classes of adsorbents are described herein, along with some typical applications, although no attempt has been made to be exhaustive. Many varieties (activated aluminas, silica gels, activated carbons, zeolites, and polymeric adsorbents) are practically commodities and are generally available off the shelf. New, customized adsorbents can also be synthesized to have different properties, which may translate into better performance. A new adsorbent may take months or years to perfect; hence, a rule of thumb is that there is never enough time to develop a new adsorbent for a specific application.

Following an Edisonian testing approach, most minerals and many synthetic inorganic materials have been tried as adsorbents. Some have proved desirable, despite being mediocre adsorbents, simply because they are inexpensive. Others, fortuitously, are effective adsorbents. Some inorganic materials act more as "absorbents" than adsorbents, since they are not porous solids with active surfaces. Those have applications from flue gas desulfurization to drying to recovery of polychlorinated biphenyls. Among them are metal chlorides ($CaCl_2$), oxides (CaO, MgO, and ZnO for life support in the space program), silicates ($MgSiO_3$), sulfates ($CaSO_4$, the familiar "Drierite"),

kieselguhr (or diatomaceous earth), and even sodium bicarbonate and limestone (for flue gas treatment). Some are used in an anhydrous state, whereas others are hydrated. Other inorganic adsorbents have been developed recently (e.g., pillared clays, aluminophosphates, and mesoporous adsorbents) that have not yet been commercialized. Those covered below are commercial products and are frequently encountered.

14.2.1 Adsorbent Selection Criteria

Adsorbent selection criteria for any application generally include the following main attributes: capacity, selectivity, regenerability, kinetics, durability, and cost. These attributes represent combinations of properties that are strongly affected by the pertinent conditions. For example, the first four govern how much adsorbent is necessary for a particular application, and the last two affect the annual cost. Furthermore, the first three are tied to the equilibrium characteristics, about which much can be said (see Section 14.3). Likewise, kinetics is covered in more detail in Section 14.4. Both will be discussed briefly here, however. Finally, adsorbent cost obviously depends on both its price and lifetime, which can depend on its resistance to attrition, degradation, fouling, and so on.

Rarely will a single adsorbent be optimal in all of these respects. Frequently it will be possible to narrow the choice to one or two classes of adsorbents, leaving a vast array of possible particle sizes, shapes, pretreatment conditions, and so forth. Final decisions should always be based on data. To make budget estimates, however, a number of different approaches can be derived from rules of thumb to provide quick experimental feasibility tests. Potential sources of such information are adsorbent or equipment vendors, published or commercial databases, and in-house or external laboratories.

14.2.2 Adsorbent Characteristics

14.2.2.1 Capacity, Selectivity, and Regenerability

Adsorption capacity (or loading) is probably the most important characteristic of an adsorbent. More detail is provided in Section 14.3.2. The loading is the amount of adsorbate taken up by the adsorbent, per unit mass (or volume) of the adsorbent, and it depends on the fluid-phase concentration, the temperature, and other conditions (especially the initial condition of the adsorbent). Typically, adsorption capacity data are plotted as isotherms (loading of adsorbate on the adsorbent versus fluid-phase adsorbate concentration at constant temperature), isosteres, isobars, and others mentioned later. Examples are shown in Figures 14.1 through 14.3. Adsorption capacity is of paramount importance to the capital cost, because it sets the amount of adsorbent required and also the volume of the adsorber vessels; the costs of both are significant if not dominant. When comparing alternate adsorbents, it is fair to express their capacity on a per unit volume basis, since that fixes

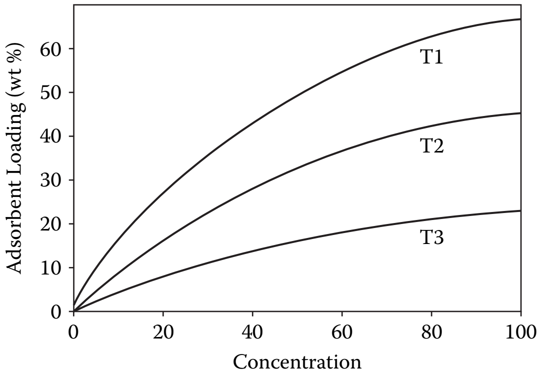

FIGURE 14.1 Typical Type I isotherms at increasing temperatures, $T_1 < T_2 < T_3$.

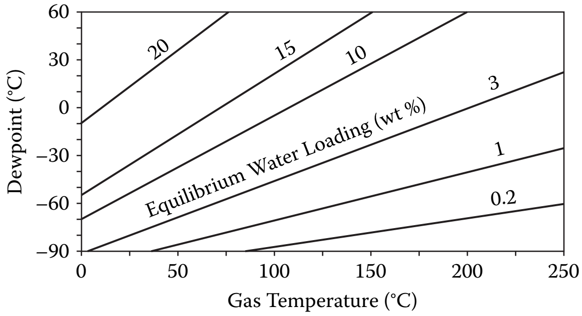

FIGURE 14.2 Isosteres: water vapor on 5A zeolite (activated at 350°C and 0.01 torr).

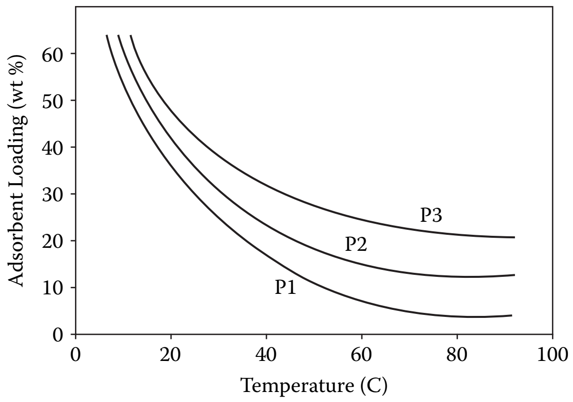

FIGURE 14.3 Isobars at various pressures, $P_1 < P_2 < P_3$.

the cost of the vessels, pipes, and other equipment. Conversely, the adsorbent is practically always sold on a per unit mass basis, so most isotherms are plotted on the basis of capacity per unit mass.

Six common isotherm shapes are shown in Figure 14.4. In fact, those are the classic isotherm types suggested by Brunauer et al. (1940). Each can be represented by numerous empirical equations, some of which are discussed later. The inherent shapes or types arise from the pore structure of the adsorbent, the nature of the forces between the adsorbent surface and adsorbate, and the dependence on concentration. Besides isotherms, other properties are related to adsorption capacity, especially surface area and pore size distribution. Some other properties are application oriented, such as CTC (carbon tetrachloride) index, iodine number, methylene blue factor, and molasses number, all defined in Table 14.1. They are frequently employed to describe activated carbons.

Selectivity is related to capacity, but there are several distinct definitions, as discussed later. The simplest is the ratio of the capacity of one component to adsorb on the adsorbent to that of another at a given fluid concentration. That ratio generally approaches a constant value as the concentration drops toward zero. Of course, the concentrations of interest may not be near zero, so the choice of definitions becomes subtle. The closest analogy is to relative volatility (e.g., in distillation) in that the closer it is to unity, the larger the required equipment. An ideal situation occurs when the major component is not adsorbed much (so it can be thought of as an inert "carrier"), which leads to a very large selectivity. Despite the attractiveness of an analogy to relative volatility (with a range from 0 to ∞), some people prefer a bounded selectivity (with a range from 0 to 1), and they employ the inverse of the ratio mentioned above. Thus, it is necessary to clarify the definition first, or to speak of "good" or "bad" instead of "large" or "small."

All cyclic adsorption applications rely on regenerability, which allows the adsorbent to operate in sequential cycles with uniform performance. This means that each adsorbable component

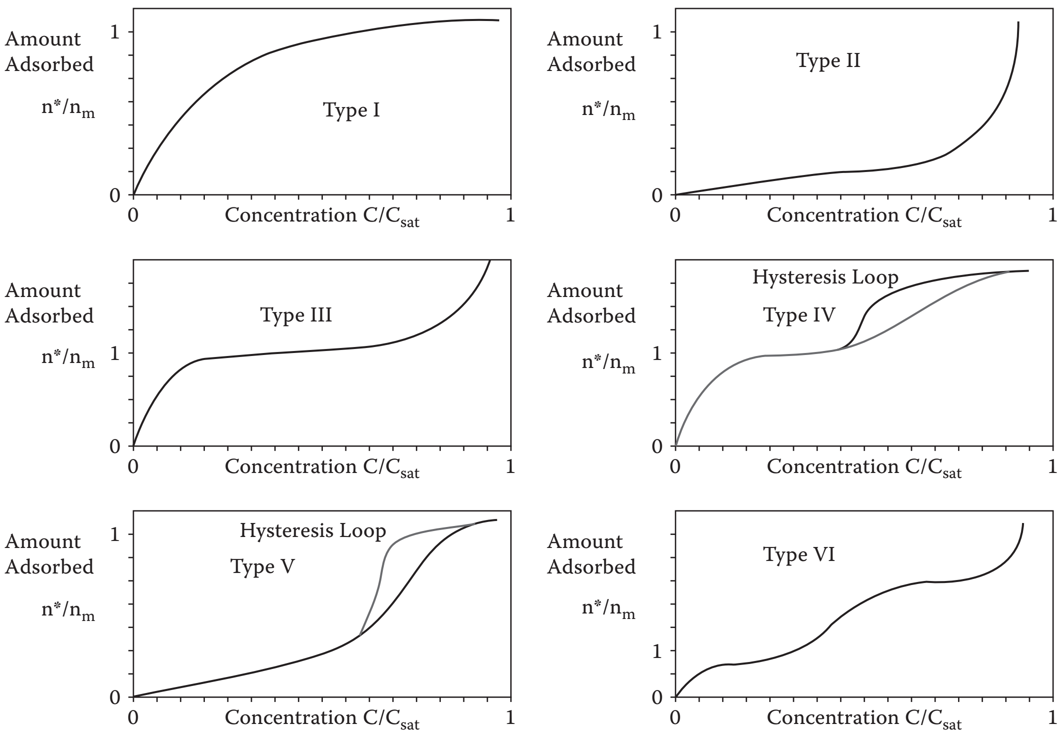

FIGURE 14.4 Isotherm classifications [Brunauer, Deming, Deming, and Teller (1940)].

(adsorptive or adsorbate) must be relatively weakly adsorbed (or physisorbed). The heat of adsorption provides a measure of the energy required for regeneration, and hence low values are desirable. Regeneration may be accomplished by a thermal swing, pressure swing, or chemical reaction (e.g., by displacement, elution, or supercritical extraction), or sometimes by a combination of those. Displacement would involve introducing a species that adsorbs more strongly than the adsorbate of interest, while elution would entail dissolving the adsorbed material by a solvent that is adsorbed weakly, if at all. Chemical methods require a separate separation operation that may be costly, plus the regenerated bed must be purged of the regenerant. In some cases, regeneration takes place by contacting the adsorbent with another fluid not used during loading. This requires draining or displacement, which might be time consuming and should be avoided whenever possible. The regenerability of an adsorbent affects the fraction of the original capacity that is retained for cyclic usage (sometimes called the *working capacity*) and the time, energy, and other requirements for regeneration.

14.2.2.2 Kinetics

Mass transfer kinetics is a catch-all term related to intraparticle mass transfer resistance. It is important because it controls the cycle time of a fixed-bed adsorption process. Fast kinetics provides a sharp breakthrough curve, while slow kinetics yields a distended breakthrough curve. The effect of a distended breakthrough curve can be overcome by increasing the amount of adsorbent and hence pressure drop in the bed. On the other hand, kinetics has been exploited as the basis of adsorptive separations. The most common example is the PSA process that splits nitrogen from air using a carbon molecular sieve, which relies on the relatively fast diffusion of oxygen compared with the much slower diffusion of nitrogen. In conventional adsorption processes, however, slow diffusion of any adsorbate is a disadvantage. To compensate for slow diffusion, it is also possible to use small particles, but there is a corresponding sacrifice resulting from the increased pressure

drop. The usual solution to that dilemma is to use relatively large particles and to employ an extra increment of adsorbent.

14.2.2.3 Pore Structure and Surface Area

Typical adsorbents have very large internal surface areas as a result of their porous structures, often varying from 5 to 3000 m^2/g. Accordingly, pore structures are described by their size, shape, and connectivity. Three pore size (d_p) ranges are commonly cited: micropores (d_p < 20 Å), mesopores (20 Å ≤ d_p < 500 Å), and macropores (d_p ≥ 500 Å). Shapes range from slits to straight, cylindrical holes to narrow pore mouths that open to larger cavities. Connectivity can go from highly ordered and crystalline as in zeolites to more random and even amorphous, as in some silica gels and activated carbon. To envision how pore structure relates to surface area, it may help to consider an adsorbent particle as a partly filled bookshelf. The outer boundary of the shelf corresponds to the external surface of a particle. Gaps between the shelves correspond to macropores, the spaces between adjacent books correspond to mesopores, and the spaces between individual pages of the books correspond to micropores. Stretching that analogy, it is easy to see that, on a "unit volume" basis, the external area, as well as the area attributed to the macropores (shelves), is small. In contrast, the mesopores (book covers) contribute more area than the macropores, but the micropores (pages) can dwarf the others.

Surface area is a relative term, since the value depends on the way it is measured. As explained more fully below, the surface area is inferred from the apparent monolayer loading (plateau on the isotherm) of a standard adsorbate (e.g., nitrogen at its normal boiling point). The numerical value is obtained from the monolayer loading using the adsorbate's density and molecular dimensions. Values typically correlate with capacity and for various adsorbents are in the range of, say, 5 to 3000 m^2/g. This means that if you held in your hand the same mass of adsorbent as that of a penny (2.5 g), the area available would range from 3.7 × 3.7 m^2 to nearly two football fields! Some specific ranges are listed for common adsorbents in the next section. Even though it can be measured repeatably and is widely accepted as a key criterion, surface area alone is not a proper basis for choosing an adsorbent.

The *BET surface area* measurement is attributed to Brunauer et al. (1941). It is usually conducted with nitrogen at its normal boiling point (–195.8°C) and measured up to atmospheric pressure (p/p_{vap} = 1). Essentially, the monolayer capacity (or loading) is estimated using the BET isotherm (see Table 14.3 and Section 14.3.2), and the numerical value is converted to a surface area using a factor that is believed to represent the coverage area per molecule for nitrogen. From the same data, it is possible to extract the cumulative pore volume.

The pore size distribution (PSD) indicates the fraction of the space within a particle occupied by micropores, mesopores, and macropores. An adsorbent's pore size distribution roughly indicates its potential uptake capacity, may reveal possible mass transfer constraints, and can show its potential for separating molecules by a sieving effect. In fact, sometimes pore size information is gleaned from diffusion rate data for molecules of known sizes, i.e., the extent to which sieving effects are observed.

Both measurement and modification of pore size distribution are rapidly growing fields. Pore size distributions are often reported in either differential or cumulative form. The former provides the percent or fraction of volume as a function of pore radius or diameter (i.e., dV/dr). That form makes it easy to discern the average pore diameter and skewness of the distribution. In contrast, the cumulative PSD clearly depicts total pore volume as a function of pore diameter and shows relative amounts of microporosity and macroporosity. Figures 14.5 and 14.6 show representative differential and cumulative PSDs, respectively, of some common adsorbents.

Figure 14.7 illustrates how the pore sizes of some common adsorbents relate to the sizes of several molecules and elements. The latter values are Lennard–Jones (6–12) apparent collision diameters, extracted from viscosity measurements. For many adsorbents, only a minimum pore size is shown

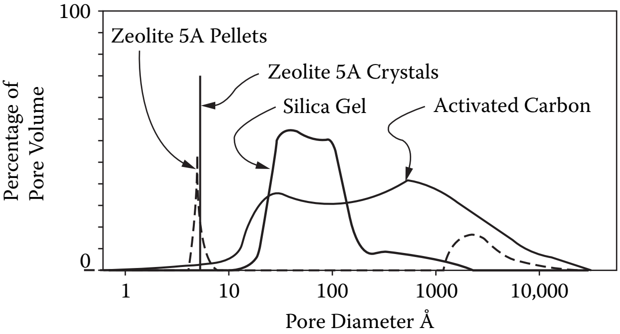

FIGURE 14.5 Differential pore size distribution for common adsorbents.

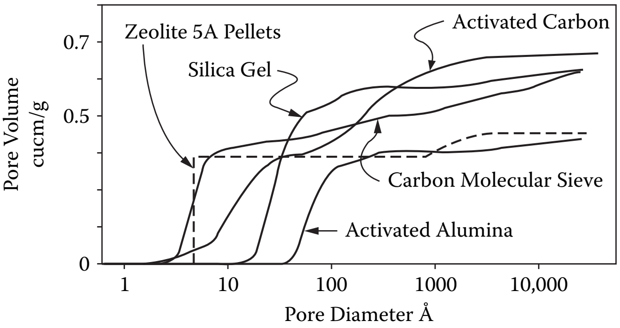

FIGURE 14.6 Cumulative pore size distribution for common adsorbents.

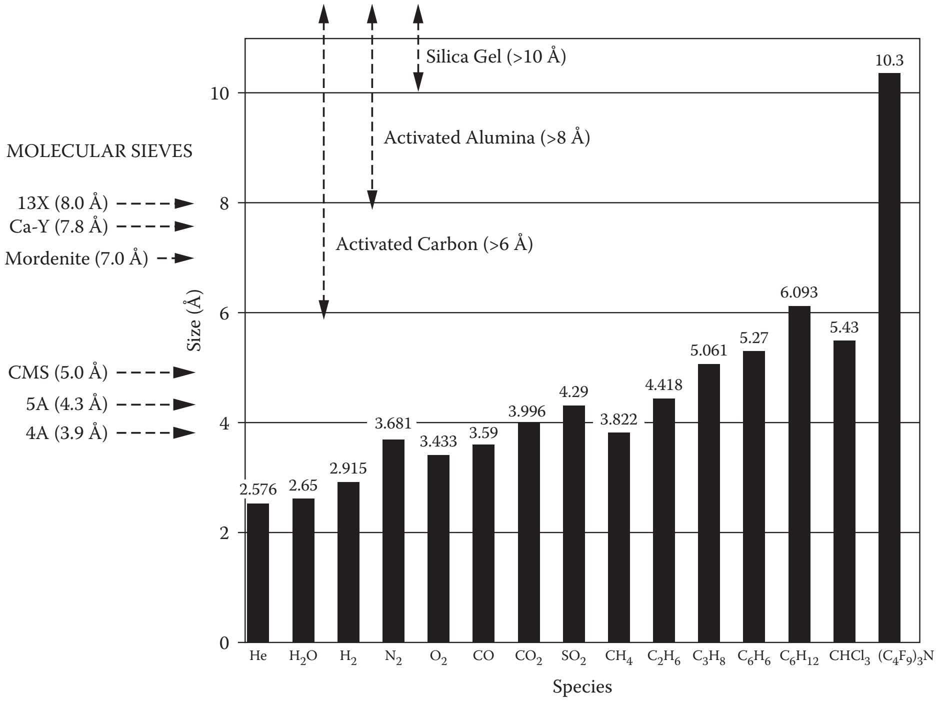

FIGURE 14.7 Molecular diameters and pore dimensions for common adsorbents.

(ignoring the average and range), while for molecular sieves the nominal micropore size is shown (ignoring the macropores). Perfluorotributylamine, as shown here, is larger than most micropores.

14.2.2.4 Particle Size Distribution

Adsorbent particles are available in diverse shapes and sizes. The most common forms are granules, flakes, pellets, powders, and beads. Granules can be nearly spherical or nearly flakes, depending on the starting material and the manufacturing methods. Pellets are generally cylindrical rods with length-to-diameter ratios of 1 to 10. Sometimes they are made in other shapes (e.g., hollow cylinders and trochoidal shapes), but they are more expensive and may not behave identically to ordinary pellets because of different stresses imposed during production. Beads generally offer superior attrition resistance and may promote better flow distribution than other shapes.

14.2.2.5 Durability and Cost

Durability relates to various possible modes of attack that could reduce the life expectancy of the adsorbent, such as chemical, physical, or biological fouling, degradation, and attrition. To combat those effects, the adsorbent, binder, and surface groups (depending on the type of adsorbent) should be physically strong and inert to the carrier or solvent, and should not irreversibly react with (or chemisorb) the adsorbate(s) or contaminants.

Attrition generally has three potential causes: crushing due to an imposed normal force, shearing or abrasion due to tangential stresses, and wear due to impingement of entrained particles at high velocity. Those causes of attrition are affected by operating conditions such as velocity and flow orientation, bed height, temperature, pressure, and vibration, which contribute to the stresses on the adsorbent particles. Normal forces frequently result from pressure gradients, especially in PSA systems, but they can also be associated with thermal expansion and contraction, mostly of the vessel wall (e.g., during TSA operation). Most adsorbents exhibit low coefficients of thermal expansion, so they do not induce much thermal stress. Resistance to normal forces can be quantified as an adsorbent's "hardness" or "crush strength." There are also standard tests for tangential stresses, i.e., to measure "abrasion resistance." The other forms of wear cannot be accurately quantified, but they are no less important.

Attrition can cause a host of problems, from increased pressure drop due to the presence of "fines" in the intersticies between whole particles to total failure of the adsorber when adsorbent dust is conveyed into the pipes and fittings downstream. In addition, a short-term loss of working capacity (mentioned earlier) commonly occurs during the first few cycles of operation of fresh adsorbent, followed by gradual decay, perhaps over hundreds of cycles, due to aging (partial collapse of the adsorbent's pore structure), chemisorption (poisoning), or other causes. It is that decay plus attrition losses that essentially govern the life of the adsorbent.

Adsorbent costs vary with time, supplier, and other factors, even for the same exact material. Prices often range from $0.50 per pound for some commodity adsorbents to $100 per pound or more for more exotic materials. Some that are impregnated with expensive metals are much higher priced. Price is also sensitive to quantity. For example, from a laboratory supply house, in 100-g quantities, activated alumina and silica gel cost as much as $70 to $140 per pound. But in tonnage quantities, they may sell for less than $1 to about $4 per pound.

14.2.3 Common Adsorbents

In this section, we focus on the properties, uses, and origins of a few generic types of commercial adsorbents. Neither the list nor the descriptions are comprehensive. The intent is to provide some background information regarding the most important aspects.

14.2.3.1 Aluminas

Activated alumina is produced from hydrated alumina, $Al_2O_3 \cdot n\ H_2O$, where $n = 1$ or 3, by dehydrating (calcining) under controlled conditions to get $n \approx 0.5$. This form, being hydroxylated, augments adsorption by hydrogen bonding. It is a white or tan opaque material that has a chalky appearance. Several grades are available from various manufacturers. The distinctions among products mostly are related to the specific crystal structures that alumina can exhibit. For example, stable crystalline forms are usually not thought of as adsorbents because of their low surface areas. Conversely, transitional forms, such as gamma and eta alumina, have defect spinel structures that lead to both higher concentrations of surface acid sites and effective surface areas from 200 to 400 m^2/g. Common forms are beads or balls 1 to 8 mm dia., granules, extrudates (pellets) 2 to 4 mm dia., and powder. Activated aluminas are widely used as catalysts (or catalyst supports) and as desiccants. Ancillary uses as an adsorbent are for removal of oxygenates and mercaptans from hydrocarbon feed streams, fluoride ions from water, HCl from hydrogen in catalytic reforming, and others. For most gas-phase applications, pretreatment requires heating to about 250°C.

14.2.3.2 Silicas

Silicas are also highly hydroxylated SiO_2, so adsorption results, to a considerable extent, from hydrogen bonding. Most silica gels are transparent or translucent. Some silica gels are alloyed with a few percent alumina, which yields an opaque white or tan appearance. Several forms are available that encompass diverse types of silica gels, porous borosilicate glass, and aerogels. The last is a relatively new, exceedingly porous material currently with few commercial applications. Its unique characteristics make it an interesting prospect for the future. Silica gel and porous glass are both nondusting and resistant to attrition.

There are more than a dozen varieties of SiO_2; most adsorbent forms are rigid (but not crystalline) assemblages of spherical microparticles made of colloidal silica. Aerogels are a form of open-celled porous glass. Effective surface areas range from 300 to 900 m^2/g, depending on the density, with more dense materials having finer pores and larger surface areas. Common forms are beads 1 to 3 mm dia., granules, extrudates (pellets) 2 to 4 mm dia., and powder. The largest uses of silica gel and porous glass are as a desiccant. Other uses as an adsorbent are for separation of hydrocarbons, dewpoint reduction for natural gas, and drying of liquid hydrocarbons. Pretreatment for gas-phase applications (especially as a desiccant) requires heating to about 200°C.

14.2.3.3 Zeolites

In the mid-1700s, a Swedish mineralogist named Cronstedt discovered a mineral that appeared to boil when heated. He named it *zeolite,* from the Greek *zeo* (to boil) and *lithos* (stone). The observed boiling effect is caused by the expulsion of adsorbed water from inside the zeolite. The term zeolite now refers to a class of aluminosilicates that are stoichiometric blends of silica and alumina. They are generally opaque and white or tan in appearance. There are about 40 natural and 150 synthetic types having the general formula $M_{x/n}[(AlO_2)_x(SiO_2)_y] \cdot w\ H_2O$, where M represents a cation of valence n, w is the number of water molecules per "cage," and x/y is the Al-to-Si ratio. The sum $x + y$ is the number of tetrahedra per unit cell. Those that contain roughly equal amounts of silica and alumina are hydrophilic, whereas those that contain predominately silica (e.g., with Al-to-Si ratios > 10) are hydrophobic. Frequently, there is water of hydration within the crystals, and to balance the charges, cations are associated with the alumina. The presence of water is largely associated with field-dipole interactions, which can be large for zeolites.

Internally, zeolites are inherently crystalline and exhibit micropores within those crystals that have uniform dimensions, as depicted in the pore size distribution shown in Figures 14.5 and 14.6. The micropores are so small and uniform that they commonly can distinguish among nearly identically sized molecules. As a result they are frequently called "molecular sieves." That term,

however, is broad and encompasses materials that are made from aluminophosphates, titanosilicates, and so forth. As mentioned earlier, Figure 14.7 illustrates the sizes of a few atoms and some simple molecules along with the micropore diameters of some common zeolites.

Most zeolites sold as commercial adsorbents are composites of very fine crystals held together with a binder. Surprisingly, the binder may also exhibit substantial adsorption capacity. The adsorption capacity of zeolites is the result of micropores that are so small that it is impractical to express an effective surface area. To promote crystal uniformity, most commercial zeolites are synthesized in autoclaves under tightly controlled conditions. The resulting crystals exist in a metastable form, and more than 100 distinct forms have been produced. Typical zeolites include faujasite (also called zeolite X and zeolite Y), mordenite, silicalite, zeolite A, zeolite L, zeolite β, zeolite ρ, zeolite ω, Boggsite, chabazite (also called zeolite D), clinoptilolite, erionite, and ferrierite. Only a handful are commercially significant (e.g., A, X, Y, mordenite, ZSM-5, and silicalite), although the first four of those have a few different common "exchange" forms and are produced in different sizes and shapes. Some of the variety is summarized in Table 14.1. Particle selection includes 1- to 6-mm dia. extrudate, 0.5- to 3-mm beads, 20 × 40 to 6 × 12 mesh, and powders. Applications of zeolites include gas or liquid drying, separation of oxygen from air, normal paraffins from naphtha, and *p*-xylene from other isomers. Activation for gas-phase applications typically requires more stringent conditions than for silica or alumina, namely, 300°C under full vacuum or an inert purge gas.

14.2.3.4 Carbons

Activated carbons are produced from wood, coal, peat, coconut shells, saran, recycled tires, and other sources. The final adsorbents may look similar to the casual observer (i.e., black granules or pellets), but appearances can be deceptive.

Activation produces a wide range of internal pores and carbon surfaces (e.g., graphitic versus oxidized), which generally enhance the adsorptive capacity. By varying activation conditions, differences of the internal surfaces are produced, even for materials that appear to be identical. Another feature that varies, depending on the nature of the base material, is the ash content, which is of course inorganic; typical values are between 2% and 25%, but the average is about 7%. Alkali ash near or at the surface can be removed by acid washing, or other minerals may be deposited by impregnation. The microscopic structure (pore size distribution and surface area), surface qualities, and chemical composition affect adsorption characteristics and therefore affect the performance parameters (capacity, selectivity, regenerability, kinetics, compatibility, and cost). Specifications are maintained only through tight quality control.

Effective surface areas generally range from 300 to 1500 m^2/g, depending on the base material, activation method, density, and so on, although some made from petroleum coke exceed 3000 m^2/g. Larger surface areas are often assumed to be better, but surface area does not always correlate with capacity. Even when it does, kinetics and other aspects may outweigh the effect of capacity on overall cost and performance.

Common forms are beads 1 to 3 mm dia., granules, extrudates (pellets) 2 to 4 mm dia., and powder. Some typical applications are water and wastewater treatment to remove hazardous organic compounds or those that impart odor or taste, cleanup of off-gases containing volatile organic compounds (especially solvents which might be recovered and odoriferous chemicals that are merely trapped), upgrading methane from substandard natural gas wells, food decolorization, and pharmaceutical purification. Impregnated activated carbons are widely used in gas masks and to remove other specific contaminants in gas or water. Impregnants include sulfuric acid (for ammonia or mercury), iron oxide (for hydrogen sulfide or mercaptans), zinc oxide (for hydrogen cyanide), and a combination of heavy metal salts (for phosgene, arsine, and nerve gases). Pretreatment for gas-phase applications is often performed as the last step of manufacture.

Adding to the diversity are products called "carbon molecular sieves," which are analogous to zeolites and other crystalline molecular sieves mentioned previously. While micropores in zeolites

tend to have rounded apertures, the carbon-based counterparts are more slit-like, as in the space between layers of graphite. To date, only one type of commercial separation employs this material: separation of nitrogen (at 97% to 99.99%) from air by PSA, which exploits the size difference between oxygen (3.43 Å) and nitrogen (3.68 Å).

14.2.3.5 Polymers

Polymeric adsorbents, including ion exchange resins, tend to be opaque spherical beads; most are white or tan, but some are brown, orange, or black. Some are inert, polystyrene-divinyl benzene, polymethacrylate, divinylbenzene/ethylvinylbenzene, or vinylpyridine beads, while others, which contain acidic or basic functional groups, are ion exchange resins. Internally, many of these polymer beads contain "microbeads" that are joined together at a few points each, creating a macropore structure. In addition, some polymeric adsorbents are activated via pyrolysis, in much the same way as carbon, yielding black materials.

Some polymeric adsorbents are sufficiently hydrophilic to be used as a desiccant, while others are quite hydrophobic. The effective surface area is usually smaller than for activated carbon, e.g., 5 to 800 m^2/g. The corresponding pore diameters range from about 20 to 2000 Å, or from 3 to 2000 Å if activated. The available forms are generally limited to beads of 0.3 to 1 mm dia., usually in a relatively narrow range. Larger particles are not yet commercially available. A minor drawback of these materials is that they tend to shrink and swell with cyclic use. For gas-phase applications, they may require conditioning prior to use (e.g., washing with water and/or another solvent followed by drying).

The range of applications is somewhat restricted, since the cost of most polymeric adsorbents is typically about ten times more than that of other common adsorbents. In some instances, polymeric materials are the only choice. In other cases, they compensate for the cost differential by yielding much better performance, especially for high value-added uses. Current applications include recovery and purification of antibiotics and vitamins, decolorization, decaffeination, hemoperfusion, separation of halogenated light organics from water, and treatment of certain industrial wastes such as aqueous phenolics and VOC recovery from off-gases.

14.2.3.6 Biomass

Some adsorbents are organic materials that function as solid "absorbents" rather than adsorbents. Among these are cellulose (the most abundant biopolymer in nature), chitin (the second most abundant biopolymer in nature), collagen, wool, starch-polyacrylamide gels (which absorb many times their own weight of water at ambient temperature but release most of it by gentle heating), polysaccharrides derived from corn, and miscellaneous forms of biomass (e.g., residue from crop harvests). The latter materials fall in the fuzzy gap between adsorbents and absorbents. Nevertheless, some of these may have niches, but none is a general-purpose adsorbent.

14.3 ADSORPTION THERMODYNAMICS

Adsorption relies mainly on the physisorption of molecules (and noble gases) and is analogous to condensation. Knaebel et al. (1999) indicated that two types of forces contribute to physisorption: *van der Waals* (or dispersion) forces and *electrostatic* forces. Van der Waals forces relate to polarizability, i.e., the ease with which an atom's or molecule's electron density can be distorted. That effect increases as atoms within a group in the periodic table become larger. The outcome is a favorable interaction energy that is significant for highly polarizable species. Similarly, electrostatic forces, which are relevant only if the surface is polar, are caused by polarization forces, field-dipole interactions, and field gradient-quadrupole interactions. In that vein, polarization forces are causative, while polarizability represents a latent tendency.

For sorbate, field-dipole interactions occur that exhibit a permanent dipole moment (e.g., H_2O), which interacts with the surface electric field to give an attractive energy. An example is hydrogen

bonding, which is important for hydroxylated surfaces and sorbates such as water and alcohols. Basically, hydrogen atoms are often covalently bonded to highly electronegative atoms at the surface, and the latter draw the electron clouds of the former, leaving their nuclei exposed. The nuclei, in turn, form purely electrostatic bridges to other atoms of the adsorbate or surface. Field gradient-quadrupole interactions arise for nonpolar, electrically neutral molecules (such as CO_2 and N_2) that exhibit significant quadrupole moments. In the presence of a spatially varying electric field, the attractive energy is proportional to the product of the local field gradient and the quadrupole moment.

Thus, the magnitude of physisorption forces is most strongly affected by the size, polarity, polarizability, and quadrupolarity of sorbate atoms or molecules, as well as the electric field strength and the local field gradient of the solid surface.

Chemisorption differs from physisorption in that it involves the formation of chemical bonds and electron transfer between adsorbate and adsorbent. It is of primary concern with regard to catalysis, and it is only useful as an extreme measure for separation purposes. Removal of chemical warfare agents from breathing air is a prime example. One way to discern between physisorption and chemisorption is by heat effects and the effect of temperature. For example, physisorption is always exothermic, i.e., $\Delta H_{ads} < 0$. Furthermore, the adsorbed state is more ordered than the fluid state, so $\Delta S < 0$. To be thermodynamically feasible, $\Delta G_{ads} < 0$, so $\Delta H_{ads} < T\Delta S$. In contrast, endothermic adsorption is possible for dissociative chemisorption, even if the entropy of the adsorbate decreases, because the entropy of the adsorbent may increase to more than offset that, e.g., by expanding.

The loading due to physisorption decreases monotonically with temperature, while that due to chemisorption can increase with temperature, especially considering rate effects. The net contribution of chemisorption may be nil at low temperatures and rise to levels much higher, even substantially above the boiling point, where physisorption would sharply diminish. Physisorption is practically fully reversible, even when multilayered, whereas chemisorption may or may not be reversible. To clarify, it must be reversible to exhibit catalytic behavior, but it tends not to be when it acts as a poison. Physisorption is not very specific, except in molecular sieves, which discriminate based on size and steric effects. In contrast, chemisorption is much more specific, depending on conditions and the nature of the sorbate and adsorbent as well as its previous treatment.

14.3.1 Adsorption Equilibrium and Heats of Adsorption

The importance of adsorption equilibrium cannot be overstated, since it is often the constraint that has the greatest impact on adsorption applications. In fact, to address most adsorption applications (whether to design a process, to debottleneck an existing process, or even to solve problems in which adsorption is peripherally related), it is necessary to obtain equilibrium data, as described in Section 14.3.2, and then put it into a useful form—usually as a correlation, as described in Sections 14.3.3 and 14.3.4. This section first clarifies what is meant by equilibrium data and heats of adsorption.

The terms adsorption capacity and loading are used generically to express the amount of adsorbate taken up by the adsorbent. To solve problems, it is necessary to express loading quantitatively, e.g., as an explicit function of partial pressure or concentration and temperature:

$$n_i^* = f(p,T) \quad \text{or} \quad f(C,T) \tag{14.1}$$

In the next section, we will see specific functions that are commonly used to represent data. It should be noted that many additional factors affect the adsorption capacity, such as pretreatment, exposure history, presence of contaminants or competitively adsorbed substances, and so forth. Although those factors can strongly affect adsorption performance, they are difficult to predict or even correlate. From here on, we assume that the adsorbent has been properly pretreated and that the other adverse effects are negligible.

Most fundamental equations have direct analogies to vapor–liquid equilibrium and simple gas laws. For example, an adsorbed component is frequently viewed as a two-dimensional fluid that exhibits a spreading pressure on the adsorbent, in contrast to its partial pressure in the gas phase. There is a corresponding empirical relationship between the spreading pressure, area covered per mole adsorbed, and temperature, analogous to the ideal gas law, but it is called the "ideal surface gas" equation. When applied to adsorption of mixtures, it is called the "ideal adsorbed solution" theory, developed by Myers and Prausnitz (1965). Equilibrium calculations mainly involve the interactions of one molecule (or atom) of adsorbate with the adsorbent surface; i.e., they neglect adsorbate-adsorbate interactions. This viewpoint is valid only in the most idealized conditions. Normally, the surface is irregular or heterogeneous (both energetically and geometrically), which can be taken into account by many theories, and the adsorbed molecules (or atoms) interact with each other via mutual repulsion (or sometimes attraction).

As mentioned above, equilibrium data can be presented and used in a variety of forms: isotherms (loading vs. concentration at constant temperature), isosteres [partial pressure (or dew-point, or some other form of concentration) vs. inverse absolute temperature at specific degrees of loading], and isobars [loading as a function of temperature for given partial pressures (or some other concentration)], listed in order of decreasing prevalence. The object of isosteres and isobars is to plot data on coordinates for which approximate linearity is expected, to make interpolation and extrapolation easier.

The heat of adsorption is a measure of the energy required for regeneration in gas- or vapor-phase applications, and low values are desirable. It also indicates the temperature rise that can be expected due to adsorption under adiabatic conditions. Again, there are several definitions: isosteric, differential, integral, and equilibrium, to name a few. The most relevant (because it applies to flow systems instead of batch systems) is the isosteric heat of adsorption, which is analogous to the heat of vaporization and is a weak function of temperature. The definition is

$$q_{st} = -R\left[\frac{\partial \ln p}{\partial(1/T)}\right]_{n^*} \tag{14.2}$$

where p and n^*, respectively, would be total pressure and loading for a pure gas or partial pressure and component loading for a mixture. Besides an indication of the energy required for regeneration, this term shows how the adsorbate interacts with the adsorbent. To illustrate, a plot of isosteric heat of adsorption vs. loading generally follows one of three trends (monotonically decreasing, increasing, or constant) as loading increases. The first case indicates that adsorption is strong at low concentrations, possibly due to a heterogeneous surface at which the "strong" sites are filled first. The net effect is that regeneration is likely to be difficult. The second case indicates the reverse, and regeneration is likely to be relatively easy, especially if the heat of adsorption is also low. The third case is neutral. Other, less utilitarian heats of adsorption are defined in Table 14.1.

14.3.2 Sources of Equilibrium Data

There are two types of sources of equilibrium data: literature and laboratory. In many ways, it is easier and cheaper to obtain data or correlations from the open literature. Unfortunately, there are not many compilations, so it may not be easy to find applicable data, even if they exist. A few that may prove useful are the *Adsorption Equilibrium Data Handbook* by Valenzuela and Myers (1989), *Carbon Adsorption Isotherms for Toxic Organics* by Dobbs and Cohen (1980), and *Adsorption-Capacity Data for 283 Organic Compounds* by Yaws, Bu, and Nijhawan (1995). Individual reports of equilibrium data are abundant and may be found in specialized journals such as *Adsorption, Adsorption Science and Technology, Journal of Colloid and Interface Science, Langmuir*, and *Separation Science and Technology*, as well as other more general journals such as *AIChE Journal,*

Chemical Engineering Science, Industrial Engineering Chemistry Research, and *Journal of Chemical and Engineering Data.*

Except for the most common applications, one is unlikely to find data or correlations that cover the proper range of conditions for a very wide range of adsorbents (so as to choose the best). In addition, accurate predictions are currently impossible, so it is *always* necessary to obtain data under relevant conditions. Consequently, most applications will require measurements in a laboratory. Isotherm measurements require great care. There are three basic types of equipment: volumetric, gravimetric, and chromatographic. The equipment and techniques are reviewed briefly here.

Volumetric measurements for gases generally involve a vessel containing an adsorbent that is subjected to a step change of pressure (measured via a pressure transducer). The final pressure can be used to calculate the amount adsorbed. For liquid–phase volumetric measurements, the dry adsorbent is contacted with a liquid of predetermined concentration, and the final concentration is measured. A variety of instruments can be used *in situ*, but it is also acceptable to extract small samples with a syringe for individual analysis. For liquids or gases, this method is generally the best in terms of flexibility, accuracy, and cost.

The gravimetric approach mainly applies to gas–phase adsorption. It involves measuring the amount taken up by the adsorbent by weight. These isotherm measurements are quick and accurate, and the interpretation is easy. Some types of equipment are elaborate, with a small adsorbent-bearing pan suspended from a quartz spring. With this approach, the main problem is cost, plus the fact that the equipment tends to be finicky (each seal is subject to leaks). Other problems sometimes overlooked are adsorption on the walls rather than on the adsorbent and buoyancy effects (which may cause a 10% error). Another version uses a column of adsorbent through which gas of a known concentration is passed. Periodically, the flow is stopped, and the column is sealed and weighed. The adsorption capacity can be determined once a steady state is reached. This is more tedious but is reliable and relatively inexpensive. Alternatively, employing thermogravimetric analysis (TGA), the adsorbent can be heated strongly, and the off-gases can be trapped and analyzed to infer the adsorbate composition.

Finally, chromatographic analysis is primarily a screening technique in which adsorbents are crushed and placed in a chromatographic column, then a pulse of the components of interest is injected into a nonadsorbing carrier fluid. In principle, the technique applies to both gases and liquids, but the former application is much more popular. The Henry's law coefficient can be determined readily from the retention of each peak. This general technique can also be applied in stepwise (rather than pulse) experiments using a material balance and integrating the breakthrough curve to ascertain the amount adsorbed.

14.3.3 Isotherm Equations

An isotherm is a set of equilibrium capacity (or loading) data over a range of fluid-phase concentrations at a fixed temperature. Many semitheoretical equations are used to fit isotherm data, and those having more parameters can account for more subtle effects. In most cases, simpler is better.

Brunauer, Deming, Deming, and Teller (1940) observed that isotherm data followed patterns, i.e., Types I–V shown in Figure 14.4. They also suggested a powerful but complex four-parameter equation (referred to as the B.D.D.T. equation) that fits all of the forms. Most other equations apply to Type I, II, or IV data, which represent "favorable" equilibrium (concave downward). A few others apply to Types III and V data, which represent "unfavorable" (concave upward) equilibrium.* Frequently, if an isotherm exhibits hysteresis (shown for Types IV and V), there may be an adverse impact on kinetics and regenerability. Hysteresis occurs when desorption follows a different path

* Generally speaking, *favorable* isotherms are promising for uptake. In contrast, adsorbents that exhibit *unfavorable* isotherms would not perform well in most adsorption applications.

TABLE 14.2
Characteristics of Several Commercial Zeolites

Zeolite Type	Cationic Form	Nominal Pore Diameter (Å)	Si/Al
3A	K	3.0	1.0
4A	Na	3.9	1.0
5A	Ca	4.3	1.0
10X	Ca	7.8	1.2
13X	Na	8.0	1.2
Y	K	8.0	2.4
Mordenite	Na	7.0	5.0
ZSM-5	Na	6.0	31.0
Silicalite	—	6.0	∞

from adsorption, usually as a result of liquid filling pores in a certain way that is not the same as when they are emptied.

The following paragraphs describe the isotherms and explain the terms that are listed in Table 14.3. Most can accept any form of concentration, *C*, for the fluid phase (e.g., having units of mol/m^3, lb/ft^3, and so on) or a convenient variable (e.g., partial pressure, ppm, and so forth). Some, however, are restricted to relative saturation, i.e., expressed as a fraction. Generally, they can fit adsorbent loading, n^*, having units of mmol/g, lb/ft^3, g/100 g, and others. Finally, the parameters *A, B*, and so forth are determined empirically.

The simplest equilibrium concept is that the extent of adsorption is proportional to the fluid-phase concentration, i.e., Henry's law [a in Table 14.3]. A principle of thermodynamic consistency is that isotherms should reduce to Henry's law at the limit of zero loading. If not, the equation (or data) is thermodynamically inconsistent and therefore fundamentally flawed. Conversely, there is pragmatic appeal to the premise that if an isotherm equation fits, one may use it, even though some scientific principle may be violated. The hazard of that approach arises if the data are flawed, causing an erroneous fit, which could lead to a defective design or mistaken predicted performance.

The Langmuir isotherm [b in Table 14.3] accounts for surface coverage by balancing the relative rates of uptake and release, the former being proportional to the fraction of the surface that is open, and the latter proportional to the fraction that is covered. The equilibrium constant for those rates is *K*, which also is the Henry's law coefficient. When the fluid concentration is very high, a monolayer forms on the adsorbent surface, having a loading of n_M. Those two parameters help us understand the nature of adsorption (although for some isotherms, n_M does not strictly refer to a monolayer but instead may denote a maximum). Hence, they are used directly in the equations when appropriate. When possible, the equivalent terms are listed in Table 14.2.

Freundlich recognized that, when data do not fit well on linear coordinates, the next logical step is to try log-log coordinates, and that led to the isotherm [c in Table 14.14. 3] bearing his name. It is probably the most commonly used isotherm equation, despite being "thermodynamically inconsistent."

The Brunauer–Emmett–Teller (B.E.T.) and B.D.D.T. isotherms [d and e in Table 14.3] account for pore filling via multiple layers instead of just a monolayer, and they use C/C_{sat}, that tends toward unity as the pores are completely filled. The B.D.D.T. isotherm includes the number of layers explicitly (*m*), as well as a heat of adsorption term (*q*). The B.E.T. isotherm is mostly used to estimate surface areas, not for process calculations [see Equation (14.10)].

The dual-mode isotherm is merely a combination of Henry's law and the Langmuir isotherm. Other isotherms, such as the Redlich–Peterson, Langmuir–Freundlich, Sips, and Toth [g, h, i, and j, respectively, in Table 14.3] versions extend the Langmuir isotherm by accounting for subtle

[1] The Henry's law constant, K, is commonly defined as the initial slope of "fractional coverage" (or $\theta = n^*/n_M$) vs. concentration or partial pressure, which leads to awkward units, and the maximum loading, n_M, must be known. Less commonly but more sensibly, the slope of n^* versus C or p can be used. That choice is unavoidable if saturation is not observed.
[2] n_M corresponds to the "monolayer" loading for Equations a through e, while for the rest it represents a sort of "maximum" loading. Details go beyond the scope of this chapter.
[3] B.D.D.T. = Brunauer–Deming–Deming–Teller; m is the number of monolayers, and q is a heat of adsorption.
[4] The adsorption capacity, n^*, and maximum loading, n_M, for this isotherm are expressed as the *volume* adsorbed per unit mass or volume of adsorbent. The function $n^* = f(\varepsilon)$ is called a characteristic curve and can fit data for one component over a range of temperature—and sometimes for a family of components. The *adsorption potential*, ε, is defined in Table 14.1. β is called an affinity coefficient that can force data for diverse components to fit a common characteristic curve.

nonlinearities and are "power-law" forms. The last of this type is the UNILAN isotherm (k). Its name comes from UNI for "*uni*form distribution" and LAN for "*Lan*gmuir local model." It has a strong theoretical basis but is difficult to grasp, since it employs the logarithm of a ratio containing exponential functions. Despite that, the UNILAN isotherm and the Toth isotherm, although slightly different from the one shown here, were used predominantly by Valenzuela and Myers (1989) in their thorough and precise compilation of isotherm data.

Polanyi recognized in 1914 that there was an analogy between adsorption and condensation. Through the use of free energy, he arrived at a term called the *adsorption potential,* ε_i, for component "i." The definition is

$$\varepsilon_i = RT \ln(f_i^* / f_i) \approx RT \ln(p_i^* / p_i) \approx RT \ln(C_i^* / C_i) \qquad (14.3)$$

where the *pure* fluid fugacity and vapor pressure (or solute solubility limit) are f_i* and p_i* (or C_i*), and the *equilibrium* fugacity and partial pressure (or solute concentration) are f_i and p_i or (C_i), respectively, all at the temperature of interest, T. For vapors (neglecting fugacity coefficients), the adsorption potential is equivalent to the work required to compress the adsorbable component from its partial pressure to its vapor pressure. In addition, to apply this approach to liquids requires deducting a correction factor from ε_i to account for the displaced solvent.

Dubinin and coworkers showed that a specific adsorbent adsorbs nearly equal volumes of similar compounds when their adsorption potentials are equal. In this case, the adsorbed volume is estimated from the liquid density, usually at the same temperature. Their reasoning is that the adsorbed state closely resembles the liquid phase. They suggested a plot of volume adsorbed vs. adsorption potential would produce a "characteristic curve," applicable to that group of compounds for the specific adsorbent. Most people who use this type of isotherm equation have adopted W as the symbol for loading, volume (of liquid) adsorbed per unit mass, or volume of adsorbent, but we will retain n* and recognize that the units are specialized, as noted in Table 14.3. From the measured data (moles or mass adsorbed), one calculates the volume adsorbed using V_m, the molar volume of the saturated liquid evaluated at the adsorption pressure, but sometimes evaluated at the normal boiling point or another condition. Regardless, it should be consistent and clearly stated. It is then easy to extrapolate to other temperatures and other similar adsorbates for a given adsorbent. The main drawback is that the characteristic curve does not reduce to Henry's law at low coverage.

The isotherms developed by Dubinin and coworkers employ a power to which the adsorption potential is raised that indicates the prevalent type of pores. The Dubinin–Radushkevich equation [1 in Table 14.3] was intended for microporous adsorbents, since the exponent is 2. The Dubinin–Astakhov equation (m) allows the exponent B to vary, but a reasonable lower limit is unity (for macroporous adsorbents). The Dubinin–Stoeckli equation (n) allows a distribution of pore sizes, which is a feature of many adsorbents.

For this type of isotherm, n_0 represents the maximum loading, which correlates with pore volume among different adsorbents. The other isotherm parameters, k_0 and β_0 [no relation to the terms in Equations (14.4) or (14.5)], represent the *characteristic parameter* of the adsorbent and an *affinity coefficient* of the compound of interest, respectively. The characteristic parameter, k_0, defines the shape of the n* versus ε curve. The affinity coefficient, β_0, adapts the compound of interest to the characteristic curve. It is a "fudge factor" that has been correlated to the ratio of molar volumes, parachors, or polarizabilities (via the Lorentz–Lorenz equation) of the compound of interest to that of a reference component (e.g., benzene or n-heptane). These three methods are roughly equivalent in accuracy. The molar volume version is $\varepsilon_i = \varepsilon_{ref}V_i/V_{ref}$. The only controversy is whether to use the actual temperature to estimate volumes or some other temperature such as the normal boiling point.

For given a set of data, which isotherm equation (or equations) fits best? And what is the impact of the quality of fit on predicted performance? Unfortunately, neither question cam be answered fully. It is fair to say that the greater the number of parameters in an equation, the more likely it is to fit well; and the better it fits, the more valid will be subsequent process simulations. That should be balanced against the statistical significance of the parameters. Finally, the isotherm fit that best accommodates heat effects and multicomponent aspects, if any, will be superior. An example that illustrates different degrees of quality of fit of four equations to one set of data is provided in Section 14.5.4. Specialized programs are available that fit equations and plot the results.

The term *regenerability* was also referred to previously without giving an exact definition. To do so implies choosing the regeneration method. Regenerability would then revolve around the isotherm (or loading) under the process conditions vs. during regeneration. For a TSA cycle, this would mean looking at the appropriate isotherms for uptake and release and assessing the change of loading. Likewise, for chemical regeneration (e.g., by displacement or elution) or for a PSA

cycle, it would mean looking at the loading under the relevant conditions. Of course, kinetics could affect the ability to attain those loadings, but that is covered later.

14.3.4 Mixture Equilibria

Selectivity is a means by which mixture equilibria can be grasped. Several different definitions exist, but all basically are ratios of "what is adsorbed" to "what remains in the fluid phase" at equilibrium. Selectivity, therefore, provides a simple description of the nature of multicomponent equilibria, although the values are seldom employed in mathematical models. Some common definitions are

$$\alpha_{ij} = \frac{y_i / y_j}{x_i / x_j} \tag{14.4}$$

$$\alpha'_{ij} = K'_i / K'_j \tag{14.5}$$

$$\beta_{ij} = \frac{1 + \frac{1-\varepsilon}{\varepsilon} K'_j}{1 + \frac{1-\varepsilon}{\varepsilon} K'_i} \tag{14.6}$$

$$\beta'_{ij} = K'_j / K'_i \tag{14.7}$$

where x_i and y_i are mole fractions in the fluid phase and adsorbed phase, respectively; $K'_i = K_i n_{Mi}$; and ε is the overall void fraction of the adsorbent. As mentioned in Tables 14.3 and 14.4, K_i is called the Henry's law constant, and n_{Mi} is the nominal monolayer loading. Following convention, the first component, *i,* is more strongly adsorbed than component *j.* In that case, α and α' vary between unity and infinity, as does the relative volatility, while β and β' vary between zero and unity. The ratio defined by Equation (14.4) may vary as the fluid composition varies. Conversely, Equation (14.5) is frequently used to compare adsorbents or operating conditions because it is

TABLE 14.4
Multicomponent Isotherm Equations

Name	Equation Form
a. Henry's Law	$n_i^* = K_i n_{Mi} C_i$
b. Markham–Benton[1]	$n_i^* = K_i n_{Mi} C_i/(1 + \Sigma\, K_j C_j)$
c. Schay[2]	$n_i^* = (K_i n_{Mi} C_i/\eta_i)/[1 + \Sigma\, (K_j n_{Mj} C_j/\eta_j)]$
d. Yon–Turnock[2]	$n_i^* = n_{Mi}(A_i/\eta_i)C_i^{B_i}/[1+\Sigma(A_j/\eta_j)C_j^{B_j}]$
e. Sips–Yu–Neretnieks	$n_i^* = n_{Mi} K_i C_i (\Sigma K_j C_j)^{D_i - 1}/[1+\Sigma(K_j C_j)]^{D_i}$
f. Redlich–Peterson–Seidel (C_{ref} = 1 [=] C_i)	$n_i^* = A_i C_i/[1+B_i C_{ref}^{D_{ii}} C_i^{E_i - D_{ii}} \Sigma(A_{ij} C_j)^{D_{ij}}]$

[1] Isotherm parameters can be estimated from pure component values.
[2] η_i is a lateral interaction parameter for component *i*. It is an additional empirical coefficient that can be determined from multicomponent data.

constant (at a given temperature), although it normally applies only at the limit of zero concentration. When discussing results, it is a good idea to clarify the definition of what is meant by selectivity or to speak of "good" or "bad" instead of "large" or "small."

There are five common means of dealing with mixtures rather than single adsorbable species. First and easiest, one may pretend that the mixture consists only of the major adsorbable component. That can be catastrophic. The second approach, treating the constituents independently, is useful and accurate when a nonadsorbing carrier contains very dilute contaminants. It is also very easy, since only pure component isotherms are required. Third, one may apply a method developed by Tien and coworkers (Jayaraj and Tien, 1984; Kage and Tien, 1987; Moon, Park, and Tien, 1991) called *species grouping*. The idea is to deal with a mixture of, say, ten components by identifying two or three (sometimes fictitious) components to represent the entire set. That reduces the complexity, saves time and money, and is fairly accurate if only an approximate answer is desired. It requires some pure component isotherm data to know how to group the species. The fourth method is to use one of several empirical isotherm equations that account for "competitive" adsorption of the relevant components. This method requires both pure component and mixture isotherm data. Depending on which equation is selected, the data analysis and fitting are more involved than for pure components, but not enormously so. In that case, the results are compact and relatively simple to use for design or simulation. Examples of the equations are listed in Table 14.4.

The fifth approach is more a field than a concise method, since it embodies so many theoretical concepts and associated methods. All are grouped together as "adsorbed mixture models." Basically, this involves treating the adsorbed mixture in the same manner that the liquid is treated when doing VLE calculations. The major distinction is that the adsorbed phase composition cannot be directly measured (i.e., it can only be inferred); hence, it is difficult to pursue experimentally. A *mixture model* is used to account for interactions, which may be as simple as Raoult's law or as involved as Wilson's equation. These correspond roughly to the Ideal Adsorbed Solution theory and Vacancy Solution model, respectively. Pure component and mixture equilibrium data are required. The unfortunate aspect is that they require iterative root-finding procedures and integration, which complicates adsorber simulation. They may be the only route to acceptably accurate answers, however. It would be nice if adsorbents could be selected to avoid both aspects, but adsorbate-adsorbate interactions may be nearly as important and as complicated as adsorbate-adsorbent interactions.

14.4 DYNAMICS OF ADSORPTION

14.4.1 Overview of Rate Phenomena

To perform adsorber simulations or even to select an adsorbent, one must appreciate the impact of processing conditions, geometry, and transport constraints on performance. This might mean solving the governing partial differential equations or just gaining an awareness of the variables and parameters that affect transport phenomena, especially those regarding the adsorbent. At least two constraints of importance include intraparticle diffusion and pressure drop in the packed bed (see Do, 1998; Kärger and Ruthven, 1992; and Tien, 1994).

Film diffusion resistance, axial dispersion, and axial and radial temperature gradients (implying significant resistances to intraparticle heat transfer, as well as axial and radial conduction and convection) may all be relevant. Furthermore, the adsorbent itself, and internal fittings and devices (e.g., for bed retention or flow distribution), may affect flow behavior and pressure drop. Accordingly, these may affect performance, but accounting for them is not generally practical. Even if the equations could be written, determining the applicable coefficients would be very time consuming.

Mass transport in an adsorbent particle can be viewed as a combination of several mechanisms, as shown in Figure 14.8. Macropore and micropore diffusion are shown and could be considered as examples of intraparticle diffusion. Bulk flow or conveyance through the particle (e.g., via connected pores) is shown in that figure but, to be significant, requires high porosity or a large

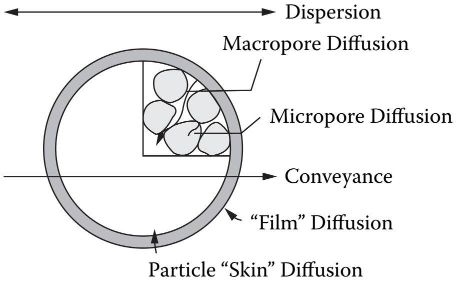

FIGURE 14.8 Illustration of mass transfer mechanisms for a single particle.

pressure gradient. Other facets not shown, but overlapping with those, are mesopore diffusion and surface diffusion. In the latter case, strongly adsorbed components tend to form two or more layers. When that occurs, the outer layer(s) may be mobile, exhibiting what is called *surface diffusion*. The effect is that the adsorbed molecules migrate quickly because of their high density relative to the fluid-phase counterparts.

14.4.2 Mass Conservation and Transport

This section is concerned with the resistances that govern sorption. It begins with the intraparticle aspects, extends to the fluid phase, and finally looks at overall adsorber behavior by considering performance and dynamics as affected by the effects of conditions and parameters on adsorber behavior.

The intraparticle diffusion mechanism is characterized by an effective diffusivity, D_{eff}. For macropore diffusion control alone,

$$D_{eff} = \frac{\varepsilon_p D_{AB}}{\tau} \tag{14.8}$$

and the dimensionless time is $D_{eff}t/\ell^2$, where D_{AB} is the solute diffusivity in the fluid; t is the elapsed time; ε_P is the particle void fraction; τ is its tortuousity; and ℓ is the characteristic length, which equates to the particle radius, r_p, for a bead or cylinder, microcrystal radius, r_c, or particle thickness, h_p, for granules or flakes.

More generally, adsorption is controlled by a combination of transport mechanisms in macropores or micropores, depending on the pore size distribution, the sorbate concentration, the isotherm, and other conditions. The combining bulk diffusion with surface diffusion gives the effective macropore diffusivity:

$$D_{eff} = \frac{\dfrac{\varepsilon_p D_{AB}}{\tau} + (1-\varepsilon_p)\dfrac{dq^*}{dc} D_s}{\varepsilon_p + (1-\varepsilon_p)\dfrac{dq^*}{dc}} \tag{14.9}$$

The effective Knudsen diffusivity (for rarefied gases) in micropores, in cm^2/s, is

$$D_{K_{eff}} = 19{,}400 \frac{\varepsilon_p^2}{\tau a_{BET} \rho_p} \left(\frac{T}{M}\right)^{1/2} \tag{14.10}$$

The effective average pore diameter is $d_{pore} = \varepsilon_p/a_{BET}\rho_p$, and the BET surface area is a_{BET}.

Combining Equations (14.8) and (14.9) gives the overall effective diffusivity in the transition regime:

$$D_{eff}^{*} = \left[\frac{1}{D_{eff}} + \frac{1}{D_{K_{eff}}} \right]^{-1} \tag{14.11}$$

To understand how these parameters are involved in uptake or release rates, consider the fractional change, F, following a sudden change of composition. The expression is a solution of Fick's law. The *initial* response ($D_{eff}t/\ell^2 < 0.4$) and the *final* response ($D_{eff}\,t/\ell^2 > 0.4$) of a spherical particle, respectively, are approximated by

$$F \equiv \frac{C_t - C_0}{C_f - C_0} \approx \frac{6}{\sqrt{\pi}} \left(\frac{D_{eff}t}{\ell^2} \right)^{1/2} - 3\frac{D_{eff}t}{\ell^2} \bigg|_{initial} \quad \text{or}$$
$$\approx 1 - \frac{6}{\pi^2} e^{-\pi^2 D_{eff}t/\ell^2} \bigg|_{final} \tag{14.12}$$

where the C_0, C_f, and C_t represent the initial, final, and instantaneous values of concentration averaged over the particle. For a flow system, $t \approx \ell/v_i$, where $v_i = v_s/\varepsilon_B$ = the interstitial velocity, and $v_s = Q/A_{cs}$ = the superficial velocity, where Q is the volumetric flow rate and A_{cs} is the cross-sectional area of the bed. From these approximations, we can see that when $D_{eff}\,t/\ell^2$ is less than 0.001, the adsorbent is not effective. Conversely, when it exceeds unity, adsorption is largely complete. Thus, when searching for an effective (fast) adsorbent, it is usually a safe bet to choose one having a large diffusivity or small diameter. Other concerns may overrule the selection of small particles, as mentioned later.

Interstitial mass transfer in fixed beds is frequently a significant factor in adsorption dynamics. Sherwood et al. (1975) developed an equation for both gases and liquids that employs the Colburn–Chilton j-factor:

$$j_D = 1.17\ \text{Re}^{-0.415} \quad [\text{for } 10 < \text{Re} < 2500] \tag{14.13}$$

where $j_D = (k_f/v_s)\text{Sc}^{0.667}$, the Reynolds number is $Re = \rho v_s d_p/\mu$, and the Schmidt number is $Sc = \mu/\rho D_{AB}$. We are primarily interested in the fluid-to-particle mass transfer coefficient, k_f. It is mostly governed by the fluid properties (density, ρ; viscosity, μ; and diffusivity, D_{AB}).

Yoshida et al. (1962) suggested another correlation for estimating the mass transfer coefficient:

$$j_D = 0.91\ \text{Re}^{-0.51}\ \psi \quad [\text{for Re}' < 50] \tag{14.14}$$

where the modified Reynolds number is $\text{Re}' = \rho v_s/\mu a_p \psi$, in which $a_p = 6/d_p$ for beads; ψ = shape factor is 1.0 for spherical beads, 0.95 for granular adsorbents, 0.91 for cylindrical pellets, and about 0.86 for flakes; and $D_{Abeff} = D_{AB}/\mathcal{T}$, where $\mathcal{T}$ is an apparent tortuosity factor that lumps the fluid phase resistance (film diffusion) with the intraparticle mass transfer resistance.

For practical purposes, these only depend on one adsorbent parameter, the particle diameter, d_p. As can be seen, $k_f \propto d_p^{-0.415}$ to $d_p^{-0.51}$, so for a given fluid and flow rate, a tenfold increase of the particle diameter would lead to a 60 to 70% decrease of the mass transfer coefficient. Conversely, a tenfold increase of the velocity often leads to a four- to threefold increase of the mass transfer coefficient. Generally, a large value of k_f is desired, although if achieved by employing high velocity, v_s, the associated pumping or compression costs will be high, and the time of exposure in Equation (14.12) will be short.

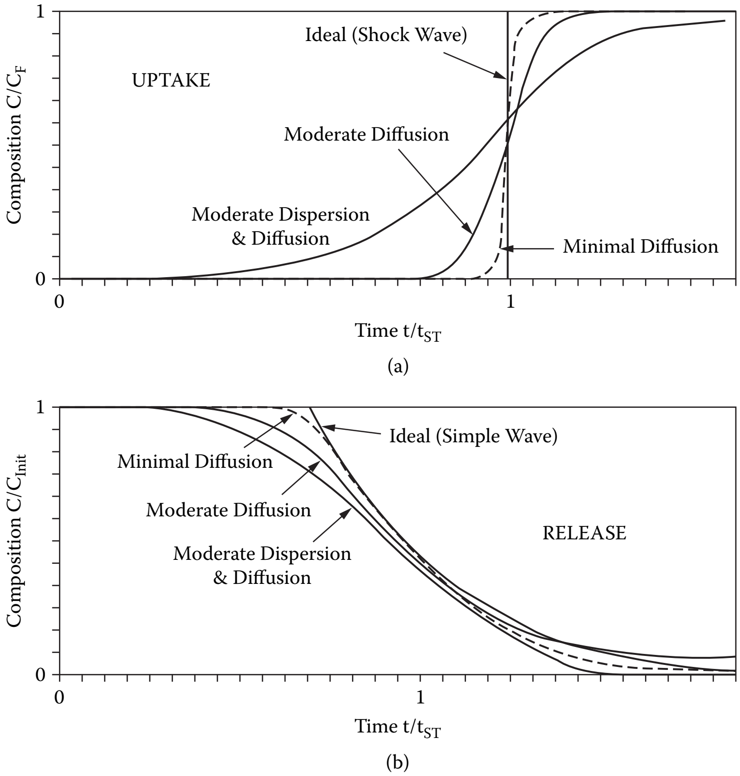

FIGURE 14.9 Realistic and ideal uptake and release breakthrough patterns.

The shape of a breakthrough curve is critical in predicting performance and depends on geometry, adsorbent properties, and operating conditions. An illustration of breakthrough behavior in fixed-bed adsorbers is shown in Figure 14.9. From that figure, we can classify breakthrough patterns for uptake as a *self-sharpening front* or *constant pattern front* or *shock wave*. In contrast, breakthrough patterns for regeneration are referred to as *gradual transitions* or *proportional patterns* or *simple waves.*

Figure 14.10 is a plot of single-component uptake breakthrough data in which a bed of length L_B initially contains fluid at C_0, and the feed concentration is C_F. The upper part of that figure shows the breakthrough curve, L_B, acquired at the end of the bed. That is, it shows the effluent concentration history, $C(t, L_B)$, expressed as $(C - C_0)/(C_F - C_0)$, vs. time. The lower part shows the corresponding loading change of the adsorbent, $(\bar{n}_A - n_0^*)/(n_F^* - n_0^*)$, versus position. This sketch is slightly more abstract than the fluid-phase concentration part for two reasons. First, data of this sort are seldom available. Second, any version would represent a "snapshot" of the state at a specific time. The one shown is the adsorbent bed at imminent breakthrough. The constant pattern assumption (mentioned previously) holds when $C_A/C_{AF} = \bar{n}_A/n_A^*(C_{AF})$. The data shown in Figure 14.10 require certain assumptions to be valid; for example, the flow rate and pressure are constant; the isotherm is "favorable," and the system is nearly isothermal; and the adsorbent is uniform along the axis and across the cross section.

Specifically, in the upper part of Figure 14.10, point 1 represents *imminent breakthrough*, where the effluent concentration first deviates from C_0 reaching C_{IB}, and the corresponding time is called t_{IB}. Likewise, we could consider point 3, where the concentration is practically that of the feed, to be *complete breakthrough*, represented by C_{IB} and t_{CB}. To be very specific, the values could be defined according to process or instrumentation limits, e.g., $C_{IB} = 0.01 \times C_F$ and $C_{CB} = 0.99 \times C_F$.

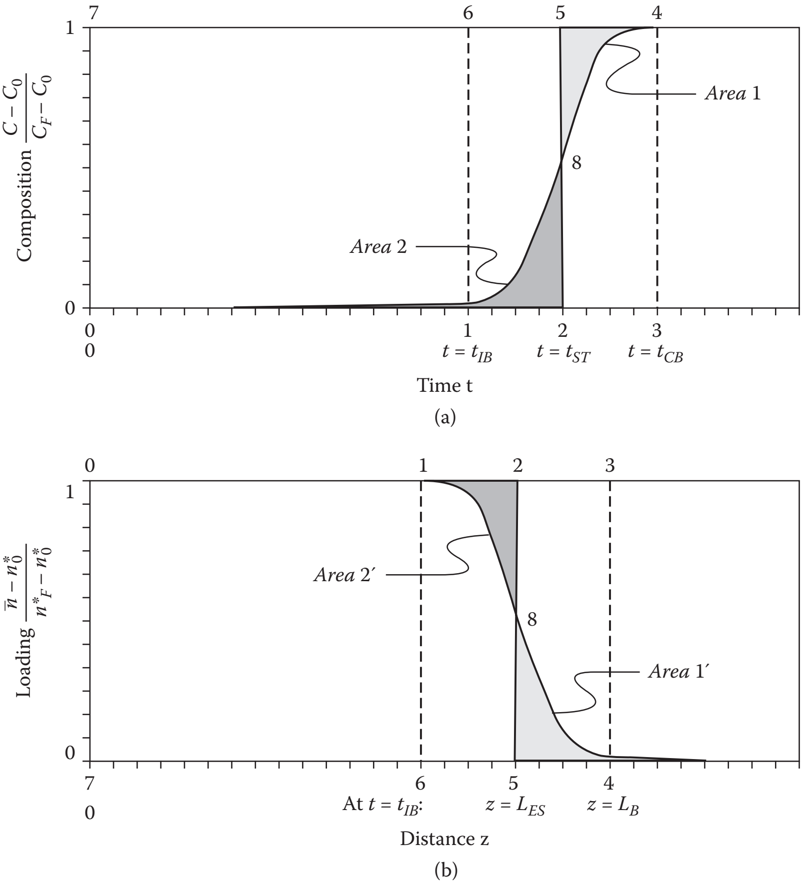

FIGURE 14.10 Breakthrough history (t) and profile (z). Times and positions are labeled to represent specific sets of conditions.

To determine the stoichiometric breakthrough time involves integration. Basically, the points 1 through 6 are chosen such that the area of the rectangle 1-2-5-6 equals that above (or below) the curve 1-8-4-6, and likewise the area of the rectangle 2-3-4-5 equals that below (or above) the curve 1-3-4-8. The result of those is that Area 1 = Area 2 and Area 1′ = Area 2′, and the time dividing them (at point 2) is by definition t_{ST}. If the curve is symmetric, point 8 will lie at the mid-point between the feed and initial concentrations, but that is only coincidental.

Before delving into specific mathematical models, it might be helpful to look at the basic mass conservation equation, because some terms that represent adsorbent properties appear in it. The material balance equation for solute A is

$$\varepsilon_B \frac{\partial C_A}{\partial t} + (1-\varepsilon)\rho_p \frac{\partial \bar{n}_A}{\partial t} + \varepsilon^v \frac{\partial C_A}{\partial z} = E_{ax} \frac{\partial^2 C_A}{\partial z^2} \tag{14.15}$$

where ε = bed void fraction, ρ_p = particle density, ρ_B = bulk density = $(1 - \varepsilon_B)\rho_p$), C_A = solute concentration in fluid, $\bar{n}_A$ = adsorbent loading (averaged), v = interstitial velocity (v_s = superficial velocity = ε^v), and E_{ax} = axial dispersion coefficient. If the column is well designed, the last term can be made negligible. Among these terms, the particle density and void fraction are inherent properties of the adsorbent. Of course, the adsorbent loading is, too, but it also depends on other operating conditions.

14.4.2.1 Local Equilibrium Model

The local equilibrium model assumes that all types of diffusion are instantaneous. It generally predicts shock waves and simple waves, which are ideal versions of the transitions that typically occur. For all that, it can produce useful results with extreme ease (compared with other, more sophisticated methods). Furthermore, it applies to any isotherm form and can be used for uptake or regeneration.

The local equilibrium model assumes that there are no concentration gradients within a particle or in the film surrounding a particle. Thus, the solid responds instantaneously: $\bar{n}_A \sim n_A^*(C_A, T)$. As we have seen in Equations (14.12) through (14.14), this implies that the particles are small or that the diffusivity is large. Also, neglecting dispersion (i.e., $E_{ax} = 0$) leads to the simplest possible set of equations. In virtually every case, the solution of those equations yields the best possible performance of an adsorber. One of the key results obtained by solving Equation (14.15) is the velocity of constant composition:

$$\nu_C = \left.\frac{dz}{dt}\right|_{C_A} = \frac{\nu_s}{\varepsilon_B + \rho_B \dfrac{\partial n_A^*}{\partial C_A}} \tag{14.16}$$

which can generally be used to evaluate breakthrough curves for regeneration.

In the local equilibrium model, the breakthrough curve for uptake is simply a step change from the initial concentration to that of the feed. The speed at which it moves is most important, because that relates the amount of adsorbent to the amount of material processed. This may be found by again assuming that $E_{ax} = 0$ and casting the material balance in difference form, analogous to Equation (14.15):

$$\varepsilon_B \left.\frac{\Delta C_A}{\Delta t}\right|_z + (1-\varepsilon_B)\rho_p \left.\frac{\Delta n_A^*}{\Delta t}\right|_z + \varepsilon^v \left.\frac{\Delta C_A}{\Delta z}\right|_t = 0 \tag{14.17}$$

Letting $v_{SH} = \Delta z/\Delta t$ (the velocity of the step change), $\Delta C_A = C_h - C_l$, and $\Delta n^* = n_h^* - n_l^*$, and rearranging, gives the *shock wave* velocity:

$$\nu_{SH} = \frac{\nu_s}{\varepsilon_B + \rho_B \dfrac{\Delta n_A^*}{\Delta C_A}} \tag{14.18}$$

To illustrate, the Langmuir isotherm [Equation b in Table 14.3] gives, for feed at C_h and the initial column contents at $C_l \sim 0$,

$$\frac{\Delta n^*}{\Delta C} = \frac{\dfrac{Kn_M C_h}{1+KC_h} - \dfrac{Kn_M C_l}{1+KC_l}}{C_h - C_l} = \frac{Kn_M}{(1+KC_h)(1+KC_l)} \tag{14.19}$$

The ideal breakthrough time is $t_{BT} = \Delta t_{SH}$, and it may be evaluated as follows:

$$\Delta t_{SH} = \left[\varepsilon_B + \rho_B \frac{\Delta n_A^*}{\Delta C_A}\right]\frac{L}{\nu_s} = \left[\varepsilon_B + \rho_B \frac{\Delta n_A^*}{\Delta C_A}\right]\frac{V_{ads}}{Q} \tag{14.20}$$

where Q is the volumetric flow rate and V_{ads} is the volume of the adsorbent bed (= LA_{cs}). This result applies to any favorable isotherm. It is restricted to isothermal plug flow with a constant fluid velocity. For uptake of a major gas component, allowance should be made for velocity variation.

14.4.2.2 Modified Wheeler and Robell Method

The Wheeler–Robell equation (1969) is an empirically adjusted local equilibrium model. It neglects axial dispersion but applies to any isotherm form:

$$\frac{C_A}{C_{A_F}} = e^{k_w\left(\frac{C_{AF}}{\rho_B n^*_{A_{eff}}} t - \frac{A_{CS} L}{Q_F}\right)} \tag{14.21}$$

where k_w and $n^*_{A\,eff}$ are adjustable. Determining $n^*_{A\,eff}$ empirically along with k_w leads to discrepancies compared with true equilibrium values. Equation (14.21) can be altered by determining $n^*_{A\,eff}$ independently; e.g., by measuring or predicting it. In addition, the breakthrough time can be predicted via Equation (14.20) (the local equilibrium model) using isotherm data. Solving Equation (14.21) with $C_A/C_{AF} = 0.5$ leads to the following relation for the effective capacity of the adsorbent, n^*_{AF}:

$$n^*_{A_F} = \frac{C_{A_F} t_{BT} / \rho_B}{\theta - 0.693 / k_w} \tag{14.22}$$

where the superficial residence time is $\theta = A_{CS}L/Q_F$ in units consistent with k_w and t_{BT}.

Replacing t_{BT} with the local equilibrium model result $\approx \Delta t_{SH}$ gives a modified Wheeler equation:

$$\frac{C_A}{C_{A_F}} = e^{\frac{k_w - 0.693/\theta}{\varepsilon_B + \rho_B n^*_{NF}/C_{AF}} t - k_w \theta} \tag{14.23}$$

The restrictions as written are to uptake in a clean bed of adsorbent, and only to $C_A/C_{AF} = 0.5$. They could be extended to arbitrary (but uniform) initial conditions, and they can be converted to symmetric breakthrough curve shapes.

14.4.2.3 Mass Transfer Resistances

Three main types of mass transfer resistances are recognized: *film diffusion* (which occurs at the external surface of the adsorbent), *intraparticle diffusion* (which occurs within the pores or amorphous structure of the adsorbent), and *adsorption/desorption kinetics* (which occurs at the internal surface of the adsorbent).

Film diffusion is expressed as a simple function, using the middle term of Equation (14.15):

$$(1-\varepsilon_B)\rho_p \frac{\partial \bar{n}_A}{\partial t} = k_f a_p (C_A - C^*_A) \tag{14.24}$$

where k_f = film mass transfer coefficient and a_p = area (of surface) per unit volume.

Intraparticle diffusion is commonly expressed with Fick's law using terms of pore diffusion or surface diffusion (when adsorption loading is large):

$$\frac{\partial n_A}{\partial t} = \frac{D_{A_{eff}}}{r^2} \frac{\partial}{\partial r}\left(r^2 \frac{\partial C_A}{\partial r}\right) \quad \text{or} \quad \frac{D_{A_s}}{r^2} \frac{\partial}{\partial r}\left(r^2 \frac{\partial n_A}{\partial r}\right) \tag{14.25}$$

where D_{Aeff} = effective diffusivity of A in pores, D_{AS} = diffusivity of A in adsorbed state, r = radial distance in adsorbent bead, and r_p is the nominal particle radius. Intraparticle diffusion may also be expressed with the "linear driving force" (LDF) approximation. This is equivalent to the film diffusion model when the isotherm is linear:

$$\frac{\partial \bar{n}_A}{\partial t} = \psi k_s a_p (n_A^* - \bar{n}_A) \tag{14.26}$$

where k_s = solid-phase mass transfer coefficient, a_p = area (of surface) per unit volume, and $\psi k_s a_p \approx 15 D_{Aeff}/r_p^2$ for most system, which was originally suggested by Glueckauf.

Adsorption/desorption kinetics is generally a simple rate equation based on Langmuir's isotherm derivation [see Equation (14b) in Table 14.3]:

$$\frac{\partial n_A}{\partial t} k_r \left(C_A (n^*_{\max_A} - n_A) - \frac{1}{K} n_A \right) \tag{14.27}$$

where k_r = the reaction kinetic constant and K = the adsorption equilibrium constant.

Perhaps the simplest model that employs these principles was suggested by Hougen and Marshall (1947). Hines and Maddox (1985) generalized their treatment so that virtually any form can be reduced to a LDF form. Their basic equation assumes no axial dispersion, $D_z = 0$; Henry's law isotherm, $n_A^* = K_D C_A$ (which is equivalent to $n_A = K_D C_A^*$); and that film diffusion resistance predominates, as in Equation (14.24). The result is

$$\frac{C_A}{C_{A_F}} = \bar{J}(\tau, \zeta) = 1 - \int_0^{\zeta} e^{-(\tau+\zeta)} I_0(i(4\zeta\tau)^{1/2}) d\zeta \tag{14.28}$$

where

$$\tau = \frac{k_f a_p}{(1 - \varepsilon_B)\rho_p K_D}(t - z/\nu)$$

and

$$\zeta = \frac{k_f a_p z}{\varepsilon_B \nu}$$

where ζ is commonly called the "dimensionless time" and τ is commonly called the "number of transfer units." The mass transfer coefficient, k_f, can be adjusted to fit experimental breakthrough data by accounting for the dependence of flow rate, diffusivity, and so forth.

The integration is a bit complicated, so $\bar{J}(\tau, \zeta)$ is normally evaluated from a plot of $\bar{J}$ versus τ for various values of ζ. Frequently, the following approximations are useful.

For $\tau\zeta > 36$,

$$J(\zeta, \tau) \cong \frac{1}{2}[1 - erf(\sqrt{\zeta} - \sqrt{\tau})] + \frac{e^{-(\sqrt{\zeta}-\sqrt{\tau})^2}}{\sqrt{\pi}[(\zeta\tau)^{1/4} + \sqrt{\tau}]} \tag{14.29}$$

For $\tau\zeta > 3600$,

$$\bar{J} = (\zeta, \tau) \cong \frac{1}{2}[1 + erf(\sqrt{\tau} - \sqrt{\zeta})] \tag{14.30}$$

Note that $erf(-x) = -erf(x)$, and that $erfc(x) = 1 - erf(x)$. An approximation for $erf(x)$ is

$$erf(x) \cong 1 - (A_1 t + A_2 t^2 + A_3 t^3)e^{-x^2} \tag{14.31}$$

where $t = (1 + A_4 x)^{-1}$, and the parameters are $A_1 = 0.34802$, $A_2 = -0.09588$, $A_3 = 0.7478556$, and $A_4 = 0.47047$. For example, $erf(1) = 0.842701$, while the equation above predicts 0.842718.

Extensions of the Hougen–Marshall model, developed by Rosen (1954) account for mass transfer resistances in both the fluid and solid phases. However, it is seldom practical to conduct all the experiments necessary to determine values of both coefficients and their dependence on conditions.

14.4.3 Heat Transfer

Adsorption from the gas or vapor phase is usually associated with significant heat release upon uptake, or cooling upon desorption. Three modes of operation are possible: isothermal, adiabatic, and intermediate (not quite either extreme). Isothermal operation can often be assumed for liquid-phase adsorption but generally not for gas- or vapor-phase systems. Temperature shifts affect adsorption capacity strongly but diffusivity to a lesser extent.

Following the form suggested by Equation (14.14), heat transfer to the fluid phase can be estimated by the Yoshida et al. (1962) correlations for particle to fluid heat transfer coefficients:

$$j_H = 0.91\,\mathrm{Re}'^{-0.51}\,\psi \quad [\text{for Re}' < 50] \tag{14.32}$$

$$j_H = 0.61\,\mathrm{Re}'^{-0.41}\,\psi \quad [\text{for Re}' > 50] \tag{14.33}$$

in which $j_H = (h/C_{pf}\rho v_s)(C_{pf}\mu/\lambda_f)^{2/3}$, in which the heat capacity, density, viscosity, and thermal conductivity of the fluid are C_p, ρ, μ, and λ, respectively, and the subscript f indicates "fluid phase and film temperature." As in Equation (14.14), the particle shape factor is ψ. Likewise, the modified Reynolds number, Re′, is defined as before. An alternate for the previous equations is the Wakao and Funazkri correlation for the particle to the *gas* heat transfer coefficient:

$$Nu = 2.0 + 1.1\,\mathrm{Pr}^{1/3}\,\mathrm{Re}^{0.6} \tag{14.34}$$

where $Nu = h_f d_p/\lambda_f$, in which the heat transfer coefficient is h_f and the gas phase thermal conductivity is λ_f.

Heat generation is frequently significant in adsorbers. Nevertheless, adsorbent particles are usually assumed to be at a uniform temperature. There are many reasons for this observation. Heats of adsorption (and desorption) are not sufficiently large to cause large temperature gradients within typical, small adsorbent particles, but the cumulative effects may generate swings of 10 to more than 50°C. The *thermicity* reveals the magnitude of temperature gradient expected in an adsorbent particle:

$$\beta = \frac{c_s(-\Delta H_{ads})D_{eff}}{\lambda_s T_{ext}} \approx \frac{\Delta T_{\max}}{T_{ext}} \tag{14.35}$$

in which c_s is the intraparticle concentration, ΔH_{ads} is the isosteric heat of adsorption, λ_s is the solid thermal conductivity, and T_{ext} is the external fluid temperature. For gas-phase systems, an order-of-

magnitude estimate is λ_s = 0.1 to 0.3 W/mK, ΔH_{ads} = 1 to 100 kJ/mol, D_{eff} = 1.0E–06 m²/s, T_{ext} = 300 K, and $c_s = P/RT$ = 400 mol/m³ (at 10 bar): $\beta < 2$ K.

Heat transfer to column wall depends on convection. The relevant heat transfer coefficient at the internal surface of a column may be estimated from Leva's correlation:

$$Nu = \frac{h_w d_B}{\lambda_f} = 0.813\,\mathrm{Re}^{0.19} \exp\left(\frac{-6d_p}{d_B}\right) \tag{14.36}$$

14.4.4 Pressure Drop

The third major factor in dynamics is packed bed flow behavior. The pressure drop in the adsorbent media is caused by drag due to fluid flowing through the interstices. For slow flow, the pressure drop, ΔP, across a bed of length Δz and superficial velocity v_s can be represented by Darcy's equation:

$$\frac{-\Delta P}{\Delta z} = \frac{\nu_s \mu}{k} \tag{14.37}$$

where μ is the absolute viscosity, and k = permeability, which has units called a *darcy* = 1 (cm/s)cP/atm/cm ≈ 1.0E–8 cm². Kozeny modified Equation (14.36) using the bed voidage, ε, and the specific surface, S:

$$\frac{-\Delta P}{\Delta z} = \frac{\nu_s \mu S^2}{k'} \frac{(1-\varepsilon)^2}{\varepsilon^3} \tag{14.38}$$

This equation is valid when $\mathrm{Re}' = v_s d_p/\mu(1 - \varepsilon) < 10$ and $\varepsilon < 0.5$., and experimental evidence indicates that $S^2/k' = 150/d_p^2 g_c$. Ergun (1952) combined the Kozeny equation with the Burke–Plummer equation to cover both laminar and turbulent flow conditions:

$$\frac{\Delta P}{L} = \left(\frac{150}{\mathrm{Re}'} + 1.75\right)\left(\frac{\rho_f \nu_s^2}{g_c d_p} \frac{1-\varepsilon}{\varepsilon^3}\right) \tag{14.39}$$

which is valid for the range of modified Reynolds numbers, $0.1 < \mathrm{Re}' < 10{,}000$. An alternative, called Forchheimer's law, can be written after integration as

$$\frac{-\Delta P}{\Delta z} = \alpha \nu_s + \alpha' \nu_s^n \tag{14.40}$$

in which the first term predominates at low flow rates due to viscous forces, and the second term is more significant at high flow rates. The parameters α and α' must be determined empirically. The change from streamline or laminar flow to completely turbulent flow is gradual, because flow conditions are not the same in all interstices, because of their size and distribution. When high pressure drops develop in a bed, some convective transport occurs as described by suitable equations, but the effective particle size is reduced.

Most adsorbers are designed to operate with relatively small pressure drop; relatively large particles are used, and the velocity is typically low to allow equilibration of the fluid with the adsorbent. That typically means short, fat packed beds rather than long, thin ones. Generally, pipes, valves, and fittings contribute as much to the flow restriction as the pressure drop in the adsorbent bed.

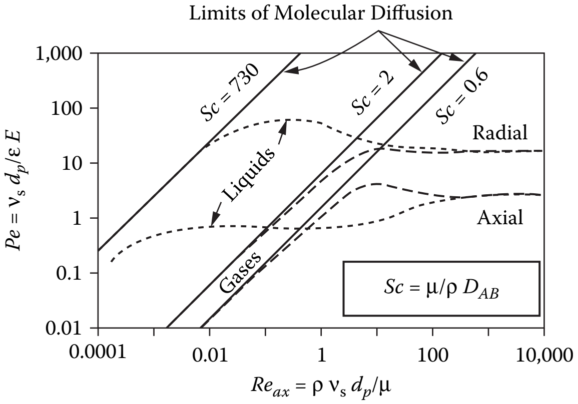

FIGURE 14.11 Axial and radial Peclet numbers for single-phase flow of a gas or liquid through a packed bed of spherical particles. The limits of molecular diffusion are shown by solid lines that represent $Pe = Re\ Sc\ \tau_B/_B$, where τ_B = bed tortuousity = 1.4 and ε_B = bed voidage = 0.4 (Sherwood et al., 1975).

14.4.5 Dispersion

The principal aspect that reflects flow distribution in fixed beds is dispersion. Flow through a packed bed is commonly represented by dispersed plug flow in which all mechanisms contributing to mixing are lumped together in effective dispersion coefficients, E_{ax} and E_r. A model analogous to Fick's law, as given by Equation (14.15), is applicable:

$$\frac{\partial c}{\partial t}+\frac{v_s}{\varepsilon}\frac{\partial c}{\partial z}=\frac{E_r}{r}\frac{\partial}{\partial r}\left[r\frac{\partial c}{\partial r}\right]+E_{ax}\frac{\partial^2 c}{\partial z^2} \tag{14.41}$$

in which the terms for adsorption have been omitted, E_{ax} = the axial dispersion coefficient, and E_r = the radial dispersion coefficient. It is evident that there are two modes of dispersion: radial and axial. Axial dispersion always adversely affects adsorption performance. Despite that, axial dispersion can be offset by radial dispersion, meaning that radial dispersion promotes plug-flow behavior, which is always beneficial to adsorption performance. There are two main dispersive mechanisms: hindered molecular diffusion (corrected for tortuosity) and turbulent mixing arising from flow around the particles. Figure 14.11 indicates the limits of hindered molecular diffusion at low flow rates: $E_{ax} = E_r = D_{AB}/\tau_B$, where τ_B = bed tortuosity ≈ 1.4 (typical) for fixed beds.

The coefficient representing axial dispersion, E_{ax}, is measured using a tracer by pulse, sinusoidal, or step-change residence time distribution tests, or by measuring backflow. Sometimes the phenomenon is represented by a "cell" model, in which the number of well-mixed cells fits dispersion. The coefficient representing radial dispersion, E_r, is determined by measuring the radial spread of a tracer from the centerline toward the wall.

The Peclet number for dispersion is defined as $Pe = v_s d_p/\varepsilon_B E$, which is dimensionless, and $v_s/\varepsilon_B = v_i$ = the interstitial velocity. A convenient way to comprehend the data for fixed beds is via Figure 14.11, which shows the trends for gases and liquids in both axial and radial dispersions. A general correlating equation for gases is

$$\frac{1}{Pe_{ax}}=\frac{K_1}{\mathrm{Re}\,Sc}+\frac{1}{Pe_{ax\infty}}\frac{1}{1+K_2/(\mathrm{Re}\,Sc)} \tag{14.42}$$

where $Pe_{ax\infty} = 2.0$, the Reynolds number is $\mathrm{Re} = \rho v_s d_p/\mu$, and the Schmidt number is $Sc = \mu/\rho D_{AB}$. The product, $\mathrm{Re}\ Sc = v_s d_p/D_{AB}$, is a Peclet number for ordinary diffusion. The coefficients K_1 and

K_2 depend on which study is consulted. In a pair of studies for relatively large particles ($d_p > 3$ mm), Wen and Fan (1975) found that $K_1 = 0.3$ and $K_2 = 3.8$ for $0.008 < \text{Re} < 400$ and $0.28 < Sc < 2.2$, while Edwards and Richardson (1968) found that $K_1 = 0.73\varepsilon_B$ and $K_2 = 9.49\varepsilon_B$, where $\varepsilon_B \approx 0.4$ to 0.6 so that the results are similar. In contrast, $Pe_{R\infty} = 11.0$. For liquids, $Pe_{Ax} \approx 0.45$ in the range $0.005 < \text{Re} < 20$.

14.4.6 Chemical Kinetics and Adsorption

Adsorption, and chemisorption in particular, is closely allied to heterogeneous catalytic reactions: both involve similar mass and heat transport constraints, in addition to bond formation at the solid surface. In fact, adsorption is viewed as a precursor to catalytic reaction, and desorption is viewed as the step subsequent to the reaction itself. Adsorption of the reactant(s) and product(s) must be strong enough to deflect the original bonds, but not so strong as to poison the catalyst. This phenomenon has been related to the adsorption potential suggested by Polanyi (see Section 14.3.2).

Regarding mass transport mechanisms, just as in adsorption, reactants transfer to the catalyst sites, and the products depart by intraparticle diffusion; either may be rate limiting. A schematic diagram showing the phenomena is given in Figures 14.12a and 14.12b. The former shows an ideal planar surface, while the latter shows crude pores. Both show counterdiffusion of the reactant, A, through the product, B, to the surface; transition from A to B at the surface; and counterdiffusion of B through A. In real systems, the mechanism is more complicated, since the surfaces are not ideal, plus diffusion through the pores is complex, even for the simplest stoichiometry.

Descriptive parameters for heterogeneous catalysts overlap with adsorbent properties, for example, the well-known B.E.T. surface area analysis and other properties mentioned in Section 14.2.2.3. The measured value may only be proportional to true catalysis, due to steric or energetic factors. Slightly different values are obtained when fluids other than nitrogen are used (e.g., CO_2 at –78°C or n-butane at 0°C).

Finally, another area of overlap is the potential presence of a false activation energy. This occurs when film diffusion is coupled with, say, a first-order reaction at the catalyst surface. The mass transfer rate $r = k\ a_s(c - c_s)$. In contrast, the inherent reaction rate is $r = k_r a_s c_s$. These two can be combined to give an expression for the surface concentration: $c_s = k_f\, c/(k_r + k_f)$, which is difficult to measure. This expression can be substituted in the original reaction rate expression to give $r = k_0 a_s c$, with an effective rate constant of $k_0 = 1/(1/k_r + 1/k_f)$. Thus, if the inherent rate obeys the Arrhenius dependence on temperature, $k_r = A\ \exp(-\Delta E_r/RT)$, and if k_f is constant, the observed Arrhenius activation energy, $\Delta E_0 = RT\ d\ \ln k_0/d(1/T)$, would be deceptively low.

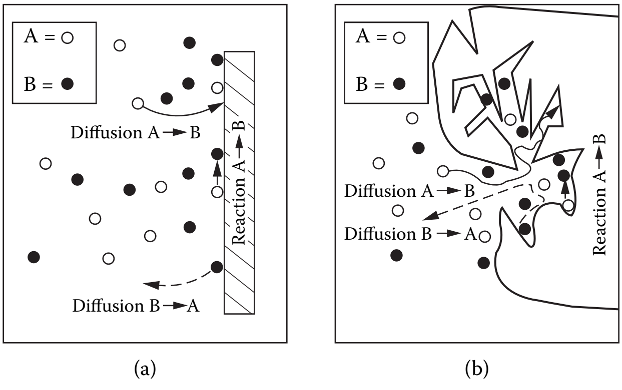

FIGURE 14.12 (a) Simplistic view of diffusion of the reactant, A, through the product, B, reaction at the surface, followed by diffusion of B through A. (b) View of interactions with intraparticle diffusion of the reactant, A, through the product, B, reaction at the surface, followed by diffusion of B through A.

14.5 DESIGN OF BATCH, FIXED-BED ADSORBERS

14.5.1 General Objectives

This section describes *batchwise* fixed-bed adsorbers in which the adsorbent is replaced with fresh material, or removed and regenerated after it is "exhausted," then reinstalled. Commercial examples include columns used for chemical feedstock purification, decolorizing solutions, and wastewater treatment. The goal is generally to employ material balance and rate equations to predict adsorber performance, possibly to analyze experimental data (e.g., breakthrough curves and temperature histories), to diagnose problems, or to assess properties or conditions. Unfortunately, various conditions often result in nearly identical behavior, so diagnosing causes may be difficult.

Often there is an economy of scale, meaning that the cost to process material drops substantially as the size of the unit increases. Unfortunately, there are rather small economic advantages for larger adsorbers, because the cost of the adsorbent typically depends on the amount purchased with an exponent of 0.8 to 1.0. Depending on the pressure rating required, the length-to-diameter ratio (*L/D*) of a typical adsorber may range from 1 to 10, with larger values favored for high pressures. Flow is oriented vertically as a rule, since the adsorbent tends to settle, which would cause void space and bypassing at the top of a horizontal bed. Control is generally based on fixed time cycles, although effluent composition is preferred for performance reasons.

Factors affecting performance are the component isotherm(s), geometry, operating conditions, mass transfer resistances (including film diffusion, intraparticle diffusion, and dispersion), and thermal effects, especially for gases. How these are taken into account varies depending on the application, the tools available, and the situation. For many applications, established methods for simulation and design are readily available. The simplest approach is to estimate the volume of the adsorber, knowing only the adsorbent's capacity at the relevant concentration and temperature, and add a large safety factor.

For more detailed designs, the equations describing breakthrough behavior in the previous section, plus a modest safety factor, may be sufficient. With complex heat and/or mass transfer issues, multiple components, or unusual equipment geometry, a standard model is likely not suitable. In such cases, experimental tests may be required to develop a suitable mathematical model; the required effort might be up to a man-year.

14.5.2 Empirical versus Theoretical Approaches

Model classifications are as follows:

Empirical. Experimental data and/or experience axes are needed; results are imprecise and prone to error, but this method is typically quick. Examples are the length of unused bed (LUB) and mass transfer zone (MTZ) methods, as discussed later.

Analytic. This is restricted to certain conditions (e.g., isothermal uptake with clean adsorbent) *or* no mass transfer resistances. Examples are the Hougen–Marshall and Thomas approaches, and the local equilibrium model. These approaches can be incorporated in a simple design procedure, as illustrated in the next section.

Rigorous. This involves solutions to numerous governing equations; they may include mass transfer resistances, heat effects, complex equilibria, pressure drop, axial dispersion, and others. The last can be time consuming; it lacks intuitive connections between performance and variables. Many applications require rigorous methods. An example is multicomponent adsorption of the type shown in Figure 14.13.

Beyond this, some methods and models do not fit these categories, because they have elements of two or all three, e.g., the modified Wheeler equation shown as Equation (14.23).

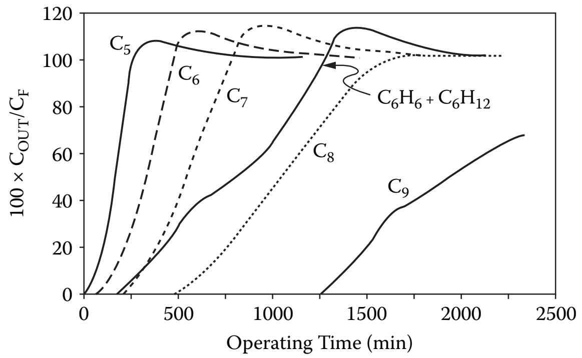

FIGURE 14.13 Breakthrough curves for hydrocarbons in silica gel at 30°C. The lower molecular weight species illustrate roll-up, which is a symptom of displacement by species of higher molecular weight.

14.5.3 Shortcut Procedures

14.5.3.1 Length of Unused Bed Method

A quick way to design an adsorber is by the *length of unused bed* (LUB) approach suggested by Collins (1967). It involves observations about the *mass transfer zone* (MTZ), so experimental data are required. A precursor was suggested by Michaels (1952) as a method of understanding ion exchange column performance. The concept assumes that the transition of concentration from that of the initial contents of the bed to that of the feed is due solely to mass transfer resistance. That is a misconception, but in many cases it suffices.

Figure 14.10 also illustrates the MTZ for an adsorbent bed of length L_B, which initially contains fluid at C_0, and the feed concentration is C_F. As before, the basic assumptions are that flow rate and pressure are constant, the system is isothermal, the adsorbent is uniform along the axis and across the cross section, and for this approach the shape of the breakthrough curve is fixed. t_{IB} is the time of incipient breakthrough, t_{ST} is the stoichiometric breakthrough time [e.g., as predicted by Equation (14.15)], and t_{CB} is the time at which breakthrough is complete. At t_{IB}, the MTZ is contained within the rectangle 1-3-4-6. Ideally, however, the length of adsorbent bed that would be at equilibrium with the feed is L_{ES}. The portion of the bed that has become saturated (to the equilibrium limit) is represented by the rectangle 0-1-6-7. Similarly, in an ideal system, the length of adsorbent bed that would be still at equilibrium with the fluid initially in the bed at t_{IB} is the "length of unused bed," $L_{UB} = L_B - L_{ES}$, represented by the rectangle 2-3-4-5. That is, the concentration in this portion of the bed would ideally be at the initial state, and that upstream would be that of the feed. In reality, of course, both segments of adsorbent are partially used.

At equilibrium, the net amount adsorbed (moles or mass) of component A, n, at any elapsed time prior to breakthrough, t, equals the amount admitted:

$$\dot{n}_A = \dot{m}(C_F - C_0)t = L_{ES}\rho_B(n_F^* - n_0^*) \tag{14.43}$$

where $\dot{m}$ is the flow rate (mass or molar, e.g., ρQ or $\rho Q/\bar{M}$, where $\bar{M}$ is the average fluid molecular weight). Thus, the length of the equilibrium section is

$$L_{ES} = \frac{\dot{m}t}{\rho_B}\frac{(C_F - C_0)}{(n_F^* - n_0^*)} \tag{14.44}$$

or, following Equation (14.20),

$$L_{ES} = \nu_s \Delta t_{SH} \left[\varepsilon_B + \rho_B \frac{\Delta n_A^*}{\Delta C_A} \right]^{-1} \tag{14.45}$$

If the front moves at the idealized shock front velocity, v_{SH}, given by Equation (14.18), then $t_{ST} = t_{SH}$ and the times and positions of the front are related as

$$\nu_{SH} = \frac{L_{ES}}{t_{IB}} = \frac{L_B}{t_{ST}} \tag{14.46}$$

This equation allows a concise expression *of* L_{UB}:

$$L_{UB} = L_B - L_{ES} = \nu_{SH}(t_{ST} - t_{IB}) \tag{14.47}$$

Combining the previous two equations yields

$$L_{UB} = L_B(1 - t_{IB} / t_{ST}) \tag{14.48}$$

Equations (14.44) through (14.48) apply to a single flow rate and cross-sectional area (not to mention temperature, pressure, feed concentration, and other conditions). By analyzing breakthrough data from one column, it is easy to determine the relationships between bed length and time. For example, given the *actual* effluent concentration history, $C(t,L_{Ba})$, and bed length, L_B, for one system, it is straightforward to identify the *actual* times, t_{IBa} and t_{STa}. From those, the *actual* length of unused bed, L_{UBa}, can be found from Equation (14.47). Likewise, the *actual* length of the equilibrium section, L_{ESa}, can be found from Equation (14.45) or (14.46). A design situation could require choosing a bed with a different, "desired" length of unused bed, L_{UBd}, based on the *desired* and *actual* stoichiometric breakthrough times, t_{STd} and t_{STa}. Under those constraints, the length of the *desired* bed can be found from Equation (14.45), $L_{Bd} = L_{Ba}t_{STd}/t_{STa}$. Subsequently, Equation (14.46) can be used to estimate L_{ESd} for the *desired* bed, $L_{ESd} = L_{Bd} - L_{UBd}$.

To scale up by this technique, i.e., to accommodate other flow rates, Q, or bed geometries, masses should be used. They are found by using the cross-sectional area of the bed and the bulk density of the adsorbent. For a cylindrical bed,

$$W_B = \rho_B \pi d_B^2 L_B / 4 \tag{14.49}$$

where W_B is the mass of the bed, and by analogy W_{UB} and W_{ES} are the mass of the unused bed and mass of the equilibrium section, calculated from their lengths, respectively:

$$W_{ES} = \rho_B Q t_{ES} \left[\varepsilon + \rho_B \frac{\Delta n_A^*}{\Delta C_A} \right]^{-1} \tag{14.50}$$

The relationship between W_B, W_{UB}, and W_{ES},

$$W_B = W_{ES} + W_{LUB} \tag{14.51}$$

The only problem occurs when $L_{UB} = f(Q)$, which must be determined empirically.

TABLE 14.5
Procedures for Design of a Conventional Adsorber

1. Choose adsorbent candidates.
   a. Measure basic adsorbent properties: densities, void fractions, particle size distribution, possibly the B.E.T. surface area and pore size distribution, as well as crush strength and attrition resistance.
   b. Evaluate isotherm(s) over the relevant range of concentrations, temperature(s), including multicomponent interference if applicable.
   c. Analyze intraparticle diffusivity at relevant concentrations, temperature(s).
   d. Ensure that the materials are chemically compatible (including minor contaminants).
   e. Consider pretreatment conditions or follow manufacturer's recommendations.
   f. Estimate life and/or replacement schedule (e.g., 20% per year).
2. Determine bed dimensions and layout.
   a. The "ideal" bed volume is determined by the feed flow rate, feed concentration, isotherm, and allowable time. The "real" bed volume is always larger and depends on the desired product concentration. In addition, most vessels will have dead volumes to accommodate bed support (or retention) and flow distribution devices.
   b. Use a model to calculate effluent concentration as a function of time for a given flow rate, feed concentration, etc. It is important to recognize that mass transfer parameters are not transferable among the models.
   c. If desired, the length-to-diameter ratio can be varied systematically for a fixed volume and compared to the required uptake times. It is critical to take into account the dependence of the mass transfer coefficient on Reynolds number, which will vary as L/D varies.
3. Assess other performance factors.
   a. Pressure drop, and associated power consumption
   b. Flow distribution (fixtures or devices)
   c. Energy requirement to maintain processing temperature range (and need for thermal insulation— internal or external)
   d. Devise control system and necessary instruments and elements.
4. Determine cost (net present value, payback time, etc.).
   a. Rank-order the candidate adsorbents at the extremes of the operating conditions.
   b. For the best adsorbent(s), optimize the operating conditions, vessels, and energy consumption.
   c. Select the best combination of adsorbent and operating conditions.
5. If performance and cost are acceptable, stop. If not, return to step 1 and repeat for other adsorbents. If no plausible adsorbents remain, consider an alternative version of adsorption (e.g., TSA or PSA).

14.5.3.2 Direct Method Using Breakthrough Models

A conventional adsorber can be designed using a breakthrough model relatively easily. Begin with the local equilibrium model, and Equations (14.18) and (14.20) in particular. The former would be useful for determining the flow rate for a given bed length and allowable breakthrough time. The latter would be useful for determining the breakthrough time for a given bed length and flow rate. That method provides no information regarding the shape of the breakthrough front, however. To take into consideration the shape requires the Wheeler–Robell, Hougen–Marshall, or Thomas model. In addition, there is a need for experimental data to assess the mass transfer coefficient associated with the selected model.

A typical design situation for a conventional adsorber begins with the feed flow rate and concentration, allowable time, temperature, pressure, and/or desired product concentration. The last quantity may be either an *instantaneous* or *average* cutoff value, depending on the situation. The sequence of steps necessary to convert that information into a design is given in Table 14.5.

14.5.4 Examples

For relatively simple applications of adsorption, the first goal is normally to find a suitable adsorbent and the quantity required, and then to settle a variety of ancillary issues regarding how the adsorbent will be used, discarded, or recycled. Typically, one would buy the adsorbent, or in some cases a modular, prefilled adsorber, which is replaced when the problem recurs or after a predetermined time.

Example 14.1 Isotherm Fitting

Consider the following adsorption isotherm data for water vapor on silica gel at 25°C. Fit the data to the Langmuir, Freundlich, Redlich–Peterson, and B.D.D.T. equations.

Relative Humidity	Loading Mol/cm^3
0.0000	0.00000
0.0116	0.00173

0.7580	0.03387
0.8250	0.03411
0.8250	0.03415

Results

The data and isotherm fits are shown in Figure 14.14. The corresponding parameters and statistics are provided in Table 14.6. The average percentage deviations for those fits are 8.8, 12.0, 7.9, and 2.7%, respectively. The average errors for the Langmuir and Redlich–Peterson equations, in particular, seem high due to relatively large percentage deviations for the first few points. These deviations are exaggerated at low loadings. That is, if an adsorbent has a maximum loading of 1 kg/kg, a discrepancy of 0.01 kg/kg would be equivalent to a 100% deviation if it occurred at 1% of the maximum loading, but only a 1% deviation if it occurred at saturation. When, however, a weighted scale is used, in which the weights are simply proportional to loading, a discrepancy of 0.01 kg/kg amounts to a 1% deviation. Applying that for this example, the weighted percentage deviations are 3.9, 4.8, 1.9, and 1%, respectively.

The B.D.D.T. isotherm essentially provides an ideal fit at low, intermediate, and high concentrations. The parameter m indicates that 4.4 layers are adsorbed on the surface at saturation. This isotherm form also discerns the "real" Henry's law coefficient, which is about four times larger than the value that the simpler equations estimate. The Redlich–Peterson equation fits the data well, although it incorrectly predicts a local maximum in loading. Hence, it is unreliable for extrapolations, and it underpredicts the loading at low concentrations (i.e., below 10% RH). The Langmuir isotherm predicts well at low concentrations but not near saturation. The Freundlich isotherm is least satisfactory in nearly every respect. It might be adequate for estimating overall life, but not for design purposes.

Example 14.2 Dilute Gaseous Emissions

Consider a process vent containing 100 ppm (vol.) each of MEK, *n*-hexane, and toluene, at a flow rate of 10 cfm and at 80°F, operating 24 hours per day.

Results

Because the contaminants are organic, activated carbon is a candidate adsorbent, with one reservation: safety. Ketones, in particular, sometimes cause fires in activated carbon. To avoid that complication, other adsorbents might be considered. We will assume that activated carbon is acceptable, in part being the least expensive on a single-use basis.

Table 14.6 lists loadings for two activated carbons: one produced from coal, *A*, and one produced from coconut shell, *B*. Carbon *B* costs 50% more than carbon *A*.

Multicomponent adsorption is complex (see Figure 14.13). Since this is a small application, delving into equilibria and column modeling is not justified. It is assumed that the lighter components are displaced by the heavier components. The feed, 10 cfm at 80°F, amounts to 9.1 scfm or 1.52 lb-mol/hr. Thus, the *loading rate* of each component that needs to be adsorbed is $0.0001 \times 1.52/MW$ (lb/h), where MW is its molecular weight. The time on line can be estimated by dividing the loading by the *loading rate*, assuming that they adsorb independently and completely (no premature breakthrough).

The best choice appears to be carbon B, since it offers a longer time on line than carbon A for the critical component, MEK, and the ratio (1.76) is greater than the cost ratio (1.5). If there were no MEK in the stream, the decision would be a tossup, since the respective carbons' loading ratios of those components are nearly identical to their cost ratios.

The final consideration is the type and cost of equipment. Modular units come packed with 150 to 500 lb of carbon. They can be installed and removed quickly and returned to the manufacturer on an exchange basis (possibly avoiding "hazardous waste" aspects). The smaller units would be packed with 4 × 6 mesh carbon and could handle up to 100 cfm, well within the range needed. For 50 lb per batch per contaminant, two parallel units would be needed to handle the MEK for 600 hr, allowing some excess to take care of rounding of the breakthrough curve. The cost would be in the range of \$600 each. Even at this low cost (\$17,520 per year, not including labor, shipping, and other costs), it might be possible to justify a small PSA unit that would recover concentrated vapor (for incineration) or a condensed product. Such systems are not yet available off the shelf, however.

Example 14.3 Dilute Liquid Solutions

Consider a feed of 0.3 mg/l (or 300 ppm) of diphenylamine in 100 gpm water, with a minimum on-line time of 500 hr.

Results

Dobbs and Cohen (mentioned earlier) reported that Filtrasorb-300 (Calgon Corp.) adsorbs 80 mg/g at this concentration. Thus, $\Delta n^*/\Delta C$ = 80 (mg/g)/0.0003 (mg/cm^3). ρ_B = 31.2 lb/ft^3 (or 0.5 g/cm^3), ε = 0.70. They also noted that a fine powder (200 × 400 mesh, or 0.05-mm diameter) required about 5 hr to equilibrate. Equation (14.12) suggests the time required to equilibrate a 0.5-mm diameter granule. Namely, the parameter $D_{eff}t/\ell^2$ would be constant, as would the effective diffusivity. Thus, $t_{3mm} = t_{0.05mm}$ (0.5 mm/0.05 mm)^2 or 500 hr! Granules will not exhibit a sharp breakthrough, so a large safety factor is needed. Accordingly, facilities often employ a slurry of powdered carbon with a downstream filter to remove the waste.

Equation (14.20) is used to estimate the bed volume, given the equilibrium breakthrough time. We find that the minimum volume of adsorbent is 112.5 gal = 15 ft^3 or roughly 470 lb. To be conservative, a *safety factor* of 3 is recommended, but even that should be tested. Thus, the bed size would be about 45 ft^3 (roughly 3 ft dia. × 6.5 ft long), containing about 1400 lb of carbon. The length-to-diameter ratio, L_B/d_B, could be optimized. To obtain a large mass transfer coefficient, that ratio should be large, but to minimize pressure drop, that ratio should be small. Generally, the optimum ratio lies in the 1:1 to 5:1 range.

Example 14.4 Gaseous Emissions

Predict the breakthrough patterns for uptake of CO_2 from air by activated carbon under the following data, and compare with the breakthrough data (Note: the symbol [=] denotes "has units of"):

ρ_B = 0.360 g/cm^3	ε_B = 0.345	d_p = 0.5 mm
d_B = 0.718 cm	L_B = 72 cm	p_{AF} = 0.1316 atm
$\dot{Q}$ = 1.85 std. cm^3/s	T = 0°C	P = 1 atm

$$n_A^* = \frac{0.0112 p_A}{1 + 7.258 p_A} [=] \frac{\text{mol (A)}}{\text{g (adsorbent)}}; \quad p_A [=] \text{atm}$$

t (min)	10.73	11.567	11.983	12.4	12.817	13.233	14.067
C/C_F	0.000	0.117	0.250	0.517	0.700	0.808	0.933

Results

(1) *Local Equilibrium Model*:
Uptake time =

$$\Delta t_{SH} = \left[1 + \frac{\rho_b}{\varepsilon_b}\frac{\Delta n_A^*}{\Delta C_A}\right]\frac{L}{\nu}$$

where

$$\nu = \frac{\dot{Q}}{A_{CS}\varepsilon_b} = 13.24\,\frac{\text{cm}}{\text{s}}$$

and

$$\frac{\Delta n^*}{\Delta C_A} = RT\frac{\Delta n^*}{\Delta p} = RT\frac{0.0112}{(1+7.258\times 0.1316)} = 128.4\,\frac{\text{cm}^3}{\text{g}}$$

$$\therefore \Delta t_{SH} = 744.\ s = 12.4 \text{ min}$$

(2) *Modified Wheeler Equation*:

$$\frac{C_A}{C_{A_F}} = e^{\frac{k_w - 0.693/\theta}{\varepsilon_b + \rho_b n_A^*/C_{AF}}t - k_w\theta}$$

where

$$\theta = V_{bed}/\dot{Q}_F = 29.56/1.85 = 15.98 \text{ s} = 0.266 \text{ min},$$

$$n_A^*/C_{AF} = 0.0007539/0.000005871 = 128.4 \text{ cm}^3/\text{g, and}$$

$$\varepsilon_B + \rho_B n_A^*/C_{AF} = 0.345 + 0.36\times 128.4 = 46.57.$$

At t = 11.98 min, choosing k_w = 1 s^{-1} yields C_A/C_{AF} = 0.2992, while k_w = 3 s^{-1} yields C_A/C_{AF} = 0.1022, but the actual value is C_A/C_{AF} = 0.250. Using the two to interpolate, we find k_w = 1.3 s^{-1} yields C_A/C_{AF} = 0.255.

Breakthrough curves for values of k_w from 1.3 to 100 are shown in Figure 14.15.

14.6 CYCLIC AND CONTINUOUS ADSORPTION PROCESSES

Cyclic adsorbers are periodically regenerated in place after they are "exhausted." The four main categories are inert-purge, displacement-purge, TSA, and PSA. Generic characteristics of those cyclic systems are explained in substantially more detail later in this section.

Continuous processes employ circulating adsorbent or moving ports so that a portion of the adsorbent is always being regenerated. Design procedures for this type of process are complicated

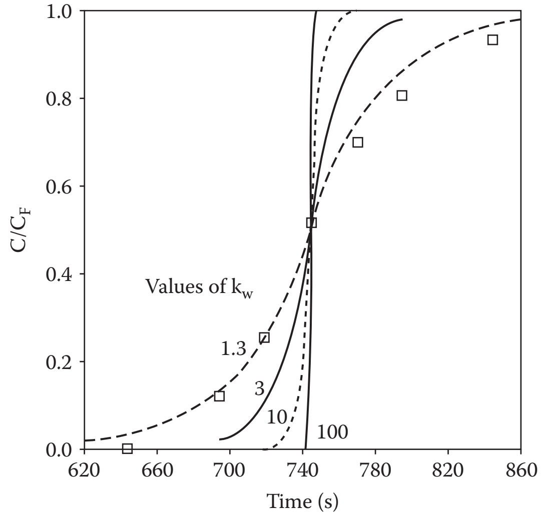

FIGURE 14.15 Comparison of breakthrough predictions for the Wheeler equation for k_w = 1.3, 3, 10, and 100 1/s. The data are shown as square symbols.

and are beyond the scope of this chapter. Nevertheless, it may be helpful to consider the features of typical continuous systems, since they may be transferred to other situations. Example flowsheets of three types of continuous process are given in Figures 14.16, 14.17, and 14.18. The first is a stirred system, which functions like a CSTR from the standpoint of the liquid. The adsorbent, however, undergoes a batchwise experience. The second flowsheet a continuous TSA system in which the adsorbent circulates through uptake and regeneration zones. The third flowsheet depicts a simulated moving-bed (SMB) system, in which the adsorbent is in a fixed bed and the feed, product, and regenerant entry and exit are shifted synchronously via valves such as in UOP's Sorbex^{SM} processes.

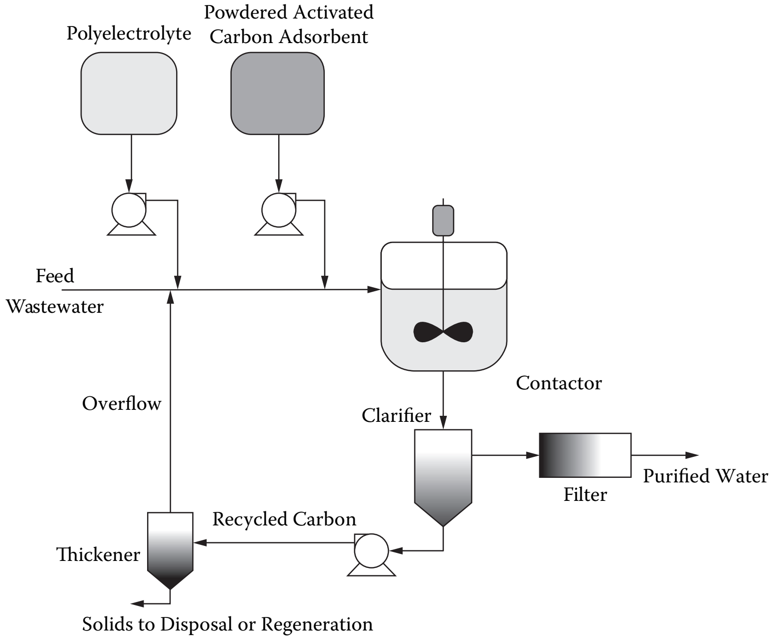

FIGURE 14.16 Powdered activated carbon system for cleanup of wastewater.

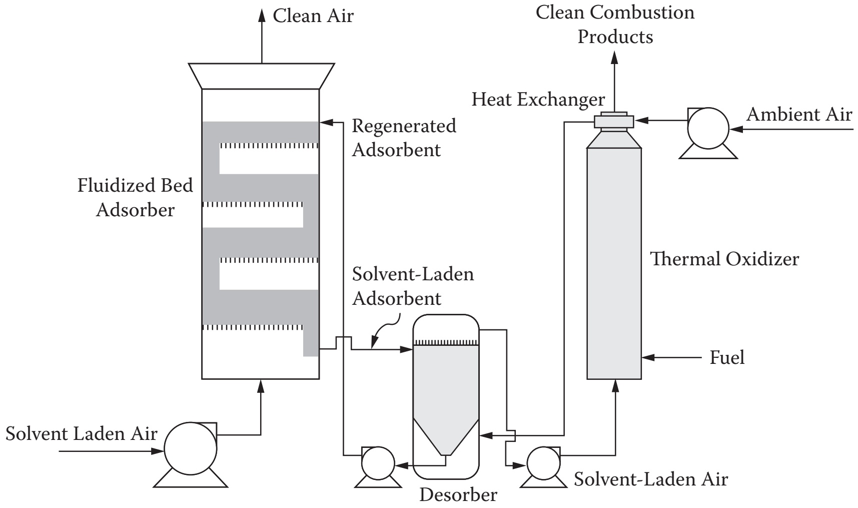

FIGURE 14.17 "Blizzard" adsorption system for cleanup of solvent-laden gas, by On-Demand Environmental Systems, Inc.

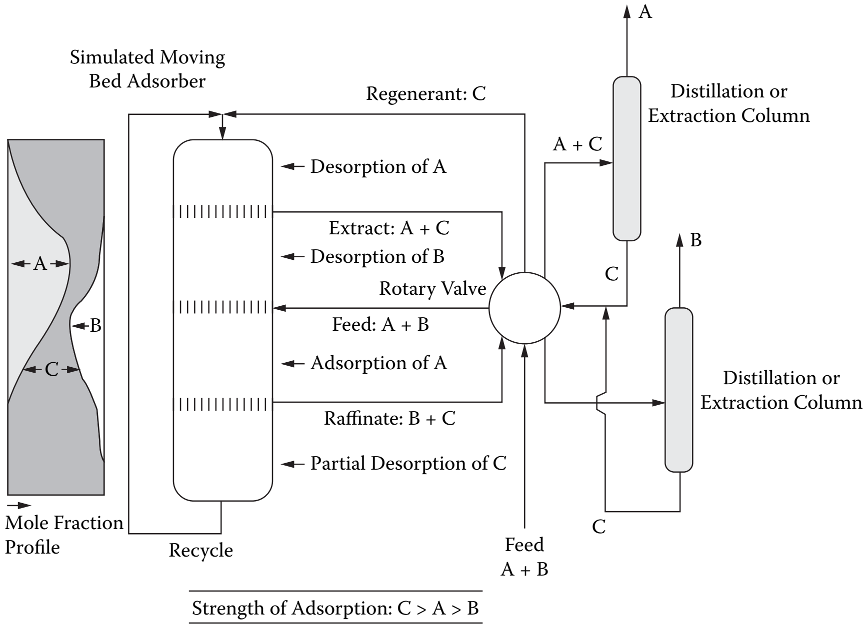

FIGURE 14.18 Simulated moving-bed adsorption system, after UOP Sorbex concept.

Generalizations about the relative merits of cyclic and continuous processes are nearly futile. Few applications are amenable to both. Rather, one or the other will usually be a clear choice. The criteria for making that choice boil down to cost and performance, and it is not possible to assert which version will prevail except under extreme conditions.

14.6.1 Inert-Purge Cycle

The simplest cycle is the so-called *inert-purge cycle*, shown in Figure 14.19. It is basically a two-step process of a few minutes' or hours' duration. First is adsorption (often with heat evolution),

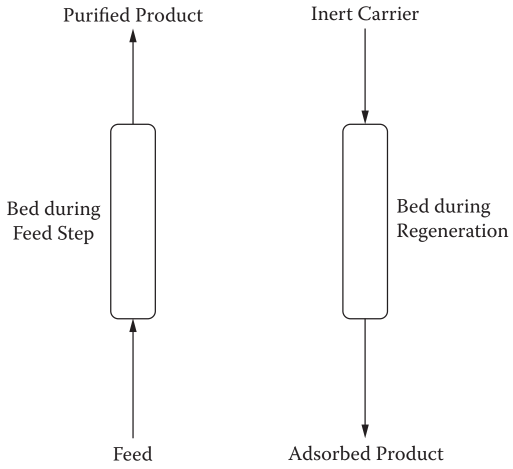

FIGURE 14.19 Simple two-column inert-purge adsorption system.

followed by regeneration with an inert fluid. It essentially transfers the adsorbed constituent from one stream to another, but in so doing it dilutes (instead of enriching) adsorbate. It also cools by desorption (i.e., the latent heat is taken up so as to achieve regeneration), and so it is advantageous to recover stored heat (which is released during uptake). The relevant breakthrough curves are shown in Figure 14.9.

14.6.2 Displacement-Purge Cycle

Another relatively simple system is the *displacement*-purge *cycle,* shown in Figure 14.20. This is also a two-step process: adsorption in which the bed (being preloaded with a strongly adsorbed component, B), is gradually displaced by a weakly adsorbed component in the feed, A, followed by regeneration via the more strongly adsorbed component. The latter step desorbs A by selectively adsorbing B and enriches the desired adsorbate A.

14.6.3 TSA Cycle

A third type of cycle is *temperature swing adsorption* (TSA). Typical TSA cycles comprise two or three steps of several minutes' to several days' duration. They are adsorption at low temperature, regeneration at high temperature, and cooling (which is optional) and may be done with solvent (or carrier) or a separate inert fluid. An illustration of how loading changes during a typical TSA cycle is shown in Figure 14.21.

TSA success usually depends on the regeneration step and the associated costs. To accomplish regeneration, one may use heated feed, hot solvent (or carrier), separate hot inert fluid, electrical current, microwaves, or steam. Steam, although widely used, usually accomplishes regeneration by conveyance rather than displacement, so the effluent composition profile is not sharp. Nevertheless, the adsorbate is enriched because the amount of fluid required for desorption is much less than that during uptake. The energy requirements of regeneration strongly affect overall cost. A typical cycle is shown in Figure 14.22.

Example 14.5 TSA Solvent Recovery

Consider *n*-heptane–laden air at 5000 ppm, 1000 metric tons of solvent/yr (= 125 kg solvent/hr), operated 8000 hr/yr. The TSA cycle duration is 6 hr (half adsorption, half desorption), and the equipment consists of two parallel beds operating sequentially.

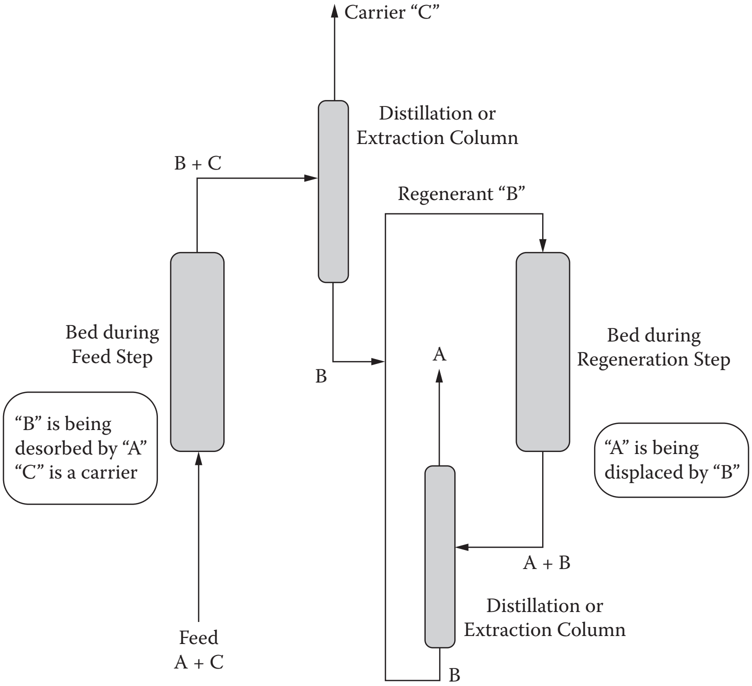

FIGURE 14.20 Two-column displacement-purge adsorption system.

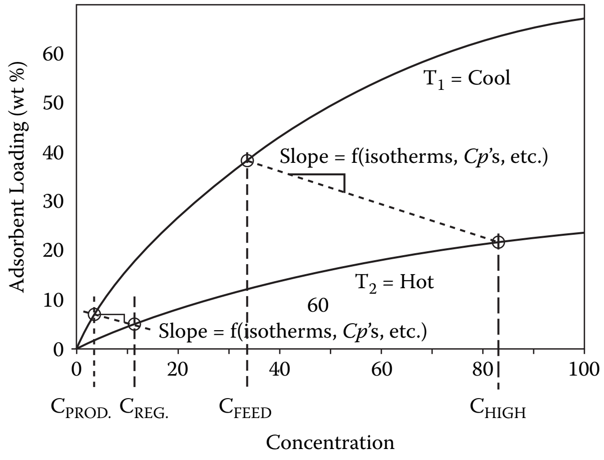

FIGURE 14.21 Isotherms at increasing temperatures, showing operating lines for a TSA cycle.

Data for typical systems are provided in Table 14.8. There we find, for *n*-heptane, the working capacity is 6 kg/100 kg loading, and the steam requirement is 4.3 kg steam/kg solvent. A mass balance yields an estimate for the required amount of adsorbent = 6250 kg/bed, and the required steam flow rate = 537.5 kg/hr.

14.6.4 PSA Cycle

The fourth and final type of system reviewed is *pressure swing adsorption* (PSA). A very simple cycle is shown in Figure 14.23. The factors governing PSA are basically no different from those

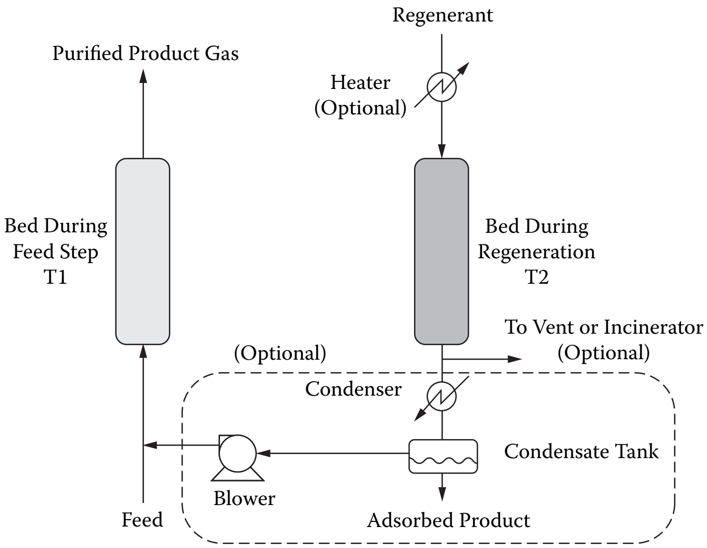

FIGURE 14.22 Typical two-column temperature swing adsorption system.

TABLE 14.7
Estimated Loadings and Service Times of Emitted Components (at 100 ppm each) for Activated Carbons A and B at 80°F

Component Name	Mol. Wt (g/mol)	Loading (lb/100 lb) Carbon A	Loading (lb/100 lb) Carbon B	Loading Ratio B/A	Max. On Line (hr/100 1b) A	Max. On Line (hr/100 1b) B

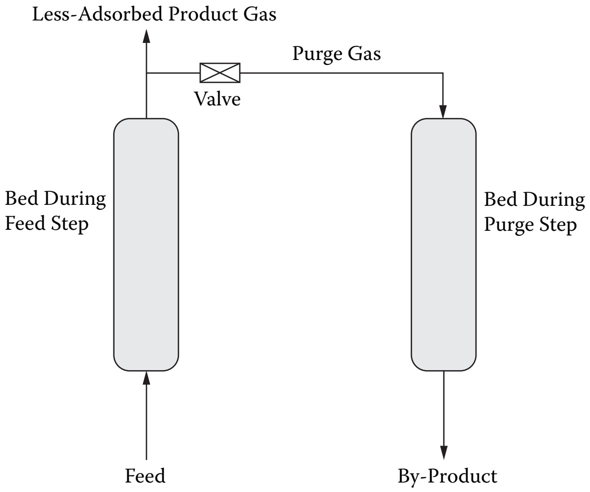

FIGURE 14.23 A simple two-column pressure swing adsorption system.

of ordinary adsorption. For example, the tendency of an adsorbent to take up one component selectively from a mixture is crucial to ordinary adsorption as well as to PSA. It is easy to envision the magnitude of the adsorbent *selectivity* by viewing the isotherms and/or by examining the effective diffusivities of each component. The isotherms indicate the *equilibrium* selectivity of the adsorbent, while the effective diffusivities provide a measure of the *kinetic* selectivity of the adsorbent. This section deals mainly with the former, although the latter is discussed briefly.

It is primarily the span of absolute pressures, coupled with differences in mole fractions (caused by pressure shifts and/or by admitting different streams to the column), that drive PSA separations. Equilibrium selectivity can cause composition shifts to occur simply by changing the pressure. To illustrate this point, consider an adsorbent bed of zeolite 5A filled with air (assumed to be only oxygen and nitrogen) at 3 atm. The mole fractions in the gas phase of oxygen and nitrogen are 0.21 and 0.79, and their initial concentrations are 24.1 and 90.8 mol/m^3, respectively. The isotherms on zeolite 5A at 45°C are plotted in Figure 14.24. Assuming that equilibrium exists, the respective loadings are 109 and 748 mol/m^3. Subsequently depressurizing the bed to 0.5 atm will shift the gas-phase composition approximately to the ratio of moles evolved. On that basis, a simple material balance shows that the new gas-phase mole fractions would be 0.137 and 0.863 for oxygen and nitrogen, respectively. More precise estimates, obtained by solving the governing PDEs, are 0.080 and 0.920 [see Equation (14.62)]. This shift, although substantial, is less than the shift that occurs on uptake, say, during the feed step. In that step, it is possible to shift the nitrogen mole fraction from less than 0.003 to 0.79. It is surprisingly easy and exciting to develop PSA systems in which such shifts occur, creating high-performance gas separations.

Skarstrom (1972), widely recognized as the inventor of PSA, cited four principles; (1) Employ short cycles and low throughput to conserve the heat of adsorption within the bed. (2) Regenerate at low pressure using some of the product for countercurrent purge. (3) Use an equal (or greater) volume for purge as fed during a cycle. (4) To obtain a pure product, the pressure ratio $\mathcal{P}$ $(= P_H/P_L)$ should exceed the inverse of the light component feed mole fraction, $1/y_{BF}$. These rules of thumb continue to be useful but have been reinforced and supplemented by simple theoretical expressions that have been experimentally validated.

Various terms characterize PSA performance. Chief among them are product purity, product recovery, adsorbent productivity, and energy requirements. The purity and recovery normally refer to the light product or sometimes the heavy product. Purity is expressed in terms of "the number of nines," e.g., five nines would be 99.999% contaminant free. Frequently, only specific contaminants are considered in the remainder, leading to delusions of absolute purity. Recovery is expressed

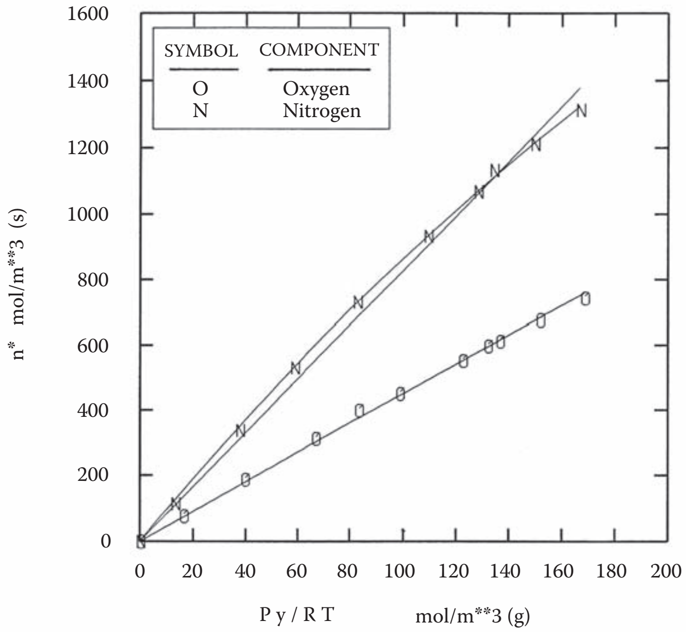

FIGURE 14.24 Isotherms of oxygen and nitrogen on zeolite 5A at 45°C.

as the fraction (or percentage) of the desired component in the product with respect to that in the feed. For example, the fractional recovery of the light component in the high-pressure product might be denoted $R_{HB} = y_{HB}\dot{Q}_{HB}/y_{FB}\dot{Q}_{FB}$, where the $\dot{Q}$'s represent molar flow rates. Adsorbent productivity is normally related to the space time and mass of adsorbent, as $P_{ads} = \dot{Q}_{HB}/M_{HB}m_{ads}$, where M_{HB} represents the mean molecular weight of the product, and m_{ads} is the mass of adsorbent. Occasionally, the units of productivity are expressed in terms of the volumetric ratio of flow to adsorbent rather than the mass ratio.

Common PSA cycles consist of 2 to 12 steps of a few seconds' to several minutes' duration. The most common steps are *pressurization* (with feed or purified light product), *feed* (at high pressure), *blowdown, and purge* (with purified product at low pressure). *Feed* involves a "wave" of the more adsorbable component moving toward the product end at high pressure. Flow stops when breakthrough is imminent and usually yields the less strongly adsorbed, or "light," product. Regeneration always occurs by *blowdown* or *depressurization*, which may be supplemented by *purging*, so it is ready for *pressurization*. Blowdown usually yields the more strongly adsorbed, or "heavy," by-product. Rinse (at high pressure) is optional, inserted after the feed step that permits adsorption of the "heavy" component, which allows the residual feed to be recovered. The heavy component can be subsequently recovered by depressurizing. Operating two beds in parallel, but 180° out of phase, generally permits continuous feeding and production.

Most cycles exploit *equilibrium selectivity* differences between species. Some exploit differences in *intraparticle diffusion rates*. These are becoming more prevalent with advances in adsorbent modification techniques. Efficient PSA cycles result from a good adsorbent, full exploitation of the input power, and careful control. The input power is exploited fully when a gas product or by-product is used to accomplish tasks as "reversibly" as possible. The shift in adsorbent loading may be 1 to 10 wt% for concentrated feeds. Generally, the energy requirements of regeneration most strongly affect overall cost.

The ratio of absolute pressures, $\mathcal{P}$, governs performance, since it governs performance and power consumption. Isotherm curvature, which becomes relevant as absolute pressure increases, leads to poorer performance at higher absolute pressures. Flow rates and step times are closely

coupled. To maximize adsorbent productivity, it is common to maximize the flow rate (and minimize the step time). Conversely, to achieve high purity and sharp breakthrough patterns, it is common to minimize the flow rate (and maximize the step time). Obviously, there exists an optimum dictated by economics and product quality constraints. The details of these trade-offs are beyond the scope of this chapter, but it is usual to maintain relatively sharp profiles at the expense of reduced adsorbent productivity.

Besides the effects mentioned above, the flow rate dramatically affects pressure drop. To compensate for the high flow rate needed to achieve high productivity, the column length and diameter may be manipulated for a given volume of adsorbent, as discussed later. Likewise, particle size may be involved in the choice of *L/D* and flow rates, as discussed below. Of course, the product of flow rate and pressure drop contributes to power consumption. The other variables directly affecting pressure drop, besides flow rate, particle size, bed diameter, and bed length, are adsorbent void fraction and fluid viscosity and density. The feed composition dramatically affects performance, especially the product recovery. It is always the case that the maximum possible recovery of a component increases as its mole fraction in the feed increases. In some situations with adsorbates having relatively low volatility, caution is warranted. This is because performance may deteriorate near the dewpoint pressure due to adsorption hysteresis, thermal effects related to conserving the heat of adsorption, and (in extreme cases) the possibility of two-phase flow.

In view of the many properties and parameters that affect PSA performance, it is possible to characterize the adsorbates and adsorbent for a prospective system in either very simple or very complex terms. The simplest version requires only information regarding the adsorption isotherms and adsorbent void fraction. In the case of linear isotherms, the properties can be combined as in Equation (14.6),

$$\beta = \beta_A / \beta_B \tag{14.52}$$

where the terms β_A and β_B can be determined via

$$\beta_i = \frac{\varepsilon}{\varepsilon + (1-\varepsilon)K_i'} \tag{14.53}$$

The values of K_i' and ε' can be measured independently in separate batchwise experiments. In fact, the isotherm slopes for oxygen and nitrogen with zeolite 5A at 45°C, as shown in Figure 14.24, are 4.51 and 8.24, respectively. The void fraction was determined to be 0.478, and the bulk density was 810.0 kg/m^3. Thus, the values for that system are β_A = 0.100, β_B = 0.169, β = 0.593. Alternatively, β may be determined for many bulk separations (e.g., oxygen from air) via a so-called breakthrough experiment. In such an experiment, a fixed bed of adsorbent having the same (or scaled-down) features of the full-scale bed is initially pressurized with the light component. Then the feed is admitted to the bed at the same pressure. By monitoring just the flow rates, the value of β may be found from

$$\beta = 1 - \frac{(1 - \dot{Q}_P / \dot{Q}_F)}{y_{A_F}} \tag{14.54}$$

where $y_{AP} = 0$, the bed pressure is kept constant with $\Delta P = 0$, and $\dot{Q}$'s are the constant volumetric flow rates.

Two distinct approaches can be taken to model a PSA system: develop a rigorous model that accounts for all significant effects, or settle for the simplest possible model and add terms if necessary. One must balance the fact that the former type requires more time to develop, a variety of empirical coefficients, and a powerful computer, while the latter may ignore effects that *could*

be important, but it is generally simple and quick to implement. For equilibrium-based separations, the latter is in most ways adequate. For kinetics-based separations, the former is essential.

Fortunately, many applications can be predicted accurately via the simplest models. They ignore transport phenomena, mainly account for mass conservation, and are called equilibrium models. Though the concept is simple, such a model can account for a wide variety of effects, including flow, pressure, and composition variations, of course, as well as nonlinear isotherms and dispersive effects due to dead space, say, at the entrance or exit of the adsorbent bed.

The model considered here is the simplest equilibrium model that applies to many cases; it is very simple to use. The coefficients required for this model have already been introduced as β, β_A, and β_B. Furthermore, in tests conducted to date, the predictions have agreed with the detailed experimental observations. The theory usually reduces to simple performance equations that relate the operating conditions and design parameters. A fairly complete review of such models appears in the book by Ruthven et al. (1994). The model proposed by Knaebel and Hill (1985) is explained briefly here.

The inherent assumptions of this equilibrium theory are

1. Local equilibrium (i.e., at each axial location) is achieved instantaneously between the adsorbent and adsorbates.
2. The feed is a binary, ideal gas mixture.
3. Axial dispersion within and at the entrance and exit of the adsorbent bed is negligible.
4. Axial pressure gradients are negligible.
5. There are no radial velocity or composition gradients.
6. Temperature is constant.
7. One hundred percent of the adsorbent is utilized during the feed and purge steps.
8. Pressure is constant during the feed and purge steps.
9. The isotherms are linear and uncoupled.

The following individual component molar balance is similar to Equation (14.15). For a binary mixture, two equations are coupled in the gas-phase but are assumed independent in the adsorbed phase:

$$\varepsilon\left(\frac{\partial Py_i}{\partial t}+\frac{\partial vPy_i}{\partial z}\right)+RT(1-\varepsilon)\frac{\partial n_i}{\partial t}=0 \tag{14.55}$$

The general subscript i refers to component A or B. By convention, the more strongly adsorbed component is identified as component A. The linear isotherm equation gives the moles adsorbed per unit volume of adsorbent in terms of the gas-phase concentration in moles per unit open volume:

$$n_i = K_i' Py_i / RT \tag{14.56}$$

Combining Equations (14.55) and (14.56) yields

$$\frac{\partial Py_i}{\partial t}+\beta_i\frac{\partial \nu Py_i}{\partial z}=0 \tag{14.57}$$

When pressure varies, and when one end is closed (e.g., during blowdown or pressurization), the overall material balance can be solved to find the interstitial velocity in the packed bed, as

$$\nu=\frac{-z}{\beta_B[1+(\beta-1)y_A]}\frac{1}{P}\frac{dP}{dt} \tag{14.58}$$

Alternatively, when pressure is fixed, the following result relates the velocities and compositions at any two points, as long as the composition profile is continuous between them, i.e.,

$$\frac{\nu_2}{\nu_1} = \frac{1+(\beta-1)y_{A_1}}{1+(\beta-1)y_{A_2}} \tag{14.59}$$

The simplicity of equilibrium-based theories results from the fact that the coupled first-order partial differential equations (material balances) can be recast as two ordinary differential equations (but these are still coupled). The mathematical technique employed is called the method of characteristics. The results are

$$\frac{dz}{dt} = \frac{\beta_A v}{1+(\beta-1)y_A} \tag{14.60}$$

$$\frac{dy_A}{dP} - \frac{(\beta-1)(1-y_A)y_A}{[1+(\beta-1)y_A]P} \tag{14.61}$$

Equation (14.60) defines *characteristic* trajectories in the *z, t*-plane. These are paths along which the composition varies, if at all, according to Equation (14.61). Thus, the latter expresses the dependence of composition on pressure along those characteristics. It should be clear from Equation (14.61) that, when pressure is constant, composition is fixed along each characteristic.

Integrating Equation (14.61) yields the composition shift due to a pressure shift as follows:

$$\frac{y_{A_{final}}}{y_{A_{initial}}} = \left[\frac{1-y_{A_{final}}}{1-y_{A_{initial}}}\right]^{\beta} \mathcal{P}^{\beta-1} \tag{14.62}$$

The prediction mentioned earlier concerning the composition shift of air in a PSA system was based on $\beta = 0.593$, as explained earlier (see Equations (14.52) and (14.53)).

Commonly, the purge and blowdown steps are governed by Equations (14.60) and (14.61). To analyze other steps typically requires additional equations that reflect the feature that enables PSA (as well as other adsorption processes) to operate efficiently. The feed, rinse, and (possibly) pressurization steps involve uptake of the more strongly adsorbed component (while the blowdown and purge steps usually do not). This phenomenon results in a sharp concentration front, sometimes called a *constant pattern* profile or a *shock wave*. Usually, it is the velocity of this sharp front through the packed bed (of a specific length) that governs the duration of the particular step.

The necessary condition for such a front to exist is that the feed must be enriched in the heavy component, compared to the initial column contents. Likewise, the velocity is controlled by the molar (or volumetric) flow rate into and out of the system; hence, the material balance is also affected.

The velocity of the shock wave depends on the interstitial fluid velocities at the leading and trailing edges of the wave. These are related, since the shock wave velocities for both components *A* and *B* are equal, for cases in which pressure varies:

$$\nu_{SH} = \frac{-\beta_A z}{[1+(\beta-1)y_{A_1}][1+(\beta-1)y_{A_2}]} \frac{1}{P}\frac{dP}{dt} \tag{14.63}$$

When pressure is fixed, the following expression is obtained:

$$\nu_{SH} = \beta_A \frac{u_2 y_{A_1} - u_1 y_{A_1}}{y_{A_2} - y_{A_1}} \tag{14.64}$$

Propagation of this composition front or shock wave dominates the feed step and pressurization with feed.

By combining the equations for the various steps, expressions for product recovery can be obtained. Some examples are given here. The result for the light product recovery of the conventional four-step cycle is

$$R_B = (1-\beta)\left[1 - \frac{1}{\rho y_{B_F}}\right] \tag{14.65}$$

The light and heavy product recoveries from the five-step cycle including rinse are

$$R_B = 1 - \frac{1}{\rho y_{B_F}} \tag{14.66}$$

$$R_A = 1 - \frac{1}{(1-\beta)\rho y_{A_F}} \tag{14.67}$$

Although many PSA applications exhibit some degradation of performance from that predicted by the equilibrium theory, only those that *rely* on differences in intraparticle diffusivities *require* detailed mathematical models. Carbon molecular sieves and special zeolitic molecular sieves have pore sizes tailored to admit compact molecules readily and to exclude marginally larger molecules. For example, splitting nitrogen from air by a carbon molecular sieve is reported to exhibit a ratio of effective diffusivities of oxygen to nitrogen of about 45. There happens to be essentially no equilibrium selectivity in that case. Similarly, for the same separation, a modified 4A zeolite exhibited an oxygen-to-nitrogen diffusion rate selectivity of about 50, but the equilibrium selectivity was about 2.0 in the reverse direction.

15.1 INTRODUCTION

15.1.1 Introduction

The process control engineer is responsible for the safe operation of a plant while reliably and efficiently producing the desired product quality. The control engineer does this by transferring the variability that otherwise goes into important controlled variables to manipulated variables and less important controlled variables. In order to meet these objectives, process control engineers use a complete knowledge of the process to attain the most desirable performance.

The refining and chemical industries are intimately involved in the effort to obtain the most efficient operation of the plant. Minimizing product variability is often a key operational objective and is directly affected by the performance of the process control system. In fact, the performance of an overall process control system is often expressed in terms of the variability in the products produced by the process. Figure 15.1 shows the measurement of the impurity in a product for the original control system (case A). Case B represents the performance of a new control system that produces a more uniform product than for case A. In addition, since case B has lower variability, the average impurity level can be moved closer to the impurity specification (case C). Many times, operating closer to the limit allows greater production rates or lower utility usage, both of which result in increased profits. Other types of operational limits are encountered, resulting from environmental regulations, capacity limits on equipment, and safety limits. In a similar manner, operating close to these limits can be economically important.

An endothermic continuous stirred tank reactor (CSTR) is shown schematically in Figure 15.2. The symbols used in the control schematics are listed in Table 15.1 The controlled variable is the temperature of the product leaving the reactor, and the manipulated variable is the flow rate of steam to the heat exchanger, which adds heat to the recycle line. The final control element is the control valve and associated equipment on the steam line. The sensor is a temperature sensor/transmitter that measures the temperature of the product stream leaving the reactor. The controller compares the measured value of the product temperature with its desired temperature (setpoint) and makes changes to the control valve on the steam to the heat exchanger. The process is the

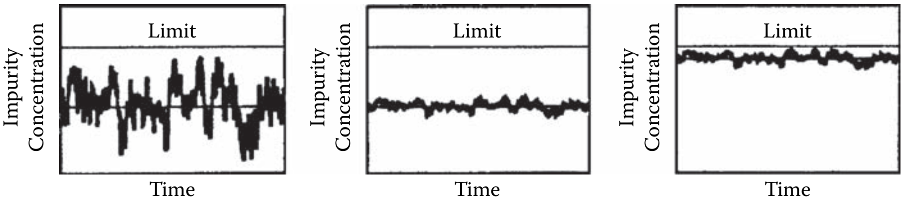

FIGURE 15.1 Comparison between impurity measurements and the upper limit on the impurity in a product for the original control system (case A), the improved control system with the original impurity setpoint (case B), and the improved control with new setpoint (case C).

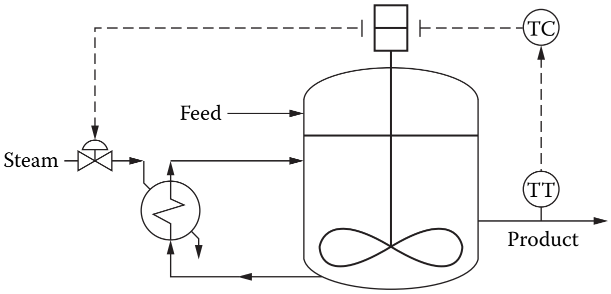

FIGURE 15.2 Schematic of an endothermic CSTR. TT = temperature sensor/transmitter, TC = temperature controller.

TABLE 15.1
Definition of Symbols for Control Diagrams

AC – analyzer controller (i.e., composition controller)
AT – analyzer transmitter (i.e., composition analyzer/transmitter)
DPC – differential pressure controller
DPT – differential pressure sensor/transmitter
HS – high select (this element selects the larger of two or more inputs)
LC – level controller
LS – low select (this element selects the lower of two or more inputs)
LT – level sensor/transmitter
PC – pressure controller
pHC – pH controller
pHT – pH sensor/transmitter
PT – pressure sensor/transmitter
RSP – remote setpoint (i.e., the setpoint calculated by another controller)
TC – temperature controller
TT – temperature sensor/transmitter
⊗ – summation block (minus signs for an input compartment denote subtraction)
+ – addition function (i.e., two inputs are added to yield the output)
× – multiplication function (i.e., two inputs are multiplied to yield the output)

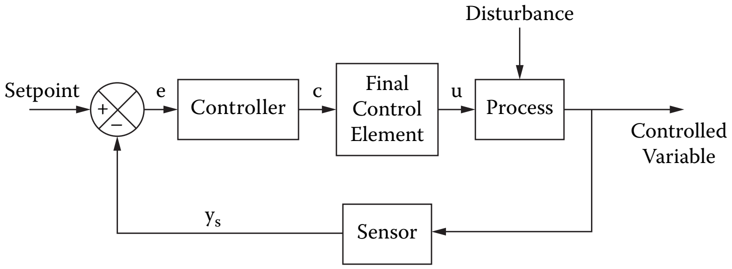

FIGURE 15.3 Block diagram of a generalized feedback system; *e* is the error from setpoint, *c* is the controller output, and *u* is the manipulated variable.

reaction mixture in the reactor and in the heat exchanger and the lines to and from the heat exchanger. Changes in the feed composition, feed rate, and quality of the steam are examples of disturbances to this process.

Figure 15.3 shows a block diagram of a generalized feedback control system for the system shown in Figure 15.2. That is, this example has a controller, a final control element, a process, and a sensor, in that order, along with feedback of the measured value of the controlled variable to the controller. In addition, the example process is affected by disturbances. Note that the sensor reading, y_s, is compared with the setpoint, and the controller chooses control action based on this difference. The final control element is responsible for implementing changes in the level of the manipulated variable. The "process" for a control loop is only the part of the system that determines the value of the controlled variable from the inputs. The overall process can be based on a number of processing units.

The symbol ⊗ in Figure 15.3 represents a summation block. The negative sign on the measurement of the controlled variable results in forming the difference between the setpoint and the measured value of the controlled variable, which is referred to as the error from setpoint. A block diagram of an open-loop process involves only the actuator, process, and sensor without the feedback of the measurement of the controlled variable to the controller.

15.1.2 General Dynamic Behavior

The simplest type of dynamic behavior results from a first-order process. Figure 15.4 shows the response of a first-order process (y) to a step change in u. The analytical solution of a first-order process subjected to a step input change of A is given by

$$y(t) = AK_p\left(1 - e^{-t/\tau_p}\right)$$

The process gain, K_p, and the size of the step change, A, determine the new steady-state value of y. The time constant, τ_p, determines the dynamic path the process takes as it approaches the new steady state, i.e., how long it takes to reach a new steady state. Note that 63.2% of the final change occurs in one time constant after the input change. Ninety-five percent occurs in three time constants, and 98% occurs in four time constants. The process gain is the steady-state change in y divided by the corresponding change in u, i.e.,

$$K_p = \frac{\Delta y}{\Delta u}$$

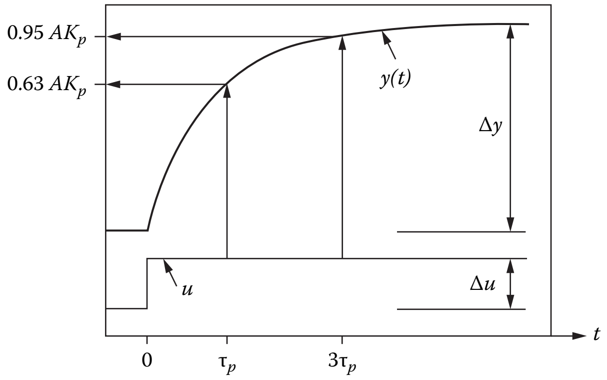

FIGURE 15.4 Dynamic response of a first-order process to a step input change.

The time constant for a well mixed vessel without chemical reaction is the volume of liquid in the vessel divided by the total volumetric feed rate, i.e., the residence time of the vessel.

Figure 15.5 shows the three general types of dynamic behavior of a second-order process, which can also be used to describe the dynamic behavior of feedback systems: overdamped, critically damped, and underdamped. Overdamped behavior is characterized by a monotonic approach to steady state. Underdamped behavior is characterized by an oscillatory approach to steady state. A critically damped response marks the boundary between overdamped and underdamped behavior.

Figure 15.6 shows the key features of an underdamped response. The rise time is the time required to first cross the final steady-state value. The response time or settling time is the time required for the response to settle to within ±5% of the steady-state change (±5% D). The decay ratio is the ratio *C/B*, which indicates how fast the oscillations damp out.

Distillation, absorption, and extraction columns have a number of combined stages, which yield high-order dynamic behavior. Figure 15.7 shows the dynamic response of 3, 5, and 15 combined stages. Note that the more stages that are combined, the slower the response becomes; i.e., the process exhibits a sluggish response. For the case corresponding to 15 stages, it requires a relatively large amount of time before a significant change in the output, *y*, can be observed. The time after an input change before a significant change in the output variable can be observed is an indication of the process deadtime.

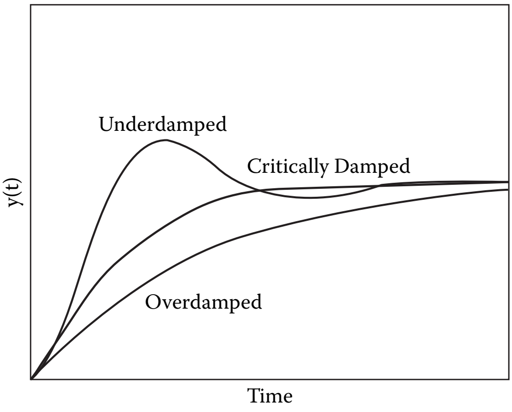

FIGURE 15.5 The three general types of dynamic behavior for a second-order process.

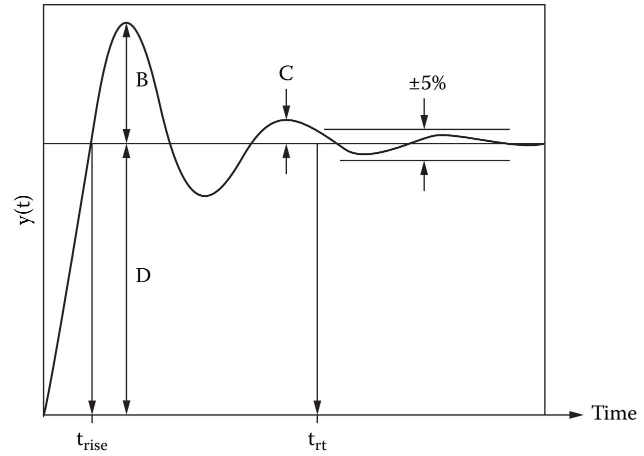

FIGURE 15.6 The general characteristics of an underdamped response.

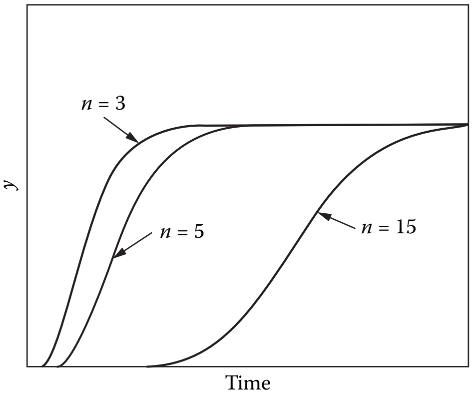

FIGURE 15.7 Dynamic response of several high-order systems.

If a process settles at a new steady state after an input change, the process is referred to as self-regulating. Levels in tanks, accumulators, and reboilers, and many pressure systems, behave as integrating processes. Consider the level in a tank for which both the flow in and the flow out are set independently. Initially, the flow out, F_{out}, is equal to the flow in, and the level is constant. Figure 15.8 shows the level as a function of time for a step change in the flow out at time equal to 10 s. Note that the level in the tank begins to decrease at a constant rate. This is an example of a non-self-regulating process, since the process does not move to a new steady state.

An inverse response can occur when opposing factors exist within a process for which there is a fast-acting, low-gain response combined with a slower-acting, high-gain response. An example of the dynamic response of an inverse-acting process is shown in Figure 15.9. Note that, initially, a decrease in $y(t)$ results, ultimately followed by an increase.

15.1.3 First-Order Plus Deadtime (FOPDT) Model

A FOPDT model is the combination of a first-order model with deadtime, which can be represented by the combination of the process gain (K_p), the process time constant (τ_p), and the process deadtime (θ_p). The process gain represents the steady-state change in the output of the process (y) for a change in the input (u). The time constant indicates how fast the process settles to the new steady

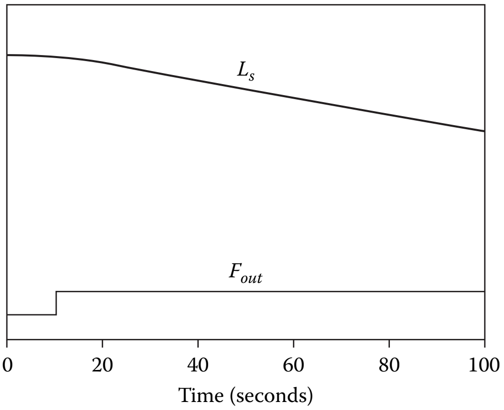

FIGURE 15.8 Dynamic response of a level in a tank to a change in the flow out of the tank.

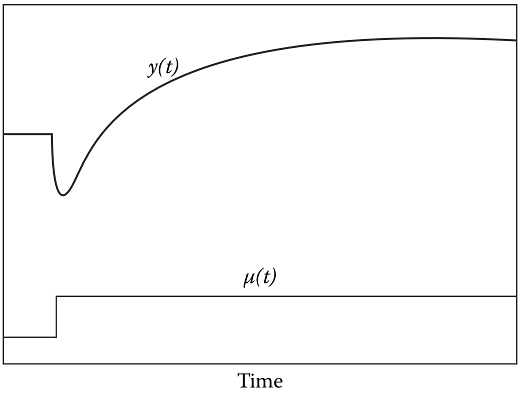

FIGURE 15.9 Dynamic response of an inverse-acting process.

state; i.e., the response time of the process is related to the time constant of the process. The deadtime indicates how soon after an input change has occurred that a noticeable change in y can be observed.

A step test (i.e., a step input change) in certain cases can be used to develop an FOPDT model. Figure 15.10 shows one such approach. First, identify the resulting change in y (i.e., Δy) and the step change in the input, Δu. Then, from the step response, identify the time required for one third of the total change in y to occur, $t_{1/3}$. Next, identify the time required for two thirds of the total change in y to occur, $t_{2/3}$. Then, the following estimates can be used:

$$\tau_p = \frac{t_{2/3} - t_{1/3}}{0.7}$$

$$\theta_p = t_{1/3} - 0.4t_p$$

$$K_p = \frac{\Delta y}{\Delta u}$$

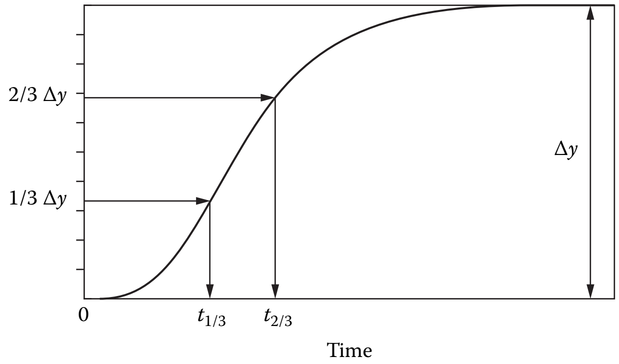

FIGURE 15.10 Graphical representation of an approach for determining the parameters of a FOPDT model.

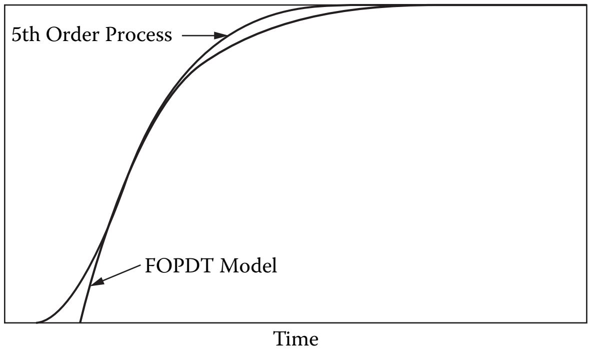

FIGURE 15.11 Comparison between a FOPDT model and an overdamped fifth-order process.

Note that $t_{1/3}$ and $t_{2/3}$ are based on the assumption that time is equal to zero when the step change in u is implemented. This modeling approach is particularly well suited for modeling high-order processes because the deadtime approximates the initial response of the high-order system before significant change has occurred. Figure 15.11 shows a fifth-order process and a FOPDT model that was selected to match this high-order process. Overall, the FOPDT model provides a good approximation for overdamped process behavior; therefore, since most industrial processes behave as overdamped systems, the FOPDT model is one of the best idealized models to represent industrial processes.

15.1.4 Closed-Loop Dynamic Behavior

Figure 15.12 shows the general range of dynamic behavior of a feedback system. Figure 15.12a shows a sluggish response of a feedback process, which is also an overdamped response. Figure 15.12b demonstrates a critically damped response, which represents the transition between overdamped and oscillatory behavior. Figure 15.12c shows an oscillatory response, which is also underdamped behavior. Although Figure 15.12c shows a response that results in a rapid decay of the overshoot, Figure 15.12d shows the case in which damping occurs much more slowly, which is referred to as *ringing*. Figure 15.12e shows the case for sustained oscillations because the amplitude of the oscillations remains constant. Figure 15.12f demonstrates unstable behavior in which the amplitude of the oscillations grows with time.

Most feedback control loops exhibit the same stages of dynamic behavior as the aggressiveness of the controller is increased. Since most processes in the chemical industry are overdamped under open-loop conditions (no feedback control action applied), the process remains overdamped when

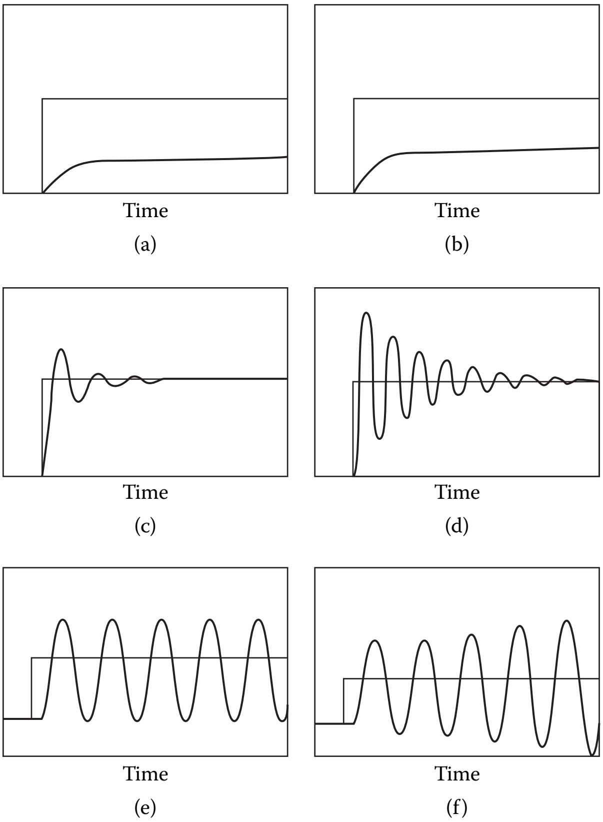

FIGURE 15.12 The general stages of dynamic behavior of a feedback system.

a small amount of feedback action is applied. As the aggressiveness of the controller is increased, the dynamic response becomes critically damped immediately before it becomes underdamped (exhibits oscillations). A further increase in the controller aggressiveness results in an increase in the rate of oscillations and a slower damping of the amplitude of the oscillations. As the controller aggressiveness is increased further, the amplitude of the oscillations eventually begins to increase, and unstable dynamic behavior results.

15.2 CONTROL LOOP HARDWARE AND TROUBLESHOOTING

15.2.1 Introduction

To apply control to a process, one measures the controlled variable and compares it to the setpoint and, based on this comparison, typically uses the actuator to make adjustments to the flow rate of the manipulated variable. The industrial practice of process control is highly dependent upon the performance of the actuator system (final control element) and the sensor system as well as the controller. If either the final control element or the sensor is not performing satisfactorily, it can drastically affect control performance regardless of controller action. Each of these systems (i.e., the actuator, sensor, and controller) is made up of several separate components; therefore, the improper design or application of these components, or an electrical or mechanical failure of one of them, can seriously affect the resulting performance of the entire control loop. The present description of these devices focuses on their control-relevant aspects. Later, troubleshooting approaches and control loop component failure modes are discussed.

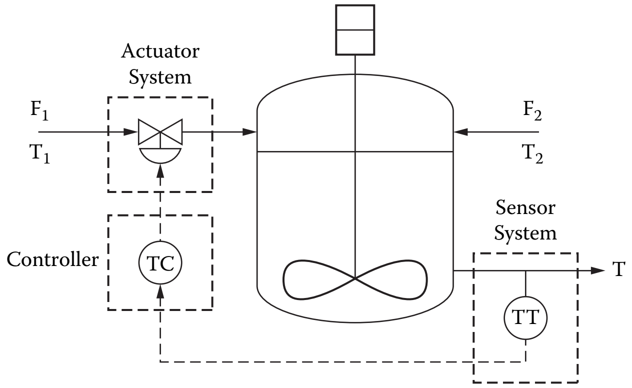

FIGURE 15.13 Schematic of the CST thermal mixer showing the actuator system, sensor system, controller, and the process.

Figure 15.13 is a schematic of a feedback control loop for a temperature controller on a mixer in which stream 1, with flow rate F_1 and temperature T_1, is mixed with stream 2, with flow rate F_2 and temperature T_2. This loop consists of a controller, a final control element, a process, and a sensor. Figure 15.14 is a schematic of the hardware that constitutes this feedback temperature control loop as well as the signals that are passed between the various hardware components. The sensor system shown in Figure 15.13 corresponds to the thermowell, thermocouple, and transmitter in Figure 15.14, while the actuator system in Figure 15.13 corresponds to the control valve, I/P converter, and instrument air system in Figure 15.14. Likewise, the controller in Figure 15.13 is made up of the analog-to-digital (A/D) and digital-to-analog (D/A) converters, the distributed control system (DCS), and the operator console in Figure 15.14. The abbreviations used in this paragraph are described in the next several sections.

A thermocouple is placed in a thermowell, which is in thermal contact with the process fluid leaving the mixing tank, providing a measurement of the temperature of the fluid inside the mixing tank. The temperature transmitter converts the millivolt signal generated by the thermocouple into a 4–20 mA analog electrical signal. When the thermocouple/transmitter system is calibrated prop-

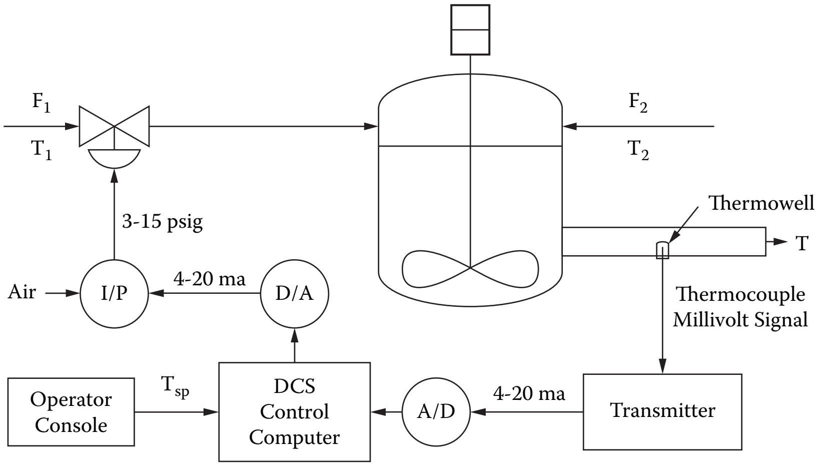

FIGURE 15.14 Schematic of the control system on the CST thermal mixer showing each component along with the various signals.

erly and the thermowell is properly designed and located, the value of the analog signal corresponds closely to the temperature in the mixing tank. The thermocouple/thermowell/temperature transmitter makes up the sensor system for this process.

The 4–20 mA analog signal from the temperature transmitter is converted into a digital reading by the A/D converter. The output of the A/D converter is a digital measurement of the temperature that is used in the control calculations. The operator console shown in Figure 15.14 allows the operator or control engineer to observe the performance of the control loop and to change the setpoint, T_{sp}, and controller tuning parameters for this loop. The value of T_{sp} and the digital value of the measured mixer temperature are used by the control algorithm in the DCS (i.e., the control computer). The output from the controller is a digital signal that is converted into an analog signal by the D/A converter. The DCS, the D/A and A/D converters, and the operator consoles are typically located in a centralized control room, while the remaining equipment (i.e., the actuator and sensor system) resides in the field near the process equipment.

The analog signal from the D/A converter goes to the current-to-pressure (I/P) converter. The I/P converter uses a source of instrument air to change the air pressure applied to the control valve (3 to 15 psig). Changes of instrument air pressure change the opening of the control valve, which result in changes in the flow rate to the process. These changes in the flow rate to the process cause changes in the temperature of the mixer, which are measured by the sensor. This completes the feedback control loop. The final control element consists of the I/P converter, the instrument air system, and the control valve.

15.2.2 Distributed Control System

15.2.2.1 Background

Based on technological breakthroughs in computers and associated systems in the 1970s, a new computer control architecture was developed and introduced by vendors in the latter part of the decade. It is based on using a number of local control units (LCUs), which have their own microprocessors and are connected together by shared communication lines (i.e., a data highway) as well as connected to operator/engineer consoles, a data acquisition system, and a general-purpose computer. This computer control architecture became known as a distributed control system (DCS) (Figure 15.15) since it involved a network with various control functions distributed for a variety of users.

The advantages of a DCS result from the use of microprocessors for the local control function. Even if a microprocessor fails, only the control loops serviced by that LCU are affected. A redundant microprocessor that performs the same calculations as the primary microprocessor (i.e., a hot backup) greatly increases the system's reliability. As a result, the probability that all the control loops will fail at the same time, or even that a major portion of the control loops will fail, is greatly reduced. In addition, the DCS is easy to expand. In comparing a DCS with electronic analog controllers, the application of conventional controls is generally equivalent, but implementing controllers is much easier and less expensive per loop using a DCS.

15.2.2.2 Structure of a DCS

A generalized schematic of a DCS is shown in Figure 15.15. A number of local control units (LCUs), which contain shared microprocessors, perform the control functions for the process in a distributed fashion. Each local control unit has several consoles attached to it. The consoles (video display units, VDUs), which utilize cathode ray tubes (CRTs), have video displays that show process schematics with current process measurements. Operators and control engineers use these displays to monitor the behavior of the process, set up control loops, and enter setpoints and tuning parameters. Normally, these consoles have touch screen capability so that, if operators want to make a change to a control loop, they touch the icon for the desired controller. Then a screen pops

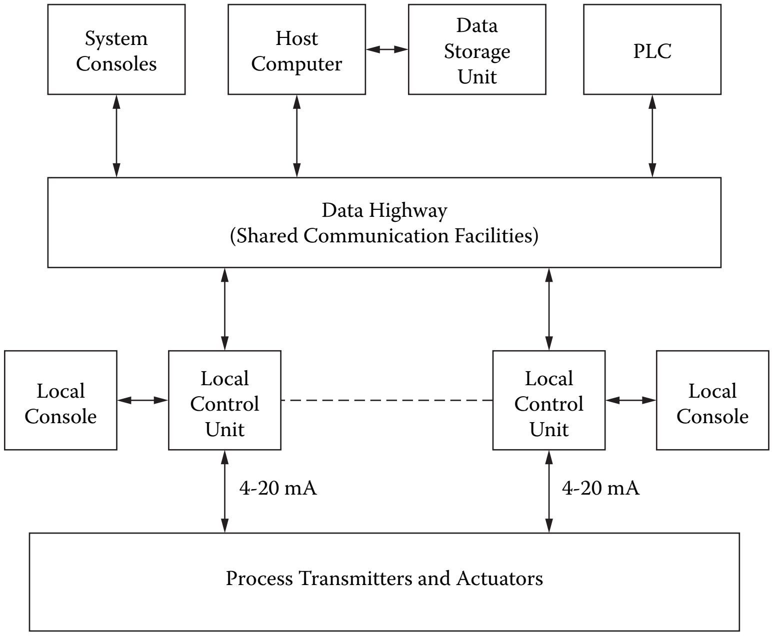

FIGURE 15.15 Generalized diagram of a DCS.

up that allows the operator to make the desired changes. On some DCSs, control loops can be conveniently set up by clicking and dragging on the tags for the desired sensor readings and the final control elements, and connecting these to the type of controller chosen. Since the local control unit is attached to the shared communications facility, a local display console can show schematics and current operating data for other parts of the plant but typically can make changes only to the control loops associated with its LCU. The local console can also be used to display historical trends of process measurements. To do this, the local console must access historical data in the data storage unit by using the data highway (i.e., the shared communication facilities).

Data acquisition is accomplished by transferring the process measurements through the LCUs onto the data highway and into the host computer, where the process data are passed on to the data storage unit. The archived process data can be accessed from one of the system consoles or one of the local consoles. In control rooms that used analog controllers, data storage for important control loops was typically accomplished using a strip chart recorder, which provided a record of previous measurements on a small roll of paper, using different colors of ink to record different process measurements.

The data highway holds the entire DCS together by allowing each modular element and each global element to share data and communicate with each other. The data highway is composed of one or more levels of communication hardware and the associated software.

System consoles attached to the data highway act as a local console for any of the local control units. In addition, system consoles can be used to change linking functions of the distributed elements.

The host computer is a mainframe that is used for data storage, process optimization calculations, and applying advanced process control approaches. Attached to the host computer is the data storage unit (usually a magnetic tape system) where archived data are stored.

15.2.2.3 Approach

The goal of a DCS is to apply the control calculations for each control loop so quickly that the control appears continuous. Since DCSs are based on sequential processors, each control loop is applied at a discrete point in time, and the control action is held constant at that level until the next

time the control is executed. The time between subsequent calls to a controller applied by the DCS is called the *controller cycle time* or the *control interval*. The fastest cycle times for controller calls within a DCS are typically in the range of 0.2 s, while most loops are called only every 0.5 to 1.0 s. The regulatory control loops typically use control intervals in the range of 0.5 to 2.0 s, while supervisory control is typically applied with control intervals of 20 s up to several minutes. This controller cycle time does not present a limitation for slower control loops such as level, temperature, and composition control loops, but it does present a limitation for fast control loops such as flow controllers and some pressure controllers. A real-time control system for the DCS is used to enforce a priority ranking of control functions. That is, certain high-priority control loops are maintained at the expense of less-important loops.

Since DCSs are based on digital controller calculations, a wide variety of special control options are available in self-contained modular form. These can be easily selected by "click and drag" action on some DCSs. In this manner, complex control configurations can be conveniently assembled, interfaced, and implemented. In addition, a variety of signal-conditioning techniques can be applied to process measurements, including filtering and validity checks.

15.2.2.4 Programmable Logic Controllers

Programmable logic controllers (PLCs) are used primarily in the chemical process industries (CPI) for controlling batch processes and for sequencing of process startup and shutdown operations. PLCs are traditionally based on ladder logic, which allows the user to specify a series of discrete operations; e.g., start the flow of feed to the reactor until the level reaches a specified value, next start steam flow to the heat exchanger until the reactor temperature reaches a specified level, next start catalyst flow to the reactor, and so on. A small PLC can be responsible for monitoring 128 separate operations, while a large PLC can handle over 1000 operations. Today, the distinction between PLCs and DCSs has become less clear, as PLCs are being designed to implement conventional and advanced control algorithms, and DCSs are offered that provide control for sequenced operations. PLCs are typically attached to the data highway in a DCS (Figure 15.15) and provide sequenced control functions during startup, shutdown, and override of the normal controllers in the event of an unsafe operating condition.

15.2.2.5 Fieldbus Technology

The fieldbus approach to distributed control is shown in Figure 15.16. Control is distributed to intelligent field-mounted devices (i.e., sensors, valves, and controllers with onboard microproces-

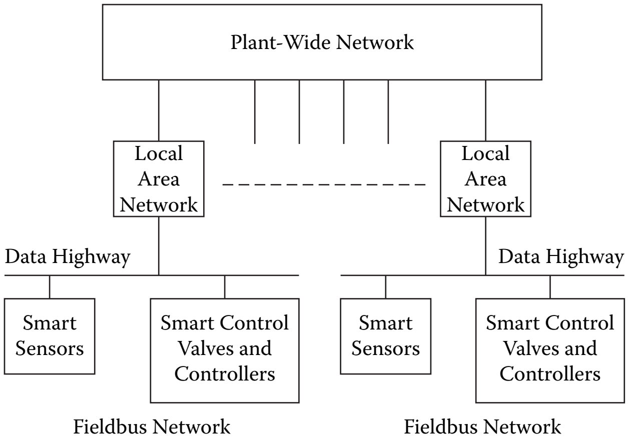

FIGURE 15.16 Schematic of the integration of the fieldbus with plant networks.

sors, which are used for complex operations and diagnostics) using a high-speed, digital, two-way communication system that connects the field-mounted devices with local area networks (LANs), process automation systems, and the plant-wide network. This communication system is similar to the data highway used by DCSs. Supervisory and advanced controls are implemented in the LANs, while the regulatory control functions are handled by the field-mounted devices on the fieldbus network. The advantage of the fieldbus design comes from the fact that many field-mounted devices can be attached to a single two-wire communication line instead of running electrical wires from each sensor/transmitter to the centralized control room and from the control room to each final control element. This results in a significant reduction in the time and cost associated with system installation. In addition, due to the standardization of fieldbus technology, all fieldbus-certified control components can be interchanged regardless of the manufacturer. Fieldbus technology is just beginning to be available commercially but is expected to remove regulatory controls from DCSs and move them into the field in the future.

15.2.3 Actuator Systems (Final Control Elements)

The actuator system for a process control system in the CPI is typically composed of the control valve, the valve actuator, the I/P transmitter, and the instrument air system. The actuator system is known industrially as the *final control element*. In addition, a variety of optional equipment is designed to enhance the performance of the actuator system, such as valve stem positioners and instrument air boosters.

15.2.3.1 Control Valves

The most common type of control valve in the CPI is the globe valve. Figure 15.17 shows a detailed cross section of a globe control valve with a plug in a cage-guided valve arrangement, along with notation indicating some of the key components of a control valve and valve actuator. The cage provides guidance for the plug as the plug is moved toward or away from the valve seal. The cage also provides part of the flow restriction produced by the control valve. The packing reduces the leakage of the process stream into the environment but provides resistance to movement of the valve stem. The travel indicator indicates the valve stem position.

Sizing of control valves is important because, if the valve is oversized or undersized, accurate control of the flow rate can be poor and a contrain for the flow rate can be contrained. A simplified valve flow equation for an incompressible fluid is given by

$$F_m = KC_v\left(x\right)\sqrt{\left(P_1 - P_2\right)/\rho}$$

where F_m is the mass flow rate through the valve, K is a constant that depends on the units used in this equation, $C_v(x)$ is the valve coefficient [which depends on the stem position (x) i.e., $C_v(x) = C_v^{\max}$ when the valve is fully open and $C_v(x) = 0$ when the valve is closed], ρ is the density of the fluid, P_1 is the upstream pressure, and P_2 is the downstream pressure. In general, control valves should be designed so that the valve provides accurate metering of the flow over a wide operating range between almost fully open ($x \sim 0.9$) and almost closed ($x \sim 0.1$). The valve should be sized to provide a wide operating range.

Figure 15.18 shows how $f(x)$ varies with stem position for three types of valves: a quick opening valve, an equal percentage valve, and a linear valve, where

$$f(x) = \frac{C_v(x)}{C_v^{\max}}$$

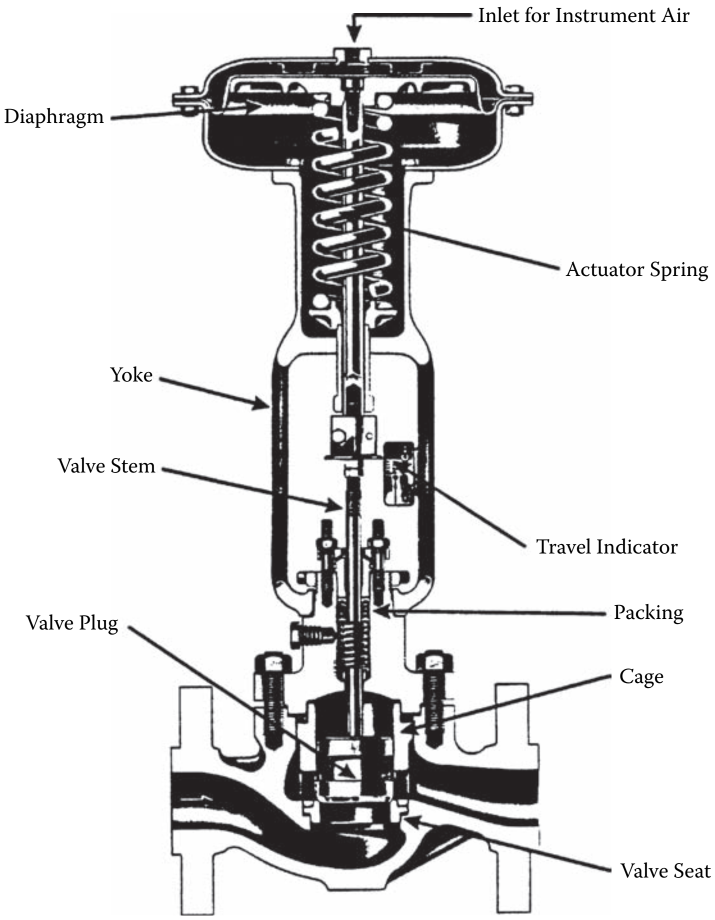

FIGURE 15.17 Cross section of a globe valve with an unbalanced plug. Courtesy of Fisher Controls.

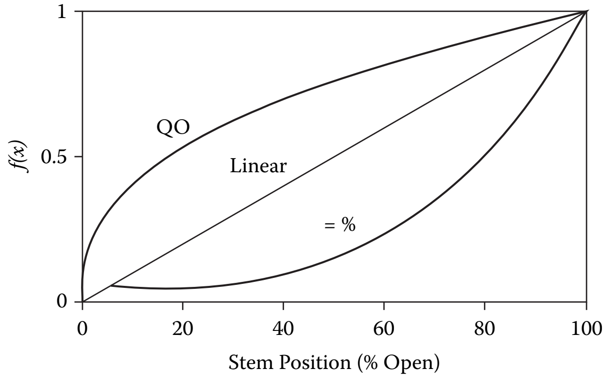

FIGURE 15.18 Inherent valve characteristics for a quick opening (QO), linear, and equal percentage valve (=%).

This figure shows the inherent valve characteristics for these valve types, which indicate how the flow rate through the valve varies with stem position for a fixed pressure drop across the valve. The design of the plugs, valve seats, and cages (where applied) determine the particular flow vs. stem position. For a quick opening valve, as the valve opens, the cross-sectional area of the restriction of the valve increases much faster than the linear or equal percentage valves. From a process control standpoint, a control valve should exhibit a linear relationship between flow rate and stem position over a wide range for the installed valve. Normally, the pressure drop across a valve changes as the flow through the valve changes and does not remain constant (e.g., Figure 15.19). An equal percentage control valve generally provides a much more linear installed valve characteristic than linear or quick opening valves, as shown in Figure 15.20. For this reason, over 90% of the globe valves used in the CPI are equal percentage valves. For applications where the pressure drop across the control valve remains relatively constant (e.g., control of the flow rate of condensing steam to a heat exchanger), linear valves are preferred. The flow rate of steam to a heat exchanger should provide a fairly constant pressure drop across the valve, since the upstream steam supply pressure remains relatively constant, as does the pressure of the condensing steam within the heat exchanger. Quick opening valves are not usually used for feedback flow control applications but are used in cases where it is important to start a flow rate as quickly as possible (e.g., coolant flow through a bypass around a control valve for an exothermic reactor). In general, if the pressure drop across a control valve going from the maximum flow rate to the minimum flow rate changes by a factor of four or more, an equal percentage valve should be used. Otherwise, use a linear valve.

Figure 15.20 indicates that this equal percentage valve should be able to perform well for a stem position between 10 and 80% open due to its superior linearity. For economic considerations,

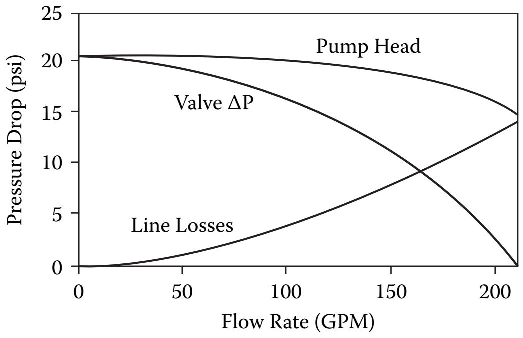

FIGURE 15.19 Pressure drop vs. flow rate for a typical flow system.

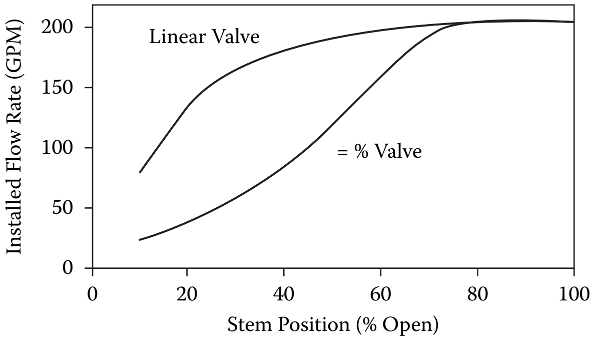

FIGURE 15.20 Installed valve characteristics for a typical equal percentage (=%) valve and linear valve.

butterfly valves, which are generally less expensive than globe valves, are also used for flow control applications for which the line diameter is larger than 6 in. Butterfly values have a significantly smaller range of valve position within which they perform well, compared with globe valves.

An important characteristic of a valve is the valve *deadband*, which is a measure of how precisely a control valve can control the flow rate. The deadband for a steering system on an automobile is the maximum positive and negative turn in the steering wheel that does not result in a noticeable change in direction of the automobile. For a control valve, deadband is the maximum positive or negative change, expressed in percent, in the signal to a control valve that does not produce a measurable change in the flow rate. Valve deadband is caused by the friction between the valve stem and valve packing and other forces on the valve stem. Typically, industrial control valves have a deadband of 10 to 25%. Generally, the larger and older the control valve is, the larger the deadband. A properly functioning valve with a valve positioner typically should have a deadband <0.5%.

Cavitation results when the liquid vaporizes and implodes inside the control valve. As a fluid flows through a control valve, the pressure drops sharply near the restriction between the valve plug and the valve seat because of high velocity in this region. As the fluid passes the valve restriction region and enters a region with a larger cross section, the pressure increases sharply (i.e., pressure recovery) as a result of the drop in the fluid velocity. Cavitation results in noise and vibration, reduced flow, and potentially rapid erosion of the body of the valve. It can be prevented by proper design using an increased downstream pressure.

15.2.3.2 Valve Actuators

The valve actuator provides the force necessary to move the valve stem position and alter the flow rate through the valve. The valve actuator must provide the force necessary to overcome pressure forces, flow forces, friction from the valve packing, and friction from the guide surfaces.

Figure 15.17 shows a cross section of a typical air-to-close actuator. The pressure of the instrument air acts on the diaphragm/spring system from the top, causing the valve to close as the air pressure supplied to the valve actuator is increased. An actuator with a control valve with an air-to-close valve actuator is also known as a *reverse-acting final control element*. For an air-to-open actuator, the instrument air enters below the diaphragm so that, as the air pressure is increased, the valve stem moves upward, opening the valve. An actuator with a control valve with an air-to-open valve actuator is also known as a *direct-acting final control element*. Valve actuators generally provide a fail-safe function.

15.2.3.3 I/P Transmitters

The I/P transmitter is an electromechanical device that converts the 4–20 mA signal from the controller to a 3–15 psig instrument air pressure to the valve actuator, which, in turn, affects the valve stem position.

15.2.3.4 Optional Equipment

Several devices are available for improving the overall performance of final control elements.

15.2.3.4.1 Valve Positioners

The valve positioner, which is usually contained in its own box and mounted on the side of the valve actuator, is designed to control the valve stem position at a prescribed position in spite of packing friction and other forces on the stem. The valve positioner itself is a feedback controller that compares the measured with the specified stem position and makes adjustments to the instrument air pressure to provide the proper stem position. In this case, the setpoint for the valve positioner can be a pneumatic signal coming from an I/P converter or the 4–20 mA analog signal coming directly from the controller. A valve with a deadband of 25% can provide flow rate precision

to less than ±0.5% using a valve positioner. Valves with low levels of valve friction can control the average flow rate to a precision approaching ±0.1% using a valve positioner.

For flow control loops that are controlled by a DCS, a valve positioner is a necessity, because the control interval for a DCS (0.5 to 1.0 s) is not short enough for accurate flow control for most flow control loops. There are three general types of valve positioners: pneumatic, electronic, and digital. Pneumatic and electronic positioners receive a pneumatic or electronic signal from the I/P converter and send a pneumatic signal to the valve actuator. A more modem type of valve positioner is a digital positioner, which receives digital analog signal directly and adjusts the instrument air pressure sent to the actuator. Digital positioners have the advantage that they can be more easily calibrated, tuned, and tested remotely, and they can be equipped with self-tuning capabilities.

15.2.3.4.2 Booster Relays

Booster relays are designed to provide extra flow capacity for the instrument air system, which decreases the dynamic response time of the control valve (i.e., the time for most of a change to occur). Booster relays are used on valve actuators for large valves that require a large volume of instrument air to move the valve stem. Booster relays use the pneumatic signal as input and adjust the pressure of a high flow rate capacity instrument air system that provides pressure directly to the diaphragm of the valve actuator.

15.2.3.4.3 Adjustable-Speed Pumps

Adjustable-speed pumps can be used instead of the control valve systems just discussed. A centrifugal pump directly driven by a variable-speed electric motor is the most commonly used form of adjustable-speed pump. Another type is based on using a variable-speed electric motor combined with a positive displacement pump. Adjustable-speed pumps have the following advantages compared with control valve-based actuators: (1) They use less energy; (2) they provide fast, accurate flow metering without additional device requirements; and (3) they do not require an instrument air system. Their major disadvantage is capital cost, particularly for large flow rate applications. Another disadvantage of adjustable-speed pumps, based on safety considerations, is that they do not fail open or closed like a control valve with an air-to-close actuator or with an air-to-open actuator, respectively. As a result, the CPI almost exclusively uses control valve-based actuators except for low-flow applications, such as catalyst addition systems or base injection pumps for wastewater neutralization, which typically use adjustable-speed pumps.

15.2.4 Sensor Systems

Sensor systems are composed of the sensor, the transmitter, and the associated signal processing. The sensor measures certain quantities (e.g., voltage, current, or resistance) associated with devices in contact with the process such that the measured quantities correlate strongly with the actual controlled variable value. There are two general classifications for sensors: *continuous measurements* and *discrete measurements*. Continuous measurements are, as the term implies, generally continuously available, whereas discrete measurements update at discrete times. Pressure, temperature, level, and flow sensors typically yield continuous measurements, whereas certain composition analyzers (e.g., gas chromatographs) provide discrete measurements.

Several terms are used to characterize the performance of a sensor:

- *Span* is the difference between the highest and lowest measurement values made by the sensor/transmitter.
- *Zero* is the lowest reading available from the sensor/transmitter, i.e., the sensor reading corresponding to a transmitter output of 4 mA.
- *Range* is the maximum and minimum sensor readings. For example, the range of a pressure sensor can be expressed as a maximum of 150 psig and a minimum of 50 psig, corresponding to a span of 100 psig.

- *Accuracy* is the difference between the value of the measured variable indicated by the sensor and its true value. The true value is never known; therefore, accuracy is estimated by the difference between the sensor value and an accepted standard.
- *Repeatability* is related to the difference between sensor readings while the process conditions remain constant (see Figure 2.14).
- *Process measurement dynamics* indicate how quickly the sensor responds to changes in the value of the measured variable.
- *Calibration* involves the adjustment of the correlation between the sensor output and the predicted measurement so that the sensor reading agrees with a standard.

Smart sensors are available that have built-in microprocessor-based diagnostics. For example, smart pH sensors are available that can identify the buildup of coatings on the pH electrode surface and trigger a wash cycle to reduce the effect of the coatings. In general, smart sensors are moderately more expensive than conventional sensors, but, when they are properly selected and implemented, they can be an excellent investment in terms of greater sensor reliability and reduced maintenance. Best practice[2] for instrument selection, for instrument installation, and to reduce maintenance costs has been identified for the CPI.

A wide variety of sensors are available for measuring process variables.[3] Choosing the proper sensor for a particular application depends on the controlled variable that is to be sensed, the properties of the process, accuracy and repeatability requirements, and costs, both initial and maintenance. The following is a coverage of the most commonly used sensors in the CPI that are used for feedback control.

15.2.4.1 Temperature Measurements

The two primary temperature-sensing devices used in the CPI are thermocouples (TCs) and resistance thermometer detectors (RTDs). Thermocouples are less expensive and more rugged than RTDs but are an order of magnitude less precise than RTDs. Typically, RTDs should be used for important temperature control points, such as on reactors and distillation columns.

15.2.4.2 Thermowells

Thermowells typically are cylindrical metal tubes that are capped on one end and protrude into a process line or vessel to bring the TC or RTD into thermal contact with the process fluid. Thermowells provide a rugged, corrosion-resistant barrier between the process fluid and the sensor that allows for removal of the sensor while the process is still in operation. Thermowells that are coated with polymer or another adhering material can significantly increase the lag associated with the temperature measurement, i.e., significantly increase the response time of the sensor.

15.2.4.3 Repeatability, Accuracy, and Dynamic Response

TCs typically have a repeatability of ±1°C, whereas RTDs have a repeatability of ±0.1°C. Accuracy is a much more complex issue. Errors in the temperature reading can result from heat loss along the length of the thermowell, electronic error, sensor error, error from nonlinearity, calibration errors, and other sources.[4]

The dynamic response time of a TC or RTD sensor within a thermowell can vary over a wide range and is a function of the type of process fluid (i.e., gas or liquid), the fluid velocity past the thermowell, the separation between the sensor and inside wall of the thermowell, and material filling the thermowell (e.g., air or oil). Typical well-designed applications result in time constants of 6 to 20 s for measuring the temperature of most liquids.

15.2.4.4 Pressure Measurements

Pressure sensors respond very quickly and are commonly used to measure flow rates and levels. Repeatability for pressure measurement is generally less than ±0.1%.

15.2.4.5 Flow Measurements

The most commonly used flow meter is an orifice meter. An orifice meter uses the measured pressure drop across a fixed area flow restriction (an orifice) to predict the flow rate. The pressure drop across an orifice is usually measured using a differential pressure (DP) cell. A straight run of pipe preceding the orifice meter is required. If not, an error as large as 15% can result in the predicted flow rate. Since the orifice meter is based on a measured pressure drop, it is a very fast-responding measurement. Orifice meters typically provide repeatability in the range of ±0.3 to ±1%. Other types of flow meters are used for flow rate control in special situations, including vortex shedding flow meters and magnetic flow meters. Flow measurement devices, whichever type is chosen, are typically installed upstream of the control valve to provide the most accurate, lowest-noise measurement. Installing the flow sensor downstream subjects the sensor to flow fluctuations and even two-phase flow, and these reduce sensor accuracy and increase measurement noise.

15.2.4.6 Level Measurements

The most common type of level measurement is based on measuring the hydrostatic head in a vessel using a differential pressure measurement. This approach typically works well as long as there is a large difference between the density of the light and heavy phases. This approach usually has relatively fast measurement dynamics, since it is based on a pressure measurement. Level measurements typically have repeatability of approximately ±1%.

Differential pressure measurements can be used to determine the level in a vessel. This approach directly measures the hydrostatic head. Because of plugging and corrosion problems, it may be necessary to keep the process fluid from entering the differential pressure transmitter. In addition, it is important to keep vapor from condensing in the upper tap and collecting in the low-pressure side of the differential pressure transmitter. This usually can be accomplished by insulating the pressure tap and wrapping it with resistive heating tape. Other level-measuring approaches are based on a variety of physical phenomena and are used in special cases.

15.2.4.7 Chemical Composition Analyzers

The most commonly used on-line composition analyzer is the gas chromatograph (GC), but infrared, ultraviolet, and visible radiation analyzers have made inroads recently. On-line composition measurements are generally relatively expensive.

15.2.4.8 Sampling System

The sample system is responsible for collecting a representative sample of the process and delivering it to the analyzer for analysis. Obviously, the reliability of the sample system directly affects the reliability of the overall composition analysis system. The transport delay associated with the sample system contributes directly to the overall deadtime associated with an on-line composition measurement. This difference in sampling deadtime can have a drastic effect on the performance of a control loop. Table 15.2 summarizes the dynamic characteristics and repeatability of typical control valve systems and several different types of sensors.

TABLE 15.2
Summary of Control-Relevant Aspects of Actuators and Sensors

	Time Constant (sec)	Valve Deadband or Sensor Repeatability	Turndown Ratio, Rangeability or Range
Control valve*	3–15	10–25%	9:1
Control valve w/valve positioner*	0.5–2	0.1–0.5%	9:1
Flow control loop w/valve positioner*	0.5–2	0.1–0.5%	9:1
TC w/thermowell	6–20	±1.0°C	–200 to 1300°C
RTD w/thermowell	6–20	±0.1°C	–200 to 800°C
Magnetic flow meter	<1	±0.1%	20:1
Vortex shedding meter	<0.1	±0.2%	15:1
Orifice flow meter	<0.2	±0.3–±1%	3:1
Orifice meter w/smart transmitter	<0.2	±0.3–±1%	10:1

15.2.4.9 Transmitters

The transmitter converts the output from the sensor (i.e., a millivolt signal, a differential pressure, a displacement, and so forth) into a 4–20 mA analog signal that represents the measured value of the controlled variable. Consider a transmitter that is applied to a temperature sensor. Assume that the maximum temperature the transmitter is expected to handle is 200°C and that the minimum temperature is 50°C; then the span of the transmitter is 150°C and the zero of the transmitter is 50°C. Transmitters are typically designed with two knobs that allow for independent adjustment of the span and the zero of the transmitter. Properly functioning and implemented transmitters are so fast that they do not normally contribute to the dynamic lag of the process measurement. Modem transmitters have features that, if not applied properly, can reduce the effectiveness of the control loop. For example, excessive filtering of the measurement signal by the transmitter can add extra lag to the feedback loop, thus degrading control loop performance.

15.2.5 Troubleshooting Control Loops

Control engineers spend a major portion of their time troubleshooting control loops. An operator may point out that a particular loop has been behaving erratically and ask the control engineer to improve its performance. The control engineer may discover that an important loop is under manual operation (open-loop operation). A final product may have excessive variability in its impurity levels, and the control engineer's job is to reduce the variability to an acceptable level. In this latter example, several control loops may require scrutiny. When one or more loops is not performing properly, troubleshooting is required to return them to the expected performance levels, or at least to identify the source of the problem. To effectively troubleshoot control loops, the control engineer must understand the proper design and expected performance of the hardware that compose a control loop.

Troubleshooting control loops involves identifying the source of the problem from an overwhelming number of possible causes. The size of this problem requires a systematic approach when troubleshooting. Control loop troubleshooting is too often treated as an afterthought and performed haphazardly. This section presents a general troubleshooting procedure as well as a detailed analysis of fault detection for the final control element, the sensor system, the control computer or DCS, and the process.

15.2.5.1 Overall Approach

The key to effective troubleshooting is expressed in the old adage, "divide and conquer." It is important to locate the portion of the control loop hardware that is causing the poor performance: the final control element, the sensor system, the controller, or the process. The place to start is to test each system separately to determine whether that portion of the control loop is operating properly. The final control element can be evaluated by applying a series of input step tests. That is, the input to the final control element, which is normally set by the controller, can be manually adjusted. The test allows the determination of the dynamic response and deadband of the actuator system. If the performance in these two areas is satisfactory, there is no need to evaluate the actuator system further.

Sudden changes in control loop performance from satisfactory to unacceptable may be caused by recent changes in the process. Considering what changes have been made to the process can expedite the troubleshooting process. For example, the controller could have been retuned. A new analyzer could have been installed. A new instrument technician could be responsible for calibrating and maintaining an analyzer. The feed to the unit could have significantly changed. These examples and many more can be directly related to the source of poor control loop performance. When something significant has changed, it can provide a valuable clue that allows quicker determination of the source of the problem with a poorly performing control loop.

When troubleshooting a more complex control system, it is advisable to start by comparing the existing control loops with those from the piping and instrumentation diagram (P&ID). The current problem may be the result of inappropriate modifications to the original control configuration.

15.2.5.2 Final Control Element

The final control element consists of the instrument air system, the I/P converter, and the control valve (the valve and the valve actuator). The fastest way to identify gross problems with the final control element is to plot both the manipulated variable and the controller output. If the manipulated variable does not follow the controller output, there is probably a problem with the final control element.

Even if the manipulated variable seems to follow the controller output, there could be a problem with the actuator. Estimates of the actuator deadband and dynamic response are required to determine if the actuator system is performing properly (both of which can be determined by a block sine wave test). This test is shown in Figure 15.21. A block sine wave is a series of equally sized step changes that approximate a sine wave. For the test shown in the figure, the amplitude

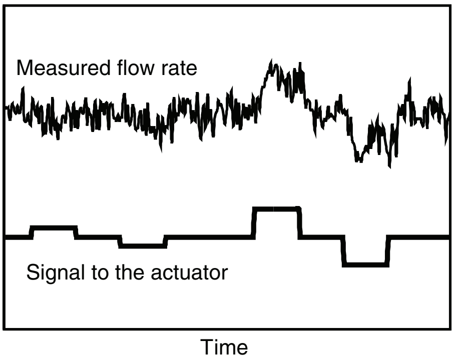

FIGURE 15.21 Results of a series of block sine wave tests to determine the deadband of the actuator. Note that the signal to the actuator and the measured value of the flow rate are plotted on different scales.

of the step change used in the block sine wave is initially small enough that consistent positive and negative changes in the measured value of the flow rate of the manipulated variable are not observed. The next block sine wave uses a larger-amplitude step change and, for this case, the measured manipulated variable can be seen to make both positive and negative changes corresponding to the positive and negative changes in the controller output. Therefore, the deadband of the actuator in this case is larger than the step size used in the first block sine wave and smaller than the one used in the second. The same block sine wave test can be used to estimate the time constant of the final control element. If the time between step changes used in the block sine wave is large enough, the settling time of the actuator can be estimated. Then, the time constant of the actuator is estimated as one quarter of the settling time.

Once the deadband and time constant of the actuator have been determined, the performance of the actuator can be assessed. The deadband for valves with positioners typically ranges from 0.1 to 0.5% of the flow rate for properly implemented systems and depends on the size of the valves, the pressure drop across the valve, the fluid properties, and other factors. The deadband for an industrial valve without a positioner typically ranges from 10 to 25%, and even higher for older valves that have not been maintained. The time constant of a properly functioning final control element is less than 2 s for a valve with a positioner or a control valve in a flow control loop. Otherwise, the actuator time constant is usually between 3 and 15 s.

If it has been determined that the actuator system is not functioning properly, one should first determine if the instrument air pressure system is operating properly. This can be done by observing that the instrument air pressure at the control valve after a step change in the signal to the final control element has been implemented in the DCS or in the control computer. If the instrument air pressure at the control valve increases sharply after the step test has been implemented, then the control valve is the source of the slow or erratic response. Another common problem is valve packing that is overtightened, which primarily increases the valve deadband. A valve that is operating below 10% or above 90% opening typically performs below standards. Another problem is an improperly tuned valve positioner. If the valve positioner is tuned too aggressively, oscillatory control performance results for the control valve, resulting in an increase in the actuator deadband. If the valve positioner is not tuned aggressively enough, the dynamic response of the actuator is slower than it should be. Table 15.3 lists a number of common problems with the components of the actuator system.

TABLE 15.3
Common Problems with the Final Control Element

- Excessive lag in the instrument air system
- Wrong type of instrument air connected to control valve. Some plants have high- and low-pressure instrument air
- Low instrument air pressure
- Wet or dirty instrument air
- Excessive deadband*
- Improperly sized control valve*
- Excessive resistance to movement of valve stem*
- Leak in diaphragm of control valve
- Debris is stuck in opening to control valve
- A plugged or obstructed instrument air line
- Plug/seat erosion in the control valve
- A bypass line open or leaking
- Flashing and cavitation
- Improperly tuned valve positioner*

* More frequently observed problems

15.2.5.3 Sensor Systems

The sensor system is composed of the sensor, the transmitter, and the sampling system that allows it to make measurements. The performance of a sensor can be assessed by determining its repeatability, time constant, and (sometimes) accuracy. Accuracy is important for a composition analyzer on a final product to ensure that the product meets specifications. The accuracy of a flow transmitter is usually not important, because the flow rate is adjusted incrementally by a supervisory controller so that its actual flow rate is unimportant. The dynamics of the sensor can affect the feedback control performance if it is too slow, and a large repeatability can increase the variability in the controlled variable.

The accuracy of the sensor can be checked by comparing the sensor reading to a standard or known condition. For example, a composition standard can be processed to verify the accuracy of the GC, or a thermocouple can be placed in boiling water to check its accuracy. The repeatability of a sensor can be estimated by observing sensor readings during a period of relatively steady-state operation. The repeatability is the variation in the sensor reading caused by noise. One assumes that, during steady operation, the process was not in fact changing.

Determining the time constant of the sensor is usually more difficult than estimating the repeatability. To determine the time constant of the sensor system, one needs to know the actual process measurement. Consider a temperature measurement. A measurement of the actual process temperature is required to estimate the time constant of a sensor. Instead, the thermal resistance, which causes the excessive thermal lag of the temperature sensor, can be evaluated. The location of the thermowell should be checked to ensure that it extends far enough into the line that the fluid velocity past the thermowell is sufficient; the possibility of buildup of insulating material on the outside of the thermowell should be assessed, and the thermal contact between the end of the temperature probe and the thermowell walls should be evaluated. In this manner, an indirect estimate of the responsiveness of the temperature sensor can be developed. The velocity of a sample in the line, which delivers a sample from a process line to a GC, can indicate the transport delay associated with the sample system. A low velocity in the sample line from the process stream to a GC can result in excessive transport delay, which can greatly reduce controller effectiveness.

One should be careful to determine if the sensor used is really measuring the controlled variable of interest. Differential pressure sensors are used for pressure, flow, and level measurements. They are particularly susceptible to plugging of the sensing lines that connect the differential pressure sensor to the process itself. Plugging of the sensing lines can result from the buildup of coatings or solids or from freezing of the fluid in the pressure taps. The calibration of a differential pressure sensor is quite sensitive to the conditions of the fluid in the sensing lines. Condensate buildup in lines that should be dry can lead to large calibration errors. Table 15.4 lists some commonly encountered sources of problems for sensor systems. For a complete analysis of the sensor system, an instrument engineer or other expert familiar with that particular sensor may be required. Table 15.2 lists the expected ranges for the repeatability and the time constants for several commonly used sensors in the CPI. Deviation of the apparent repeatability or time constant from these expected values identifies a poorly performing sensor.

15.2.5.4 Controller/DCS System

The control computer/DCS system consists of controllers, A/D and D/A converters, and the signal conditioning hardware and software, i.e., filtering and validation. Each of these components requires separate evaluation. Table 15.5 lists possible problems with the controller/DCS system. One way to initially check controller tuning is to place the control loop in manual (open the control loop) and observe whether the controlled variable lines out to a steady-state or near steady-state value. Comparing the open-loop and closed-loop performance indicates whether the controller is upsetting the process. If not, disturbances to the control loop in question are the primary source of the upsets.

TABLE 15.4
Commonly Encountered Problems with Components of a Sensor System

Sensor	Common Problems
Transmitter	Not calibrated correctly*
	Low resolution
	Excessive signal filtering*
	Slow sampling
Thermocouple/RTD	Off-calibration*
	Short in the electrical circuit/grounding problems
	Improperly located thermowell*
	Thermowell with excessive thermal resistance (e.g., stainless steel thermowells)
	Partially burned out thermocouple
	Interference from heat tracing
Pressure Indicators	Plugged line to pressure indicator*
	Confusion about absolute pressure readings, gauge pressure readings, and vacuum pressure readings
	Condensation in lines to pressure indicator*
Sampling System For GC	Excessive transport delay for an analyzer
	Sample drawn from wrong process point
	Plugged sample system*
	Sample system closed off
GC	Out of calibration
	Plugging in the GC column
	Failure of electrical components in GC
	Excessive noise on measurement
	Frozen signal
	Spiking due to inadequate flushing for GCs that run multiple samples
Flow Indicator	Square root compensation applied for non-differential pressure type flow indicator
	Square root compensation not applied for differential pressure type flow indicators
	Square root compensation applied twice, i.e., once in transmitter and once in DCS
	Orifice plate installed backwards
	Damaged orifice plate
	Plugged line to differential pressure sensor*
	Flashing of liquids as they flow through an orifice meter
Level Indicator	Plugged line from process to DP cell*
	Leak in line to DP cell or in DP cell itself
	Boiling of liquid in line to or from DP cell due to a steam leak in the steam tracing line
	Solidification of liquid in line to or from process to DP cell due to failure in steam tracing
	Formation of emulsions that can confound interface level measurements
	Leak in float type level indicators
	Formation of foams that can interfere with level measurements

* More frequently observed problems.

TABLE 15.5
Possible Problems with the Controller/DCS System

- Improperly tuned controller*
- Wrong scaling for A/D and D/A converter
- Improper or lack of pressure/temperature compensation for flow measurement
- Improper selection of reverse-acting or direct-acting controller
- Too much or not enough filtering of the measured controlled variable*
- Signal aliasing due to excessive control interval (see Appendix B)
- Poor resolution on A/D or D/A converters
- Derivative action based on error from the setpoint instead of the measurement.

* More frequently observed problems.

15.2.5.5 Process

The effect of the process on the closed-loop behavior can be examined directly by opening the control loop in question and observing the process behavior. Open-loop oscillatory behavior indicates a problem internal to the process. The noise level on the sensor reading can also be assessed under open-loop conditions.

Fluctuating disturbances and process gain changes due to nonlinearity are a natural part of process control. Extraordinary disturbances combined with nonlinearity can cause an otherwise properly tuned controller to oscillate or go unstable during upset periods. Severe process nonlinearity can be identified if a closed-loop process exhibits ringing and sluggish behavior during different periods with the same controller tuning. Scheduling the controller tuning (Section 15.5.6) is one way to compensate for process nonlinearity. It may be possible to reduce the magnitude of the disturbances to acceptable levels by modifying the upstream operations (e.g., tuning upstream controllers). Excessive disturbances, when not measurable, can be inferred by observing the range of the average manipulated variable levels. If large-magnitude disturbances are affecting the process, large changes in the average manipulated variable level are required to maintain the process near its desired operating point. Excessive fouling of heat exchangers or deactivation of the catalyst can result in process gain changes that produce sluggish or unstable behavior.

Process changes that require manipulated variable levels in excess of what is physically available can also occur. After feed rate increases to a distillation column, the reboiler might be unable to provide enough heat transfer to maintain the purity of the bottom product. When this occurs, it is a physical limitation of the process and not the fault of the controller. Loss of steam pressure can also cause a constraint that can affect control loop performance. Downstream pressure changes can cause a constraint on the maximum flow rate due to an inadequate pressure driving force. Constraint control techniques should be used when manipulated variables saturate. It should be clear that a thorough understanding of the process is a prerequisite for control loop troubleshooting.

15.2.5.6 Testing the Entire Control Loop

After each of the components has been evaluated and corrected wherever possible, the closed-loop system should be checked. From an overall point of view, there are three general factors that affect the closed-loop performance of a control loop: (1) the type and magnitude of disturbances, (2) the lag associated with the components that compose the control loop, and (3) the precision to which each component of the control loop performs. Actuator deadband affects the variability in the controlled variable. The addition of lag to a control loop (e.g., sensor filtering) results in slower disturbance rejection, which can increase the variability in the controlled variable. Disturbance magnitude directly affects variability.

The performance of a closed-loop system can be assessed by the settling time, closed-loop deadband, and the variability of the controlled variable evaluated over an extended period of time. The settling time and the closed-loop deadband can be determined using a closed-loop block sine wave test. For a closed-loop block sine wave test, the setpoint for the control loop is applied in the form of a block sine wave, and the amplitude of the block sine wave is varied until the deadband is determined. During these tests, the settling time of the controller can also be estimated. An accurate determination of the variability of a controlled variable generally requires an extended period of operation. An evaluation of the variability based on a short period of time may not be representative of true system performance.

Consider a control system with an excessive lag (e.g., buildup of scale on the exterior of a thermowell) added to a control loop. The controller can be tuned for any tuning criterion (e.g., a decay ratio of 1/6 to critically damped); therefore, tuning a control loop to the desired tuning criterion is not, in itself, an indication of the performance of the control system. The settling time and the variability provide a measure of the performance of the control system. A process with the additional lag exhibits a longer settling time than a process without it. The average variability in the controlled variable over an extended period also shows that the system without the additional lag exhibits superior control performance. The variability is usually a direct measure of controller performance that generally can be related to the overall objectives of the process, but it requires a significant operating period (e.g., a week) to accurately determine. On the other hand, the settling time can be determined much more quickly and easily, but it provides only a relative measure of control performance. One can determine the relative change in controller performance by comparing the settling time before control loop troubleshooting was undertaken to it afterward.

The closed-loop deadband is an indication of the variability in the controlled variable that results from the combined effects of actuator deadband, sensor noise, and resolution of the A/D and D/A converters. The closed-loop settling time is an indication of the combined lags of the control loop components. The closed-loop performance assessment is a means of determining whether all the major problems within a control loop have been rectified.

Example 15.1 Troubleshooting Example

The following is a step-by-step troubleshooting process along with intermediate results for a temperature controller that was observed to result in sluggish closed-loop performance.

Step 1. Determine the deadband of the final control element using a series of block sine wave tests. Result: the deadband of the final control element was less than 0.4%, and the dynamic response time of the final control element was 2 s; therefore, the final control element was found to be functioning properly.

Step 2. Retune the temperature controller. Result: the controller settings did not change significantly; therefore, the controller tuning does not appear to be the problem.

Step 3. Evaluate the sensor. Check the repeatability of the sensor by observing the temperature measurements during a steady-state or near steady-state period. Result: the repeatability was less than 0.1°C, which is good for an RTD. An independent measurement of the temperature is made and compared with the sensor reading. Result: the sensor reading is observed to have excessive lag, i.e., a dynamic response time for the sensor was estimated to be about 5 min. It was determined on further examination that there was an excessive air space between the RTD element and the surface of the thermowell. The position of the RTD in the thermowell was changed, and the dynamic lag of the sensor was found to be in the proper range. The controller was retuned, and control performance was significantly improved.

15.3 PID CONTROLLERS

15.3.1 Introduction

PID controllers are simple to implement and are extremely flexible and are used for processes ranging from refineries to spacecraft to electronic devices to power plants. The PID algorithm is quite computationally efficient, and much of the flexibility of a PID controller comes from the unique characteristics of proportional, integral, and derivative action (hence PID).

15.3.2 PID Algorithms

The Instrument Society of America (ISA) standard for the PID algorithm in the position form is given as

$$c(t) = c_0 + K_c\left[e(t) + \frac{1}{\tau_I}\int_0^t e(t)dt + \tau_D\frac{de(t)}{dt}\right] \quad (15.1)$$

where K_c, τ_I, and τ_D are the user-selected tuning parameters; $c(t)$ is the output from the controller; and $e(t)$ is $[y_{sp} - y_s(t)]$. Note that c_0 is the value of the controller output when the controller is turned on. K_c is the controller gain and should not be confused with the process gain, K_p. K_p has units of y_s/c when the actuator, process, and sensor are lumped together, and K_c has units corresponding to c/y_s. Equation (15.1) is written in a form corresponding to a reverse-acting controller. Equation (15.2) lists the position form for a direct-acting controller:

$$c(t) = c_0 - K_c\left[e(t) + \frac{1}{\tau_I}\int_0^t e(t)dt + \tau_D\frac{de(t)}{dt}\right] \quad (15.2)$$

The decision between using a direct-acting controller [Equation (15.2)] or a reverse-acting controller [Equation (15.1)] depends on the sign of the process gain and whether a direct- or reverse-acting final control element is used. The usual convention is that Equation (15.2) is called a direct-acting controller; it is direct acting with regard to the process measurement, because to form $e(t)$ the process measurement is subtracted from the setpoint. Consider a heat exchanger in which the steam flow rate to the exchanger is manipulated to control the temperature of the process stream leaving it. Since an increase in steam flow to the heat exchanger results in an increase in the outlet temperature of the process stream, the process gain of this system is positive. Also, consider a direct-acting final control element on the steam that causes an increase in steam flow rate when the signal to the final control element is increased. Furthermore, consider the case in which the measured outlet temperature is below its setpoint [i.e., $e(t)$ is positive]. Since it is desired to move the controlled variable toward its setpoint, the steam flow rate to the heat exchanger should be increased; therefore, from an examination of Equations (15.1) and (15.2), it is clear that a reverse-acting controller [Equation (15.1)] should be used. On the other hand, if the direct-acting final control element is replaced with a reverse-acting final control element, a decrease in the signal to the final control element is required; therefore, a direct-acting controller [Equation (15.2)] is required. The choice between a reverse- and direct-acting final control element usually depends on whether the control element should fail open or closed when instrument air pressure is lost.

TABLE 15.6
Usual Convention for Selecting Direct- and Reverse-Acting Controllers

Process Gain	Direct-Acting Actuator	Reverse-Acting Actuator
Positive	Use reverse-acting PID	Use direct-acting PID
Negative	Use direct-acting PID	Use reverse-acting PID

Now consider a heat exchanger in which the cooling water flow rate to the exchanger is manipulated to control the temperature of the process stream leaving it. Since an increase in cooling water flow rate to the heat exchanger results in a decrease in the controlled variable for this process, the process gain is negative. Also, consider a direct-acting final control element. Similar to the previous example, consider the case in which the controlled variable is below its setpoint. Under these conditions, a decrease in cooling water flow rate is required; therefore, a direct-acting controller should be used. Finally, if a reverse-acting final control element was substituted for the direct-acting one, a reverse-acting controller should be used. Table 15.6 summarizes these results. Obviously, these different combinations of positive and negative process gains and reverse- and direct-acting final control elements can occur in the implementation of industrial process control. As a result, the process control engineer needs a way to conveniently choose a direct-acting or a reverse-acting controller. On a modern control computer (i.e., DCS), when a control loop is set up, there is typically a box to check to select a direct- or reverse-acting controller. For analog controllers, there is a switch on the back that allows the user to select the proper form.

Another way to represent the controller gain is the proportional band (*PB*), which is an approach that was in more common use 10 to 15 years ago. Proportional band can be expressed (as a percent) in terms of K_c when K_c is in dimensionless form. For example, the controller output and the error from setpoint can be scaled 0 to 100%, yielding a dimensionless K_c:

$$PB = \frac{100\%}{K_c}$$

The proportional band is small when the controller gain is large, and *PB* is large when K_c is small.

When a setpoint change is made using the forms given by Equations (15.1) and (15.2), a spike in the calculated value of $de(t)/dt$ will occur, causing a spike in $c(t)$. This behavior is called *derivative kick* and can be eliminated by replacing $de(t)/dt$ with $-dy_s(t)/dt$, yielding

$$c(t) = c_0 - K_c\left[e(t) + \frac{1}{\tau_I}\int_0^t e(t)dt - \tau_D\frac{dy_s(t)}{dt}\right] \tag{15.3}$$

for a direct-acting controller. The derivative-on-measurement form of the PID algorithm is recommended because it is not susceptible to derivative kick.

Equation (15.3) is applied within a DCS by implementing it in a digital form using the following approximations:

$$\int_0^t e(t)dt \approx \sum_{i=1}^{n} e(i\Delta t)\Delta t$$

where n is equal to $t/\Delta t$, and

$$\frac{dy_s(t)}{dt} \approx \frac{y_s(t) - y_s(t - \Delta t)}{\Delta t}$$

where Δt is the time interval between applications of the PID algorithm, i.e., the control interval. These approximations result in the digital version of the position form of the PID controller:

$$c(t) = c_0 + K_c\left[e(t) + \frac{\Delta t}{\tau_I}\sum_{i=1}^{n} e(i \cdot \Delta t) - \tau_D\left[\frac{y_s(t) - y_s(t - \Delta t)}{\Delta t}\right]\right] \tag{15.4}$$

The PID algorithm can also be applied in velocity form. Applying Equation (15.4) at $t - \Delta t$ results in the following equation:

$$c(t - \Delta t) = c_0 + K_c\left[e(t - \Delta t) + \frac{\Delta t}{\tau_I}\sum_{i=1}^{n-1} e(i \cdot \Delta t) - \tau_D\left[\frac{y_s(t - \Delta t) - y_s(t - 2\Delta t)}{\Delta t}\right]\right] \tag{15.5}$$

Subtracting Equation (15.5) from Equation (15.4) results in the velocity form of the PID algorithm:

$$\Delta c(t) = K_c\left[e(t) - e(t - \Delta t) + \frac{\Delta t}{\tau_I}e(t) - \tau_D\left[\frac{y_s(t) - 2y_s(t - \Delta t) + y_s(t - 2\Delta t)}{\Delta t}\right]\right] \tag{15.6}$$

and then

$$c(t) = c(t - \Delta t) + \Delta c(t) \tag{15.7}$$

Note that Equation (15.7) is written as a reverse-acting controller. A reverse-acting controller subtracts $\Delta c(t)$ from $c(t - \Delta t)$. The velocity form for the derivative on the error from setpoint is given by

$$\Delta c(t) = K_c\left[e(t) - e(t - \Delta t) + \frac{\Delta t}{\tau_I}e(t) + \tau_D\left[\frac{e(t) - 2e(t - \Delta t) + e(t - 2\Delta t)}{\Delta t}\right]\right] \tag{15.8}$$

Another popular version of the velocity form of the PID can be developed by eliminating proportional action for setpoint changes. Noticing that the proportional part of Equation (15.6) is simply the difference between $y(t)$ and $y(t - \Delta t)$ when the setpoint remains unchanged leads one to replace the difference between errors from setpoint with the difference between measured values of the controlled variable in the velocity form of the PID controller, i.e.,

$$\Delta c(t) = K_c\left[y_s(t - \Delta t) - y_s(t) + \frac{\Delta t}{\tau_I}e(t) - \tau_D\left[\frac{y_s(t) - 2y_s(t - \Delta t) + y_s(t - 2\Delta t)}{\Delta t}\right]\right] \tag{15.9}$$

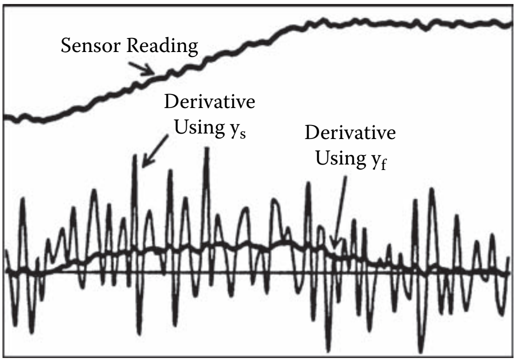

FIGURE 15.22 The instantaneous and filtered values for the derivative of a noisy sensor reading. Also shown is the value of the derivative calculated using filtered values of $y_s(t)$ with a filter factor of 0.08.

The advantage of this form of the PID controller is that it will not act as abruptly to setpoint changes as Equation (15.8). In fact, from Equation (15.8) it can be seen that only the integral action will move the process toward a new setpoint. This reduction in aggressive setpoint tracking has an effect that is similar to *bumpless transfer*, which is discussed later.

The position form of the PID algorithm calculates the absolute value of the output of the controller, whereas the velocity form calculates the change in the controller output that should be added to the current level of the controller output. The position and velocity modes are different forms of the same equation; therefore, they are generally equivalent. The velocity form is usually used industrially. In general, DCSs offer the velocity form of the PID controller in three versions: the velocity form in which P, I, and D are based on the error from setpoint [Equation (15.8)]; the form in which only P and I are based on the error from setpoint [Equation (15.6)]; and the form in which only integral action is based on the error from setpoint [Equation (15.9)].

When derivative action is applied to a process where there is significant noise on the sensor reading, erratic derivative action can result, since the difference between successive sensor readings can be dominated by the noise. Figure 15.22 shows a sensor reading with noise and the corresponding derivative value. A digital filter can be used to "smooth out" the noisy sensor reading:

$$y_f(t) = fy_s(t) + (1-f)y_f(t-\Delta t) \tag{15.10}$$

where $y_f(t)$ is the sensor reading after a digital filter has been applied, $y_s(t)$ is the current sensor reading, and f is the filter constant, which is normally between 0.01 and 0.5. The digital filter provides a running average and tends to absorb short-term variations caused by the noise. In this manner, filtered values of the controlled variable can be used where the derivative is calculated in the PID control equation, i.e.,

$$c(t) = c_0 + K_c\left(e(t) + \frac{1}{\tau_I}\sum_{i=1}^{m} e(i\Delta t)\Delta t + \tau_D\,\frac{y_f(t) - y_f(t-\Delta t)}{\Delta t}\right) \tag{15.11}$$

When the ratio of noise to measured value of the controlled variable is large, the measured value of the controlled variable used for proportional action may also require filtering [Equation (15.11)]. Figure 15.23 shows the results of a PI controller with and without filtering on the measurement of the controlled variable. For the case without filtering, the noise on the measured

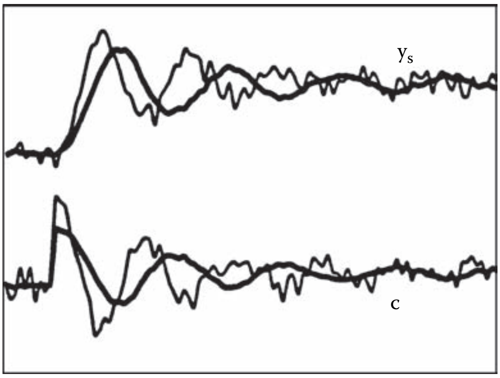

FIGURE 15.23 Comparison of the results of a PI controller with and without filtering on the measured value of the controlled variable. Thick line = with filtering, thin line = without filtering.

value of the controlled variable is passed into the controller output by the proportional portion of the controller, which in turn affects the level of the manipulated variable and thus the process. Figure 15.23 also shows the filtered value of the controlled variable and the corresponding controller output. The filtering removes most of the noise on the controlled variable so the controller output is considerably smoother. The aggressiveness of the controller, when filtering was applied, was reduced to produce the same general dynamic response. That is, filtering of the controlled variable puts additional lag into the overall process; therefore, less-aggressive tuning must be used. The detuning of the controller and the delay caused by the filtering process itself cause the filtered case to respond more slowly than the unfiltered case. It should be clear from this example that filtering is necessary in certain cases, but the minimum required filtering should be used to limit the detrimental effect of filtering on control performance.

An older version of the PID algorithm that was originally applied using analog devices is called an interactive PID controller, which is also referred to as "rate before reset" controller, since the derivative action is in series with and precedes the integral action. A PI or a P-only interactive controller is no different from the earlier form presented [i.e., noninteractive PID; Equation (15.1)]. The only difference between an interactive and a noninteractive controller relates to the PID controller. Both controllers apply the PID algorithm, but there are differences in the tuning constants. That is, for the same amount of proportional, integral, and derivative action, the interactive and noninteractive controllers have different values of the tuning constants (i.e., K_c, τ_I, and τ_D). The following are formulas for converting from interactive tuning parameters (the tuning parameters with primes) to tuning parameters for the conventional noninteractive PID form:

$$K_c = K'_c\left(1 + \tau'_D / \tau'_I\right)$$

$$\tau_I = \tau'_I\left(1 + \tau'_D / \tau'_I\right)$$

$$\tau_D = \tau'_D\left[\frac{1}{1 + \tau'_I / \tau'_I}\right]$$

Even though interactive controllers are an option on most DCSs, they are not recommended, because of the possible confusion concerning the tuning parameters; they offer no advantage over the

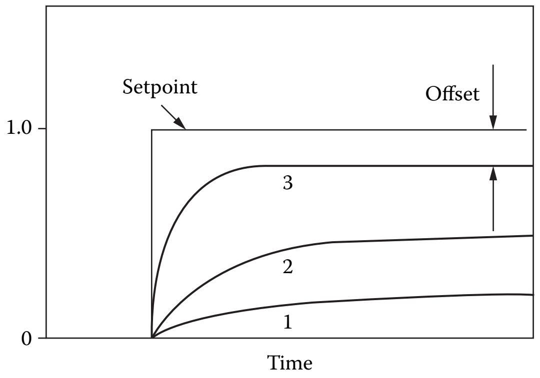

FIGURE 15.24 The effect of K_c on the response of a P-only controller for a first-order process to a setpoint change. Note that K_c is increased from 1 to 3.

noninteractive form of the PID controller. As a result, only the formulas for converting the settings from the interactive form to the noninteractive form are presented here.

15.3.3 Analysis of P, I, and D Action

The results of a theoretical analysis of proportional-only, integral-only, and derivative-only controllers[1] are summarized as follows.

15.3.3.1 Proportional Action

The key characteristics of proportional action are summarized as follows:

1. In general, proportional action does not change the order of the process.
2. The closed-loop time constant is smaller than the open-loop time constant. That is, proportional action makes the closed-loop process respond faster than the open-loop process.
3. The steady-state gain is not equal to unity. Figure 15.24 shows setpoint changes for three different values of K_cK_p. The steady-state value differs from the setpoint value, which indicates offset. Offset is the error between the new setpoint and the new steady-state controlled variable value. Also note that as K_c increases, the offset is reduced.

Figure 15.25 shows the portion of the controller signal resulting from proportional action for a PI controller that is applying a setpoint change. The proportional control action is positive when y is below y_{sp} and negative when y is above y_{sp}; its magnitude is directly proportional to the error from setpoint. Initially, the setpoint change causes a spike in proportional action, but as y moves toward the setpoint, the proportional action is reduced and eventually goes to zero as y settles at the setpoint.

15.3.3.2 Integral Action

The following are the fundamental characteristics of integral action:

1. All steady-state corrections for disturbances or setpoint changes must come from integral action.
2. There is no offset at steady state.

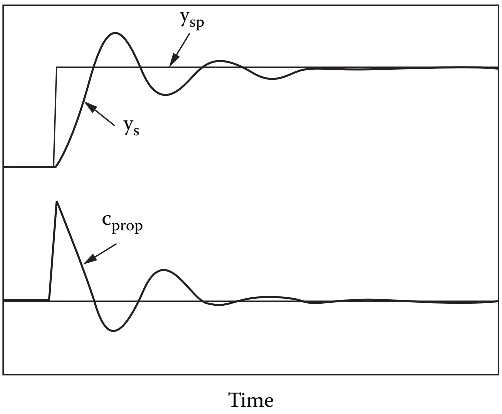

FIGURE 15.25 The portion of the controller output resulting from proportional control (c_{prop}) for a setpoint change applied by a PI controller.

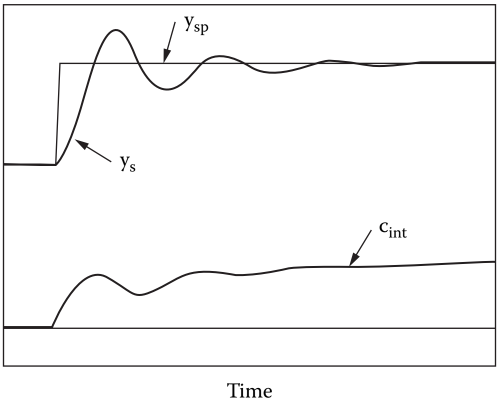

FIGURE 15.26 The portion of the manipulated variable level resulting from integral action (c_{int}) for a setpoint change applied by a PI controller.

3. Integral action increases the order of the process dynamics by 1.
4. The process becomes faster, but at the expense of larger overshoots and more sustained oscillations.

Figure 15.26 shows the portion of the controller output resulting from integral action for a PI controller for the same process shown in Figure 15.25. The peaks in c_{int} occur when y_s crosses y_{sp}. Also, as the process lines out at the setpoint, c_{int} lines out at a nonzero value.

15.3.3.3 Derivative Action

Derivative action (1) does not change the order of the process, (2) does not eliminate offset, and (3) tends to reduce the oscillatory nature of feedback control.

Figure 15.27 shows the portion of the manipulated variable level resulting from derivative action (c_{der}) for a setpoint change using a PID controller. Note that c_{der} is zero at the peaks and valleys of y, since it is directly related to the slope of y_s.

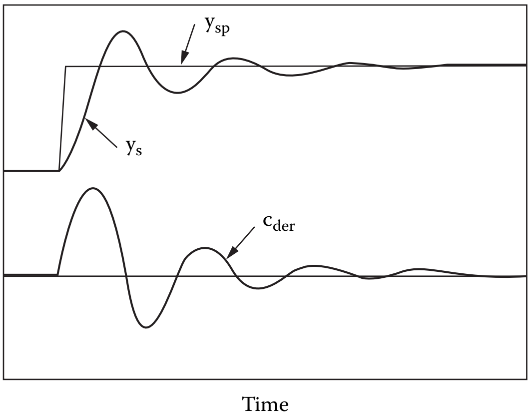

FIGURE 15.27 The portion of the manipulated variable level resulting from derivative action (c_{der}) for a setpoint change applied using a PID controller.

15.3.4 Controller Design Issues

When choosing between P-only, PI, or PID controllers, one should consider the dynamics of the combined actuator/process/sensor system. For conventional control loops in the CPI, about 93% are PI controllers, 2% are P-only controllers, and 5% are PID controllers.[2] The following guidelines can be used to choose the proper controller mode based on process dynamics and control objectives.

15.3.4.1 P-Only Control

P-only control is used for processes that are not sluggish and for which some degree of offset is acceptable. A sluggish process is characterized as a process that does not respond quickly to changes in the manipulated variable (i.e., not a first-order-like response). Typical applications are level control and pressure control. Many control loops should use P-only controllers but instead use typical PI or PI with a relatively small amount of integral action, since most operators do not want offset from setpoint.

15.3.4.2 PI Control

PI controllers are used for processes that are not sluggish and for which it is necessary to have offset-free operation. Typical applications are flow control, level control, pressure control, temperature control, and composition control.

15.3.4.3 PID Control

PID controllers are useful for certain sluggish processes. Typical applications are temperature control and composition control. A sluggish process often has a tendency to cycle under PI control due to inertia; therefore, derivative action tends to reduce the tendency to cycling and allows more proportional action to be used, both of which contribute to improved control performance. A key issue here is to determine whether a process is sluggish enough to warrant a PID controller. Assume that an FOPDT model has been fit to an open-loop step test. If the resulting deadtime, θ_p, and time constant, τ_p, are such that

$$\frac{\theta_p}{\tau_p} < \frac{1}{2}$$

the process is not sufficiently sluggish to warrant a PID controller. If

$$\frac{\theta_p}{\tau_p} > 1$$

the process is sufficiently sluggish that a PID controller should offer significant benefits over a PI controller. For

$$\frac{1}{2} < \frac{\theta_p}{\tau_p} < 1$$

either PI or PID control could be preferred. In the event that FOPDT models are not available, excessive oscillations of a PI controller or a sluggishly responding PI controller are indications that a PID controller may provide improved control performance. In addition, measurements of the controlled variable with significant noise levels can make the use of derivative action ineffective due to the sensitivity of the derivative to noise on the measurement. That is, since the measurements of the controlled variable have so much noise that, if filtering is used, the lag added by the filter can negate any benefit produced by the derivative action.

15.3.5 Analysis of Typical Control Loops

All feedback control processes involve a final control element, a process, and a sensor. That is, to change the manipulated variable level, a final control element is required. A sensor is also required to measure resulting changes in the controlled variable. The input to the final control element/process/sensor system is the controller output, c, and its output is the sensor reading. When evaluating the dynamic behavior of a process, the relative dynamics of the final control element, the process, and the sensor should be considered. For example, there are processes for which one or two of the dynamic components (final control element, process, or sensor) respond substantially faster than the slowest element and therefore can be neglected when analyzing the dynamic behavior of the overall process.

15.3.5.1 Flow Control Loop

Figure 15.28 shows a schematic of a flow control process. The dynamics of the process (i.e., flow rate changes for changes in the valve stem position) and the sensor (i.e., changes in the measured pressure drop for changes in the flow rate) are relatively fast compared with the dynamics of the control valve (i.e., changes in valve stem position for changes in the signal to the final control element). Since the overall process is relatively fast, and accurate control to setpoint is required, a PI controller is the proper choice for most flow control applications.

In spite of the fact that industrial control valves have a deadband of 10 to 25%, flow control loops are able to precisely meter deadband in the average flow typically to within 0.5% and down to 0.1% in certain cases. To understand how a flow control loop can very accurately control the flow rate using such an imprecise actuator, consider the measured flow rate and specified flow rate shown in Figure 15.29. The significant variation in the flow rate (i.e., sustained oscillations) is due to the deadband of the valve, but the average flow is precisely controlled via the high-frequency feedback control provided by the flow controller. Since the period of the flow variations is in the range of seconds, and most chemical processes have time constants several minutes or larger, the process is sensitive only to the average flow and not to flow fluctuations. Therefore, flow control loops can provide very precise metering of the average flow rate in spite of the fact that a very

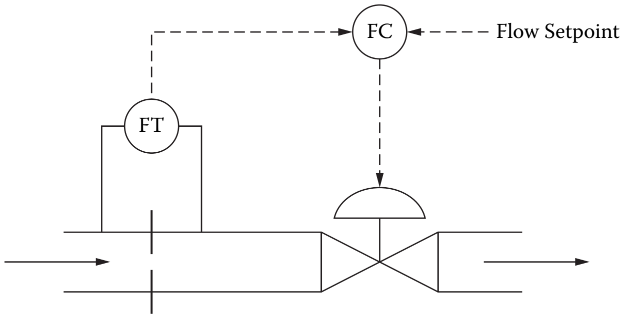

FIGURE 15.28 Schematic of a flow control loop.

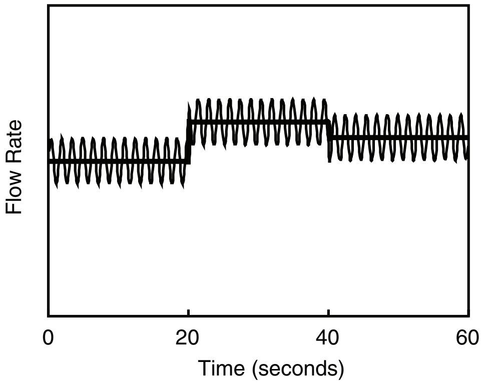

FIGURE 15.29 Measured flow rate and the specified average flow rate for a valve with a positioner. Thin line = measured flow rate, thick line = flow rate setpoint.

imprecise actuator is used. If a valve positioner is used, the valve positioner will provide the high-frequency feedback necessary to counteract the detrimental effects of the control valve deadband on the metering precision of the average flow rate. That is, the high-gain P-only controller applied by the valve positioner will open and close the valve in a manner similar to the results shown in Figure 15.29. A flow control loop applied to a control valve with a positioner will eliminate the offset that the positioner does not account for and absorb unmeasured disturbances such as changes in upstream and downstream pressures.

15.3.5.2 Level Control Loop

A schematic for a level control loop used to control the level in a tank is shown in Figure 15.30. A differential pressure sensor is used to measure the liquid level, and a flow control loop is used to control the flow rate from the tank. The output of the level controller is the setpoint for the flow controller on the line leaving the tank. Some level controllers send their outputs directly to the valve on the line, but most level controllers in the CPI are implemented as shown in Figure 15.30, using flow control loops. The objective of this loop is to maintain the level within a certain range—for example, from 30 to 40% of full level for changes in this feed rate to the tank and changes in operating conditions. On the other hand, many operators want levels controlled to specified setpoints and are not satisfied if, for example, the level is 32 or 38% when the setpoint is 35%.

The dynamics of the sensor are quite fast, and the dynamics of the flow control loop are usually fast compared with the dynamics of the process (i.e., percentage level change for change in flow

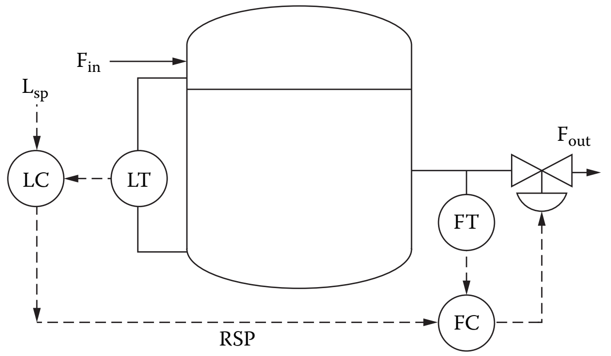

FIGURE 15.30 Schematic of a level controller applied to a tank.

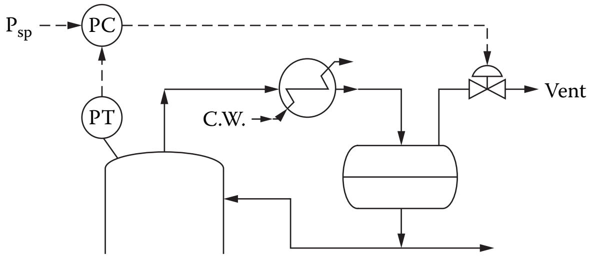

FIGURE 15.31 Schematic of a pressure controller for the overhead of a distillation column.

leaving the tank). For a typical system under open-loop conditions, a 5% level change can occur in about 1 min for about a 10% change in feed rate to the tank. Thus, the response of the final control element/process/sensor system is typically controlled by the process dynamics. Since the overall process is not generally sluggish, a P-only controller is the proper choice when offset elimination is not required. When offset elimination is required (e.g., level control for a reactor), a PI controller should be used.

15.3.5.3 Pressure Control Loop

Pressure control loops are used to maintain system pressure for distillation columns, reactors, and other process units. A pressure control loop for maintaining overhead pressure in a column is shown in Figure 15.31. The final control element is a control valve on the vent line, and the sensor is a pressure sensor mounted on the top of the column. The output from the pressure controller goes directly to the control valve on the vent line. The objective of this loop is to maintain the column overhead pressure at or near setpoint for changes in condenser duty and changes in vapor flow rate up the column.

The pressure sensor is quite fast, whereas the process (change in pressure for change in vent valve stem position) and the actuator are generally the slowest elements in the feedback system; therefore, this is also a relatively fast-responding process. The P-only controller can be used if offset elimination is not important, and a PI controller can be used when offset elimination is important.

15.3.5.4 Temperature Control Loop

Temperature control loops can be applied to control the temperature of a stream exiting a heat exchanger, of a tray in a distillation column, or of a CSTR. Figure 15.32 shows a schematic of a temperature controller applied to control the temperature of a process stream leaving a gas-fired heater. The sensor is an RTD element placed in a thermowell located in the line leaving the heater,

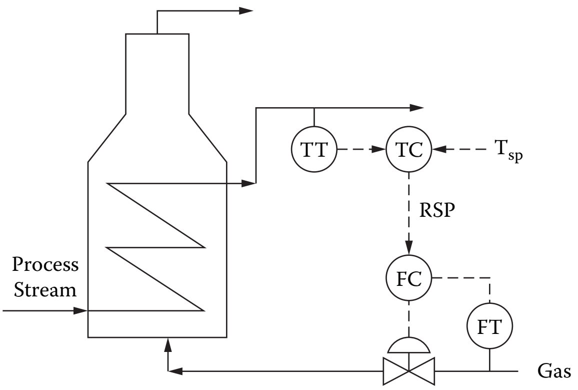

FIGURE 15.32 Schematic of a temperature controller for a gas-fired heater.

and the actuator is a flow control loop on the gas line to the heater. The objective of the temperature control loop is to maintain the temperature of the exiting process stream on setpoint in the face of changes in the temperature of the process stream entering the heater and changes in the heating value of the gas.

The dynamics of the flow control loop on the gas fuel are generally much faster than the dynamics of the process (i.e., change in outlet process temperature for a change in gas flow rate to the heater) and the sensor, which typically has a dynamic time constant between 6 and 20 s for a properly installed RTD. The process fluid entering the gas-fired heater flows by plug flow through the heat exchanger tubes that are exposed to high-temperature combusted gas. There is a thermal lag associated with changing the temperature of the metal of the heat exchanger tubes as well as transport delay caused by plug flow through the heater tubes. The transport delay and resulting overall process deadtime will increase as the feed rate of the process fluid is reduced. Since the heater is likely to behave as a sluggish process, a PID controller is generally the preferred choice in this example. Excessive sensor noise can make the use of derivative action ineffective. If this process were less sluggish, a PI controller would be preferable.

15.3.5.5 Composition Control Loop

Composition control loops are used to keep products produced by distillation columns on specification, to maintain constant conversion in a reactor, and to maintain oxygen levels in the flue gas of a boiler to eliminate carbon monoxide emissions. Figure 15.33 shows a schematic of a compo-

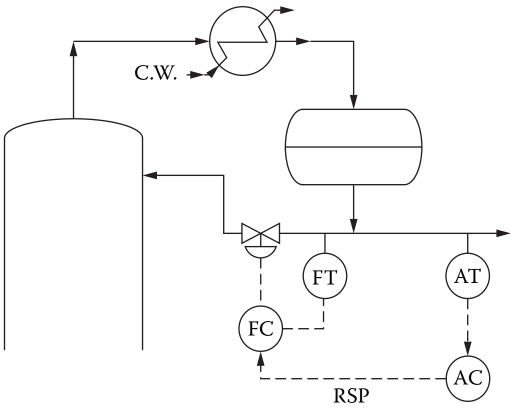

FIGURE 15.33 Schematic of a composition controller for the overhead of a distillation column.

sition loop that controls the impurity level in the overhead product of a distillation column. The sensor is a gas chromatograph that samples the distillation product, and the output of the controller for this loop is the setpoint for the reflux flow controller. The objective of the composition control loop is to keep the impurity level in the overhead product on setpoint during changes in the feed flow rate and feed composition.

The dynamics of the flow controller on the reflux are relatively fast, whereas the sensor typically can have 3 to 10 min of analyzer delay. The process (i.e., the change in impurity level in the overhead product for a change in the setpoint for the reflux flow controller) can be quite slow. If the process and analyzer delay result in a sluggish actuator/process/sensor system, a PID controller may be preferred.

15.4 PID TUNING

15.4.1 Introduction

Tuning PID loops is one of the major responsibilities of a process control engineer, and the resulting controller settings have a dominant effect on the performance of a PID control loop. Tuning a PID controller requires selecting values for K_c, τ_I, and τ_D that meet the operational objectives of the control loop, which usually requires making a proper compromise between performance (minimizing deviations from setpoint) and reliability (the controller's ability to remain in service while handling major disturbances).

15.4.2 Tuning Criteria and Performance Assessment

15.4.2.1 Tuning Criteria

To guide the tuning process, the following tuning objectives should be considered:

Deviations from setpoint should be minimized.
Good setpoint tracking performance should be attained.
Excessive variation of the manipulated variable levels should be avoided.
The controlled process should remain stable for major disturbance upsets.
Offset elimination may or may not be important.

Simultaneously satisfying each of these objectives is never possible; therefore, tuning is a compromise. For example, tuning for minimum deviation from setpoint for normal disturbances is contrary to tuning the controller to remain stable for major disturbances. That is, if the controller is tuned for normal disturbances, the closed-loop system may go unstable when a major disturbance enters the process. On the other hand, if the controller is tuned for the largest possible disturbance, control performance is likely to be excessively sluggish for normal disturbance levels.

Industrial control performance is often assessed by the variability in the final products produced. The standard deviation from setpoint (σ) can be used as a measure of variability in industrial products and thus a measure of control performance:

$$\sigma = \sqrt{\frac{\sum_{i=1}^{N} [y_s(t_i) - y_{sp}]^2}{N}}$$

where $y_s(t_i)$ is the sampled controlled variable value at time equal to t_i, and N is the number of samples. Note that the smaller the deviation from setpoint, the better the control performance.

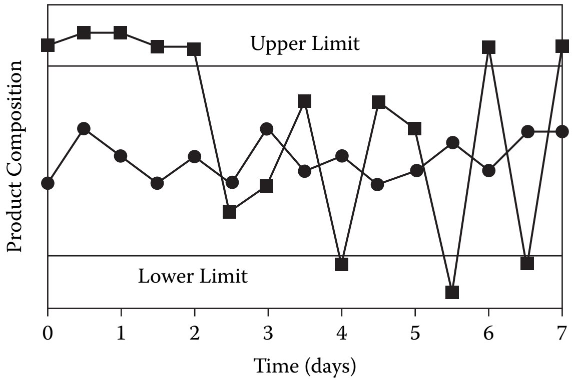

FIGURE 15.34 SPC chart based on a seven-day period of data for two different controllers on the same process.

Remember that the standard deviation is based on the error from the average value of a set of data, whereas this statistic is based on the error from setpoint.

Most companies keep statistical process control (SPC) charts that track the laboratory analysis of final products, which are typically sampled one to three times daily. Figure 15.34 is an example of an industrial SPC chart for two different controllers, for two different seven-day periods. It is easy to see which controller performed better.

15.4.3 Effect of Tuning Parameters on Dynamic Behavior

For an open-loop overdamped process, the closed-loop dynamic behavior will go through the same stages as the controller aggressiveness is increased: overdamped, critically damped, underdamped, ringing, and unstable (see Figure 15.12). For a PID controller, controller aggressiveness is increased as K_c is increased or as τ_I is decreased.

15.4.3.1 PI Control

Figure 15.35 shows the dynamic behavior of a process for a setpoint change with different amounts of proportional action. Figure 15.35b shows the results for a PI controller tuned for quarter-amplitude damping (QAD, a decay ratio of 1/4). In addition, the QAD tuning was modified by increasing K_c (Figure 15.35c) while keeping τ_I constant and by decreasing K_c (Figure 15.35a) while keeping τ_I constant. Note that the increase in K_c resulted in ringing, while the decrease in K_c resulted in sluggish behavior. In addition, larger controller gains result in longer settling times. Figure 15.36 shows similar results for the effect of variations of τ_I. Figure 15.36b shows the results for QAD tuning and is the same result as shown in Figure 15.35b. A decrease in τ_I from QAD settings results in ringing (Figure 15.36c) and an increase results in a slow removal of offset (Figure

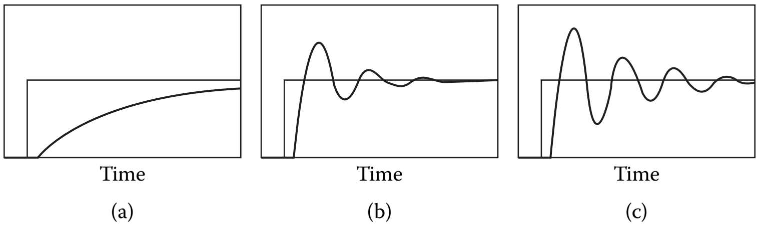

FIGURE 15.35 PI controller responses for a FOPDT process with varying amounts of proportional action. (a) K_c too low, (b) K_c tuned for QAD, (c) K_c too large.

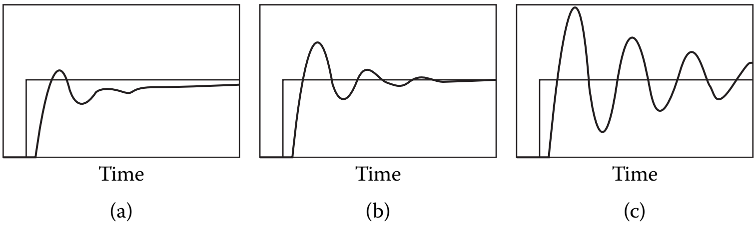

FIGURE 15.36 PI controller response for an FOPDT process with varying levels of integral action. (a) τ_I too large, (b) τ_I tuned for QAD, (c) τ_I too small.

15.36a). By comparing Figures 15.35a and 15.36a, it can be seen that when K_c is too low, long rise times and overdamped behavior result, and when integral action is too low (τ_I is too large), offset elimination is slow. Also note that ringing from too much proportional action (Figure 15.35c) and ringing from too much integral action (Figure 15.36c) are quite similar; therefore, when controller ringing results, it is difficult to tell whether there is excessive proportional action, excessive integral action, or both.

Figure 15.37 shows the manipulated and controlled variables for a QAD-tuned controller. The controller output "lags" behind the controlled variable for this case. Figure 15.38 shows the same system, except the K_c is increased by 25% and τ_I is increased by a factor of 2 (i.e., the ringing is caused by too much proportional action). The lag between the controlled variable and the controller output is significantly reduced; therefore, excessive gain reduces the lag between the controlled variable and the controller output. Figure 15.39 shows the case in which K_c and τ_I are reduced by a factor of 2 compared with the QAD settings. In this case, the lag increases significantly; therefore, excessive integral action results in an increase in the lag of the sytem. As a result, the lag between the controller output and the controlled variable can be used to determine if a controlled process is ringing from too much proportional action or too much integral action. This analysis can also be used to compare the ringing results shown in Figures 15.35 and 15.36. These results also show that the lag between the controlled variable and the controller output is larger when there is excessive integral action, but the differences are less distinct than those shown in Figures 15.38 and 15.39. With pure proportional action, the maximum *c* occurs at the maximum deviation from setpoint, which corresponds to zero lag (i.e., in phase). For pure integral action, the maximum *c* occurs when the error from setpoint changes sign, which corresponds to a large lag.

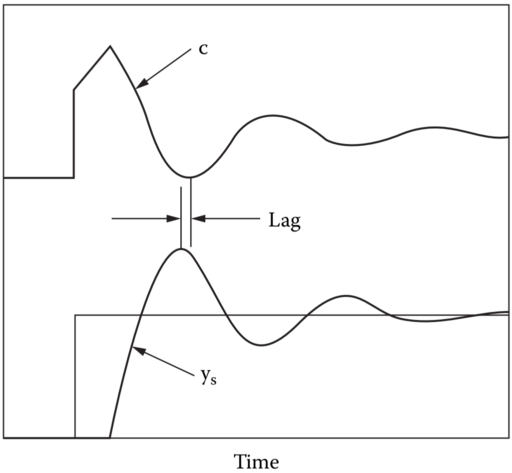

FIGURE 15.37 The lag between the controller output and controlled variable for a QAD-tuned PI controller.

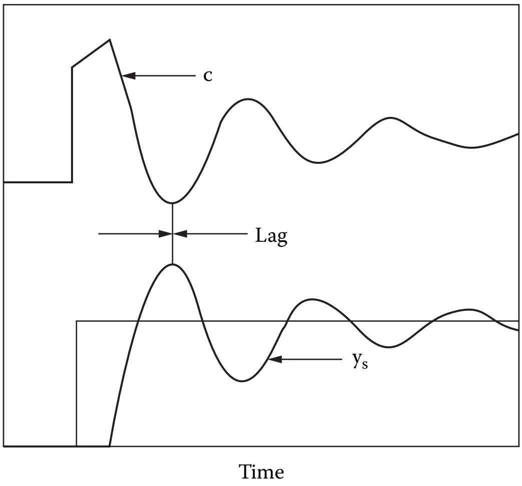

FIGURE 15.38 The lag between the controller output and controlled variables for a controller with too much proportional action.

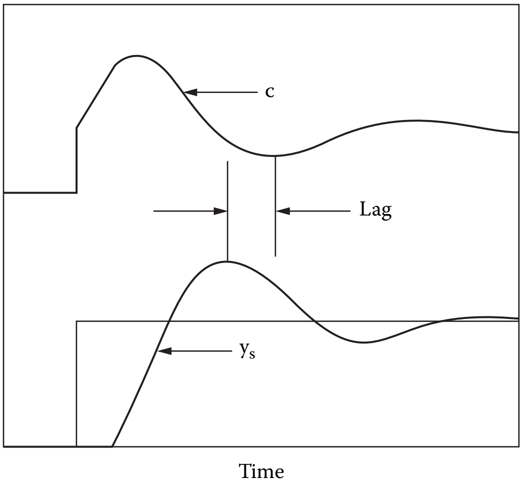

FIGURE 15.39 The lag between the controller output and controlled variable for a controller with too much integral action.

15.4.3.2 PID Control

The effect of proportional and integral action on the feedback behavior of a PID controller is similar to that observed for a PI controller. Figure 15.40a shows PID and PI control on a FOPDT process ($K_p = 1$, $\tau_p = 1$, $\theta_p = 0.1$). Figure 15.40b shows PID control and PI on another FOPDT process with more deadtime ($K_p = 1$, $\tau_p = 1$, $\theta_p = 2$). These results support the conclusion that derivative action is useful for processes that have a significant ratio of deadtime to time constant. Figure 15.41 shows a case that has too much derivative action in the PID controller. Note that the feedback response shows a "stairstep" behavior, which indicates that too much derivative action is being used. The stairstep behavior exists because, as the process moves toward the setpoint, excessive derivative action causes the process to stall or level out. When the process stalls, the proportional and integral actions act on the process to move the controlled variable toward the setpoint. When

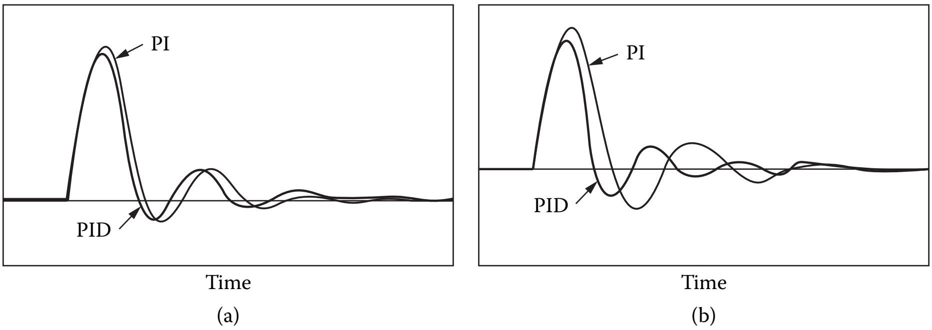

FIGURE 15.40 Comparison between PI and PID controllers for a process with (a) low deadtime and (b) larger deadtime.

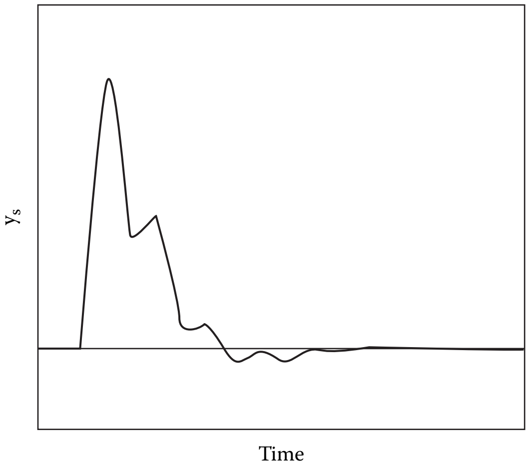

FIGURE 15.41 The control performance of a PID controller with too much derivative action.

this occurs, the derivative of the controlled variable will build up, and the derivative action will act against it, causing the stairstep effect.

15.4.3.3 Control Interval

The PID control results presented so far have been based on a continuous application of the controller. The digital application of feedback control is applied at discrete points in time. DCSs use sequential microprocessors that perform control calculations for many control loops. Typical control loops are executed every 0.2 to 0.5 s for regulatory loops and 30 to 120 s for supervisory loops. The time between control applications is the control interval, Δt. PID control is applied industrially on DCSs using digital formulas that are applied at discrete control intervals [Equations (15.6), (15.8), and (15.9)].

Consider the QAD timed continuous PI controller that was applied to the FOPDT process ($K_p = 1$, $\tau_p = 1$, $\theta_p = 5$). If these settings are applied using a control interval of 0.5, the control behavior is unstable. The PI controller was retimed using a control interval of 0.5, and the results are compared with continuous control for a setpoint change in Figure 15.42. The controller gain for discrete control ($\Delta t = 5$) was reduced by 60% compared to the continuous controller. Because of the detuning and the delayed response, the discrete controller resulted in a longer settling time.

As a general rule,[1] the control interval should be selected such that

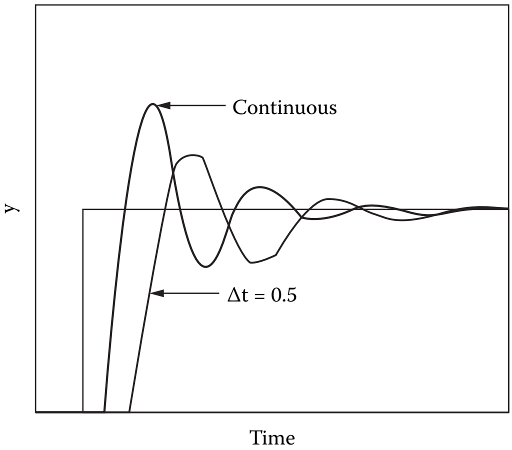

FIGURE 15.42 Comparison between a continuous PI controller and a PI controller applied each 0.5 time unit.

$$\Delta t \le 0.05\left(\theta_p + \tau_p\right)$$

to obtain control performance approaching that of continuous control. For feedback control using an on-line GC, the control interval is set by the cycle time for the analyzer updates (typically 3 to 10 min). No advantage is gained by applying control action more frequently than the GC updates, since new information on the process response is available only when the GC updates. For sensors that provide continuous readings (e.g., temperature sensors), the maximum recommended control interval is typically equal to one sensor time constant. For level, pressure, and flow loops, sensor dynamics do not usually present a significant constraint for the choice of the control interval.

15.4.4 Recommended Approach to Controller Tuning

The following procedure is recommended for tuning PID control loops:

1. Select the tuning criterion for the control loop. The tuning criterion depends on how the control loops affect the overall process objectives and can involve applying a compromise between performance and reliability.
2. Apply filtering to the sensor reading. Sensor filtering reduces the effect of sensor noise on the variability in the controlled variable but introduces lag to the feedback system, which is detrimental to control performance. Therefore, filtering should be applied carefully.
3. Determine if the control loop is a fast- or slow-responding control loop. The distinction between fast- and slow-responding control loops is concerned with the closed-loop response time of the system. If a set of controller settings can be tested using setpoint changes in a reasonable period of time (e.g., less than 10 min), the process is a fast-responding control loop. If not, it is a slow-responding control loop.
4. For fast-responding control loops, apply field tuning.
5. For slow-responding control loops, apply the ATV-based tuning procedure.

15.4.5 Controller Reliability

Controller reliability has to do with whether a controller will stay in service during major upsets. Major upsets cause significant deviations from setpoint that result in variations in the process behavior for nonlinear processes, which can significantly affect the tuning performance. That is, when the inputs to a nonlinear process change, the effective gain, time constant, and deadtime can

change. For example, if a disturbance to a process causes the process gain to increase, the time constant to decrease, and the deadtime to increase, the closed-loop behavior will move toward (if not into) unstable operation. On the other hand, if a disturbance to a process causes the gain to decrease, the time constant to increase, and the deadtime to decrease, the closed-loop behavior will become more sluggish. Therefore, a nonlinear process subjected to large disturbances should be tuned more conservatively than a more linear process with low-level disturbances to reduce the likelihood that the operation of the nonlinear process will become unstable.

The general behavior of a second-order process (Figures 15.5 and 15.6) can be used to characterize the dynamic behavior of a closed-loop process and used as the tuning criterion for a controller. For example, a controller tuned for critically damped behavior is more conservatively tuned than a controller tuned for QAD (decay ratio of 1/4). A more conservative tuning criterion should be chosen for more nonlinear processes that are subjected to large-magnitude disturbances, whereas a more aggressive tuning criterion should be used for more linear processes that are subject to low-level disturbances. More conservative settings are chosen for more difficult control problems (i.e., high nonlinearity and severe disturbances) so that larger variations in process characteristics (effective gain, time constant, and deadtime) can occur and yet the controller can remain stable. On the other hand, a more aggressive tuning should be selected for easier control problems so as not to unnecessarily sacrifice control performance (variability from setpoint).

15.4.6 Selection of Tuning Criterion

Selecting the tuning criterion for a control loop is equivalent to determining the aggressiveness of the feedback controller. If one were to choose a critically damped response as the tuning criterion, a controller with a low aggressiveness would result. On the other hand, QAD tuning criterion corresponds to a very aggressively tuned controller.

The first factor that should be considered when choosing the proper tuning criterion is how the control loop affects the overall objectives of the process. Consider the accumulator of a distillation column that feeds a plug flow reactor (Figure 15.43). Tight level control for the accumulator results in sharp changes in the feed to the reactor. Sharp, frequent changes to the feed rate to the plug flow reactor significantly upset the operation of the reactor, because the residence time of the reactor is directly related to the feed rate, and changes in the residence time affect the degree of conversion. On the other hand, if the level controller for the accumulator is tuned for sluggish performance, the changes in the feed rate to the reactor are much more gradual and smooth, allowing better operation of the reactor. From an overall process point of view, maintaining smooth operation of the reactor is much more economically important than maintaining tight level control in the accumulator; therefore, a critically damped or overdamped tuning criterion is the proper choice for the level controller on the accumulator in this example.

As another example of how the overall process objective can affect the selection of the tuning criterion, consider the CSTR and separation train shown in Figure 15.44. If the level controller for the CSTR is tuned loosely, the CSTR level can change significantly. Because the production rates of the various products are related to the residence time in the reactor, large variations in the CSTR level directly affect the product distribution. The resulting composition changes in the stream

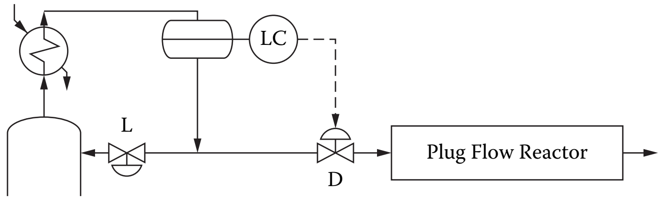

FIGURE 15.43 Schematic of a level controller that feeds a plug flow reactor.

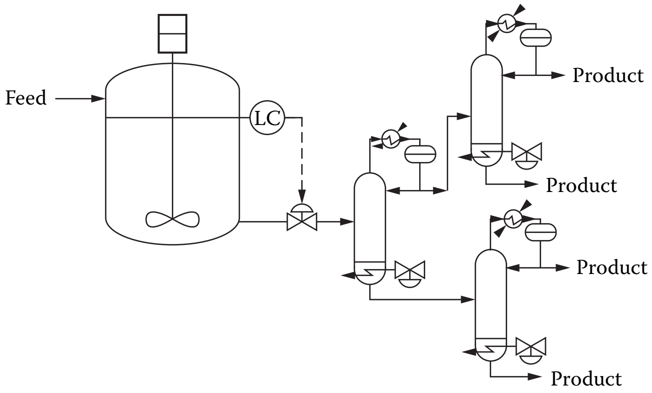

FIGURE 15.44 Schematic of a level controller that feeds a separation train.

leaving the CSTR represent major upsets for the composition controllers for the distillation columns in the separation train. Even though tight level control for the CSTR causes short-term variations in the feed to the first column, these upsets are much easier to handle than composition changes. Therefore, considering the overall process objectives, a tuning criterion corresponding to tight level control should be chosen for the level controller on the CSTR. These two examples indicate that it is important to consider how a control loop affects the overall process when selecting its tuning criterion.

If consideration of the overall process objectives does not place a limit on the aggressiveness of the tuning criterion, or if the overall process objectives dictate that minimum variability in the controlled variable of the loop in question is desirable, the selection of the tuning criterion should be based on a compromise between performance and reliability. The previous section indicates that process nonlinearity and disturbances determine the reliability of a controller. If a process is highly nonlinear and subject to large disturbances, controller reliability will likely be a problem, and a more conservative tuning criterion should be selected (e.g., a critically damped response). On the other hand, if the process is relatively linear and the disturbances are relatively mild, a more aggressive tuning criterion should be selected (e.g., a 1/6 decay ratio or 40% overshoot). Therefore, when control engineers choose a tuning criterion, they compromise between performance and reliability; they must use their knowledge of the process to evaluate the relative nonlinearity of the process and the relative degree of severity of the disturbances.

Even though QAD provides the best overall performance in terms of errors from setpoint, many companies are reluctant to have their control engineers tune even well-behaved control loops for QAD because of the 50% overshoot associated with QAD and because QAD is too close to the onset of instability. In addition, since QAD causes significant variation in the manipulated variable levels, QAD can result in unduly upsetting other parts of the process. For these reasons, it is probably better to tune well-behaved loops for decay ratios of 1/6 to 1/8. For a process that is more nonlinear with more severe disturbances, 1/10 amplitude damping or a critically damped response is more appropriate. In extreme cases, an overdamped tuning criterion may be the proper choice. No single tuning criterion works effectively for all control loops, because the process nonlinearity, disturbance type and magnitude, and operational objectives must all be considered when choosing the proper tuning criterion, and these factors change from control loop to control loop.

15.4.7 Tuning the Filter on Sensor Readings

Sensor readings should usually be filtered to reduce the influence of sensor noise on feedback control performance. Filtering, however, adds lag to the closed-loop response. In certain cases, tuning a filter on a sensor can involve balancing the benefits of reducing the noise against the

detrimental effects of adding lag to the overall process. In other cases, if possible, the time constant of the filter should be significantly smaller than the other dominant time constants in the actuator/process/sensor system so that filtering does not slow down the response of the system.

It is usually more convenient to use the filter time (i.e., the time constant of the first-order filter), τ_f, to specify the amount of filtering applied to a sensor reading. In this manner, the time constant of the filter can be directly compared to the time constants of the actuator, process, and sensor to determine whether it affects the closed-loop dynamics. The filter factor, f, and the cycle time for applying the filter, Δt_f, can be used to calculate the filter time constant by the following equation:

$$\tau_f = \Delta t_f \left[\frac{1}{f} - 1 \right]$$

For most DCSs, sensor readings are updated five or six times per second (i.e., Δt_f *is* 0.16 to 0.2 s). For a filter time constant of 3 s, the filter factor is equal to 0.06; therefore, relatively extensive sensor filtering can result for most sensors using high-frequency updating by a DCS.

The amount of sensor filtering required depends on the amount of noise on the reading. For example, a reading from a thermocouple is expected to require more filtering than a reading from an RTD, which has an order of magnitude smaller repeatability (Table 15.1), for the same application. From an examination of Table 15.2, one can see that a properly functioning sensor usually has a relatively small amount of noise. As a result, most flow, level, pressure and temperature sensors can be filtered effectively using a filter time constant of 3 to 5 s, which does not normally affect the closed-loop dynamics. Composition analyzer readings from GCs are updated so infrequently that filtering is usually not used for them. On the other hand, if composition measurements are available at a sufficiently high frequency, filtering can be used effectively.

In certain cases, the filtering of a noisy sensor is required. Noisy sensors present a challenge. A nuclear-based level sensor, a pressure sensor located too close to a 90° elbow in a line, or an orifice flow meter located immediately downstream of a control valve are examples of noisy sensors. For these cases, tuning the filter is a compromise between removing the noise from the sensor reading and adding lag to the closed-loop response when one is forced to use a noisy sensor reading.

15.4.8 Fast-Response Loops

For fast-responding loops, such as flow control and pressure control loops, the simplest and quickest tuning method available is field tuning, which is based on a trial-and-error selection of tuning parameters. Some level and temperature loops also behave as fast-responding control loops. A fast-responding control loop is defined here as a control loop that has a closed-loop response time of 10 min or less. Since these processes respond quickly, trial-and-error tuning is effective. It is usually easier to field tune a fast-responding loop rather than using other tuning methods. Use initial tuning parameters from a chosen tuning method, and adjust the tuning to meet the selected tuning criterion. The recommended procedure for field tuning, assuming that the tuning criterion has been selected and the sensor reading filtered, follows:

1. Turn off the derivative action ($\tau_D = 0$) and the integral action ($\tau_1 \rightarrow \infty$).
2. Use an initial estimate of K_c, e.g.,

$$K_c = \frac{1}{2K_p}$$

   Estimate K_p from process knowledge.

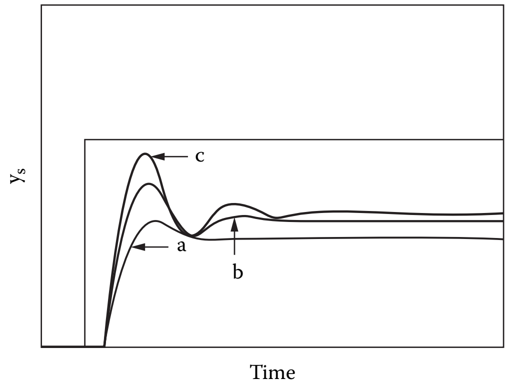

FIGURE 15.45 Selection of K_c during field tuning. (a) Results for initial value of K_c, (b) results for an increase in K_c, and (c) results for final value of K_c (1/6 decay ratio).

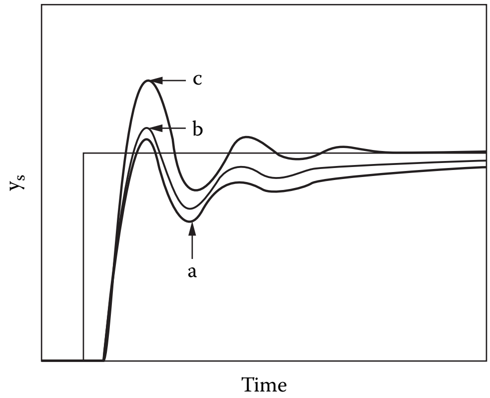

FIGURE 15.46 Selection of τ_I during field tuning. (a) Results for initial value of τ_I, (b) results for a decrease in τ_I, and (c) results for the final value of τ_I (1/6 decay ratio).

3. Using setpoint changes, increase K_c in small increments until the response meets the tuning criterion. (See Figure 15.45, which is based on a 1/6 decay ratio.) For tuning a P-only controller, the tuning procedure is completed.
4. Decrease K_c by 10%.
5. Use an initial value of τ_I, i.e., $\tau_I \cong 5\tau_p$. Estimate τ_p from process knowledge.
6. Decrease τ_I until offset is eliminated and the tuning criterion is met for setpoint changes. (See Figure 15.46, which is also based on a 1/6 decay ratio.)
7. Check to ensure that adequate levels of proportional and integral actions are being used.

15.4.9 Slow-Response Processes

For slow-response loops (e.g., certain temperature and composition control loops), field tuning can be a time-consuming procedure that leads to less than satisfactory results. Step test results can be used to generate FOPDT models, and tuning parameters can be calculated from a variety of techniques. This approach suffers from the fact that it takes approximately the open-loop response time of the process to implement a step test, and during that time, measured and unmeasured disturbances can affect the process, thus corrupting the results from the step test. In addition, it is unlikely that the selected tuning approach will result in the proper balance between reliability and

TABLE 15.7
Typical Tuning Parameters for Common Loops in the CPI

Loop Type	PB	τ_I (s)	τ_D (s)
Flow controller	100–500%	0.2–2.0	0
Gas pressure controller	1–15%	5–100	0
Liquid pressure controller	100–500%	0.2–2.0	0
Level controller	5–50%	5–60	0
Temperature controller	10–50%	40–4000	30–2000*
Composition controller	100–1000%	100–5000	30–4000*

* τ_D should always be smaller than τ_I.

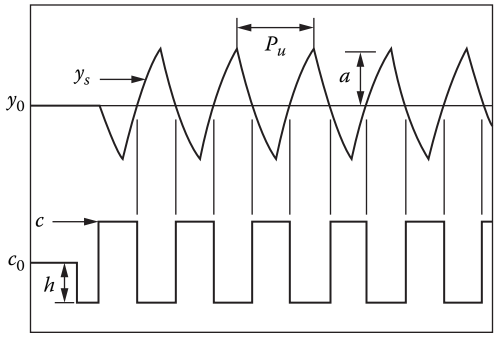

FIGURE 15.47 Graphical representation of an ATV test.

performance. Because of model mismatch and the likely selection of an inappropriate tuning criterion, significant adjustments to the tuning are still required.

The ATV[2] (autotune variation) method determines the ultimate gain and period in a manner similar to the ultimate method, but ATV tests can be implemented without unduly upsetting the process. Controller settings can be calculated, and the controller can then be tuned on-line to meet the selected dynamic performance.

Figure 15.47 graphically demonstrates the ATV method. The user must select h, the relay height used or the change in the manipulated variable that is applied. The value of h should be small enough that the process is not unnecessarily upset yet is large enough that the resulting amplitude, a, can be accurately measured.

To initiate an ATV test, the process should be at steady-state or near steady-state conditions, c_0 and y_0. Next, the controller output is set to $c_0 + h$ (or $c_0 - h$) until y deviates significantly from y_0. At that point, the controller output is set to $c_0 - h$ (or $c_0 + h$), which will turn the process back toward y_0. Then, each time y crosses y_0, the controller output is switched from $c_0 + h$ to $c_0 - h$ or from $c_0 - h$ to $c_0 + h$. The process is also referred to as a *relay feedback experiment*. A standing wave is established after 3 to 4 cycles; therefore, the values of a and the ultimate period, P_u, can be measured directly, and the ATV test is concluded. The ultimate gain, K_u, is calculated by

$$K_u = \frac{4h}{\pi a} \tag{15.12}$$

K_u and P_u can be used in one of several tuning schemes. One tuning approach is the Ziegler–Nichols (ZN) ultimate settings.[3] Consider the ZN settings for a PI controller:

$$K_c^{ZN} = 0.45 K_u$$

$$\tau_I^{ZN} = P_u / 1.2$$

ZN settings are fairly aggressive and can lead to ringing behavior for nonlinear processes due to the relatively small value of τ_I (i.e., large integral action).

Another tuning approach that was developed for processes that behave like an integrator plus deadtime system is the Tyreus and Luyben (TL) settings[4]:

$$K_c^{TL} = 0.31 K_u$$

$$\tau_I^{TL} = P_u / 0.45$$

The TL settings are less aggressive, with considerably less integral action than the ZN settings. The TL settings are recommended for more sluggish processes that are well represented as integrator plus deadtime for a good portion of its step test (e.g., a sluggish distillation column). After the ZN or TL settings are calculated, they may require on-line tuning, particularly for the ZN settings, to meet the desired dynamic performance (e.g., 1/6 decay ratio or critically damped). For example, the ZN settings are tuned on-line as follows:

$$\begin{aligned} K_c &= K_u^{ZN} / F_T \\ \tau_I &= \tau_I^{ZN} \times F_T \end{aligned} \tag{15.13}$$

by adjusting F_T on line. Note that as F_T is increased, K_c decreases while τ_I increases by the same proportion (detuning). The tuning factor, F_T, can be adjusted to meet the performance requirements for each individual application. Therefore, on-line tuning has been reduced to a one-dimensional search for the proper level of controller aggressiveness for a PI controller. If the controller is too aggressive, F_T is increased. If the controller is too sluggish, decrease F_T.

Note that the procedure based on ATV identification with on-line tuning is applicable for tuning PI controllers. It should be pointed out that, for certain cases, after this procedure has been applied, it will be evident that the proper balance between proportional and integral action has not been used, e.g., if offset elimination is slow. In these cases, adjustments in the relative amount of proportional or integral action may be required. For example, if the TL settings were used and not enough integral action resulted, the 0.45 factor in the TL settings for integral action (i.e., P_u/0.45) could be increased to speed up offset elimination. Figures 15.35 and 15.36 can be helpful in determining if insufficient proportional or integral action is being used.

As an example of an ATV test, consider its application to a dynamic simulator of a C_3 (propylene/propane) splitter. Figure 15.48 shows an ATV test and an open-loop test on the same time scale for the bottom product composition control loop. Note that the four cycles of the ATV test required 6 to 8 hr, while the open-loop test required in excess of 60 hr. The ATV results were used with TL settings, and the results for three different tuning factors are shown in Figure 15.49.

Summarizing, identifying the ultimate gain and ultimate period of a slow-response loop using the ATV method is relatively fast, providing a "snapshot" of the process without unduly upsetting the system. In addition, the on-line tuning procedure provides a systematic method of selecting the proper degree of controller aggressiveness. Therefore, the ATV test with on-line tuning represents

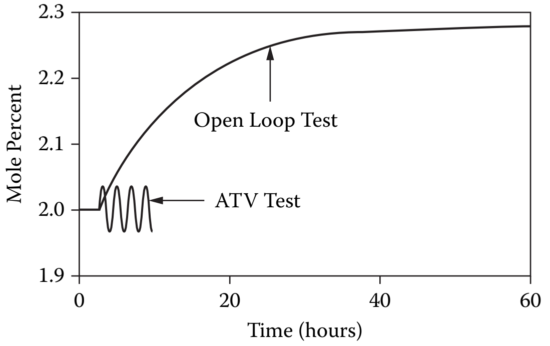

FIGURE 15.48 Comparison of an ATV and an open-loop test.

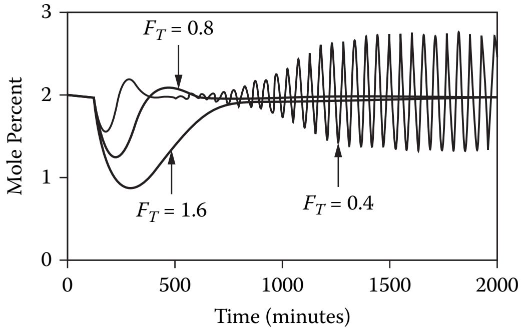

FIGURE 15.49 Effect of F_T on dynamic response.

an industrially relevant means of attaining high-quality controller tuning for loops with large response times.

15.4.10 PID Tuning

PID tuning of slow-response processes is less systematic than tuning PI controllers, since the on-line tuning procedure [Equation (4.2)] is not generally effective for PID controllers. That is, applying a tuning factor, F_T, to the derivative time and tuning a PID controller by adjusting only F_T does not, in general, lead to a well-tuned PID controller. The recommended procedure for tuning PID controllers is as follows:

1. Tune a PI controller using ATV identification with on-line tuning. Make sure that the proper balance between proportional and integral action is used. It may be necessary to reduce τ_I to produce symmetric oscillations about the new setpoint.
2. Add derivative action and tune τ_D for minimum response time. Initially set τ_D equal to $P_u/8$, where P_u comes from the ATV test.
3. Increase K_c and τ_D by the same factor until the desired dynamic response is obtained.
4. Check the response to ensure that the proper level of integral action is being used.

15.4.11 Level Controller Tuning

If a level control process is fast responding, then field tuning is effective. If the level control process is relatively slow responding, it can be helpful to use the following approach to select the initial settings for the level controller. Marlin[5] developed closed-form solutions for the dynamic behavior

of PI and P-only controls of level in a constant cross-section tank. He used these expressions to derive analytical expressions for the tuning parameters that result in a critically damped response for the closed-loop level control process:

$$K_c = \frac{-F'_{MAX}}{L'_{\max}} \Bigg\} \textit{P-only control} \tag{15.14}$$

$$\left.\begin{aligned} K_c &= \frac{-0.736\, F'_{MAX}}{L'_{\max}} \\ \tau_I &= \frac{4 A_c \rho}{-K_c} \end{aligned}\right\} \textit{PI control} \tag{15.15}$$

where A_c is the cross-sectional area of the tank, ρ is the density of the liquid, F'_{MAX} is the maximum expected step change in the feed rate to the tank, and L'_{MAX} is the desired level change that F'_{MAX} should cause under feedback conditions.

These tuning relations can be used for both tight level control and loose level control, depending on the selection of L'_{MAX}. If L'_{MAX} were selected to correspond to about a 2% level change, it would represent tight level control, and K_c would have a correspondingly high value. On the other hand, if L'_{MAX} were selected to correspond to a 40% level change, it would represent quite loose level control, and K_c would be correspondingly lower.

This analysis is based on an idealized model of the level of a tank and does not consider sensor or actuator dynamics and does not consider that horizontal tanks do not have a constant cross section. For these reasons, it is recommended that Equations (15.14) and (15.15) be used as initial estimates of the tuning parameters and that an on-line tuning factor, F_T, be used to tune for the desired level control performance:

$$K'_c = K_c / F_T$$

$$\tau'_I = \tau_I \times F_T$$

Example 15.2 Calculation of Initial Tuning Parameters for a Level Controller

Problem statement. Consider level control in a horizontal cylinder tank that is 6 ft in diameter and 20 ft long. Normally, the feed rate to the tank is 10,000 lb/hr of a dilute aqueous solution. Feed rate step changes are normally within the range of ±10% of the normal feed rate. The setpoint for the level is usually set at 20%. The pressure taps for the level indicator are located at the top and bottom of the tank. Determine the tuning parameters for a PI controller that will keep the level within ±5% of setpoint based on Equation (15.15) for ±10% feed rate changes.

Solution. By geometric analysis, the width of the liquid level in the tank at 20% full is 4.8 ft; therefore, the cross-sectional area is 96 ft^2. Using the density of pure water,

$$F'_{MAX} = (0.1)(10{,}000\,\text{lbs/h})\left(\frac{\text{h}}{60\,\text{min}}\right) = 16.67\,\text{lbs/min}$$

$$K_c = \frac{-0.736(1000\,\text{lbs/h})}{5\%} = -147.4\,\frac{\text{lbs/h}}{\%}$$

$$\tau_I = \frac{(4)(96\,ft^2)(62.4\,lbs/ft^3)(6\,ft/100\%)}{147.4\,\frac{lbs/h}{\%}} = 585\ \text{min}$$

15.5 ADVANCED PID CONTROL

15.5.1 Introduction

The performance of PID controllers suffers from several limitations: disturbances, analyzer deadtime, process nonlinearity, constraints, windup, abrupt startup of a loop, and flow control over a wide operating range. This section addresses approaches that have been developed to improve the performance of PID controllers with respect to this set of control problems.

15.5.2 Cascade Control

Cascade control significantly reduces the effect of certain types of disturbances by applying two control loops in tandem, i.e., the output of one controller is the setpoint for the other controller. The secondary or slave controller receives its setpoint from the primary or master controller and operates on a much faster cycle time than the primary. As a result, the secondary controller can eliminate certain disturbances before they are able to affect the primary control loop.

Figure 15.50a shows a schematic of a steam-heated heat exchanger without cascade control. Assume that the steam pressure increases and results in an increase in the temperature of the process stream leaving the heat exchanger. As the outlet temperature begins to rise, the PID controller on the temperature of the outlet stream begins to take corrective action by reducing the stem position of the valve on the steam line. By the time the PID controller starts to take corrective action, an excessive amount of heat has already been transferred from the steam to the process fluid in the heat exchanger.

Figure 15.50b shows the steam heated-heat exchanger with a cascade control configuration. The pressure control loop is the secondary or slave loop. The temperature control loop is the primary or master loop. Hence, the output of the temperature controller for the cascade control case is the setpoint for the pressure controller, while the output from the temperature controller for the case without cascade control goes directly to the control valve on the steam line. For the cascade control case, when the steam supply pressure increases, the pressure of steam inside the heat exchanger increases, but the pressure controller reacts quickly by closing the valve until the desired pressure of steam in the heat exchanger is reinstated. As a result, the steam pressure disturbance is almost completely absorbed by the slave loop before it can affect the master loop. In addition, the pressure control loop overcomes the detrimental effects of valve deadband by using high-frequency feedback action. Since the pressure control loop (slave loop) is much faster responding than the temperature control loop (master loop), the pressure control loop quickly compensates for specific disturbances that affect the steam pressure before they affect the temperature loop.

Figure 15.51 is a multiple-cascade configuration designed to maintain the impurity level in the bottoms product of a distillation column at its setpoint. The innermost control loop is a flow control loop on the steam to the reboiler. Cascade controllers that use flow controllers as the slave loop are the most common form of cascade control in the CPI. The flow controller provides fast response to steam pressure changes in spite of valve deadband. The setpoint for the flow control loop is set by the tray temperature controller. Tray temperature strongly correlates with product composition for a large class of industrial columns, which is an example of inferential control, as discussed in Section 15.5.5. The advantage of controlling tray temperatures on distillation columns comes from the fact that composition changes are measured much faster using tray temperatures than using online analyzers. Moreover, for fast-acting columns (i.e., when the reflux ratio is relatively low),

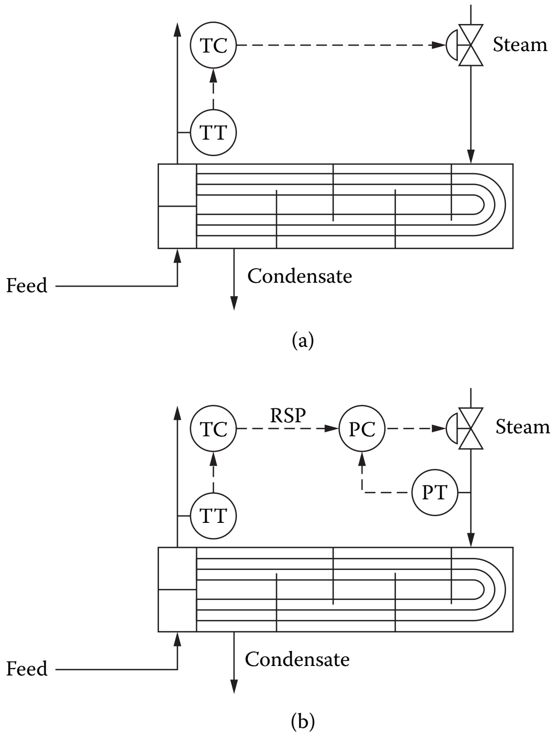

FIGURE 15.50 Schematic of a steam-heated heat exchanger with a temperature controller for controlling the temperature of the exiting process fluid. (a) Without cascade and (b) with cascade control.

feedback control using the GC can result in poor control performance, because the resulting deadtime to time constant ratio of the process is too large. For these cases, tray temperature control loops have a much smaller deadtime to time constant ratio because of the fast response of temperature sensors. Therefore, tray temperature control loops exhibit better control performance with shorter closed-loop response times than control directly off the GC. As the feed composition changes, the proper tray temperature setpoint changes. Therefore, adjustments to the setpoint for the tray temperature controllers are made by the composition control loop, which is the overall master loop for this cascade arrangement. This multiple-cascade arrangement works effectively, because the flow control loop is much faster than the temperature control loop, which is much faster than the composition control loop.

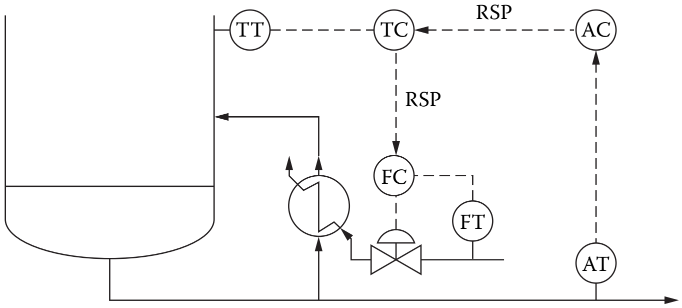

FIGURE 15.51 Schematic of a multiple-cascade configuration applied for bottoms composition control of a distillation column.

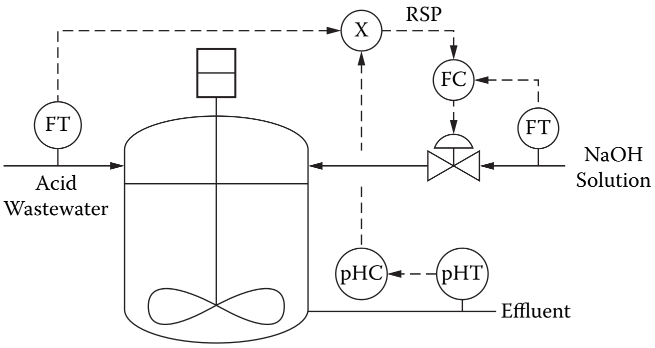

FIGURE 15.52 Schematic of ratio control applied for pH control of an acid wastewater neutralization process.

15.5.3 Ratio Control

Many processes scale directly with the feed rate to the process, e.g., distillation columns and wastewater neutralization. For distillation columns, all the liquid and vapor flow rates within the column are directly proportional to the column feed rate if the product purities are maintained and the tray efficiency is constant. For wastewater neutralization, the amount of reagent necessary to maintain a neutral pH for the effluent varies directly with the flow rate of the wastewater feed, as long as the titration curve of the wastewater remains constant. When the manipulated variable of a process is, in general, directly proportional to the feed rate, ratio control can significantly reduce the effect of feed rate disturbances on the process.

Figure 15.52 shows the application of ratio control to the effluent pH for a wastewater neutralization process applied in a mixing tank. This controller can effectively handle wastewater feed flow rate changes when the chemical makeup of the wastewater remains relatively constant. Small changes in the chemical makeup of the wastewater can usually be handled by the feedback controller, which adjusts the reagent-to-wastewater ratio to maintain the specified effluent pH.

A schematic of the stripping section of a distillation column with a ratio controller for the bottom products composition is shown in Figure 15.53. This application is similar to ratio control except that dynamic compensation is added to the measured column feed rate. If the steam flow to the reboiler were increased immediately for an increase in column feed rate, the corrective action would initially be an overcorrection. This results because, when a feed rate change occurs, it takes some time for the bottom product composition to respond. The purpose of the dynamic compensation (DC) element is to allow for the correct timing for the compensation for feed rate changes.

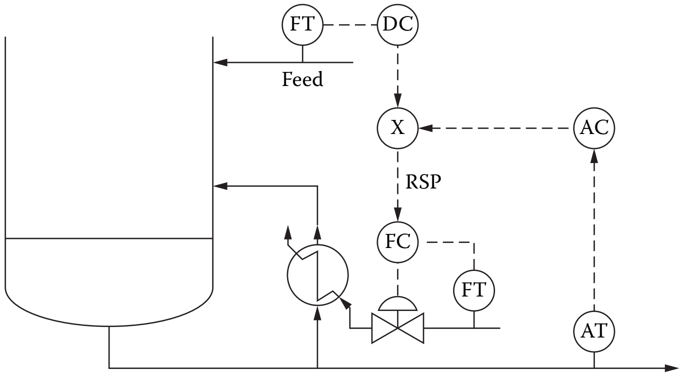

FIGURE 15.53 Schematic of ratio control for feed rate changes applied to the stripping section of a distillation column.

The dynamic element for this case can be simply a lag element, e.g., a digital filter described by Equation (15.10). The wastewater neutralization case (Figure 15.52) does not require dynamic compensation, since the process pH responses to feed rate changes and NaOH flow rate changes have similar dynamic behavior.

15.5.4 Feedforward Control

Feedforward control can be applied to process control loops that are significantly affected by disturbances that are measurable (or estimated) on-line. A feedback controller reacts to deviations from setpoint caused by the disturbance until the process is returned to setpoint. As pointed out in Section 15.3.3, since the proportional and derivative terms are zero during steady-state operation at the setpoint, the integral term in the PID controller is responsible for long-term compensation for disturbances. A feedforward controller anticipates the effects of a measured change in a disturbance (i.e., a load change) and takes corrective action before the disturbance affects the process. In effect, the feedforward controller applies corrective manipulated variable changes corresponding to the integral action that a feedback controller would generate; therefore, when a feedback controller and feedforward controller are used together, the feedback controller has much less "work" to do to compensate for a measured disturbance.

Example 15.3 Feedforward Example

Figure 15.54a shows a feedback controller applied for the level control of a boiler drum. The feedback controller compares the measured value of the level with the setpoint for the level and adjusts the flow rate of the feedwater to the drum. Therefore, when changes in the demand for steam occur, changes in the drum level result. If large swings in steam demand occur, a large gain is required for the feedback controller to maintain the level near its setpoint. But for large controller gains, the process is more susceptible to oscillatory behavior in the level and feedwater flow rate to the drum. Also, high-gain controllers are sensitive to noisy measurements of the controlled variable, and, in this case, level indicators can have significant noise levels.

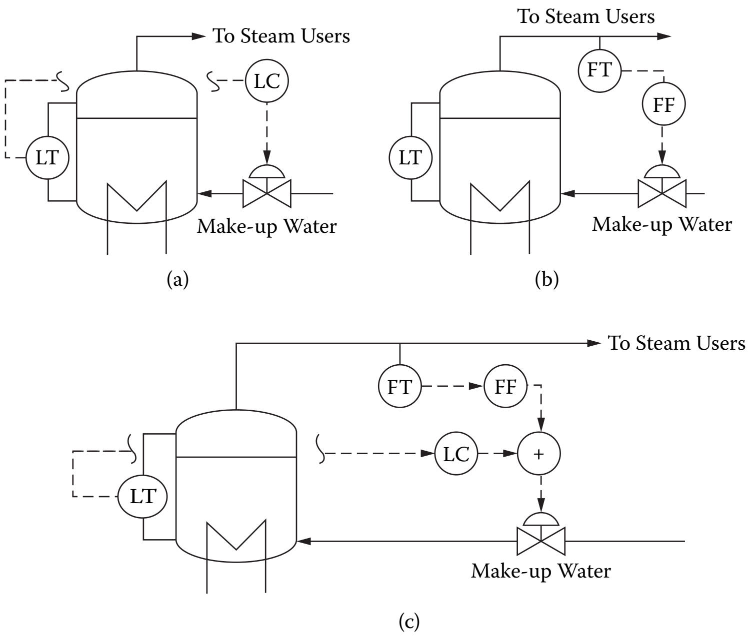

FIGURE 15.54 Boiler drum level control. (a) Feedback, (b) feedforward, and (c) feedback and feedforward combined.

Figure 15.54b is a schematic of a feedforward controller applied for steam drum level control. If the flow rate of the makeup feedwater is equal to the steam usage, the drum level remains constant. One is tempted to conclude that the feedforward controller is all that is needed for this application. Unfortunately, the measurements of the steam usage and the feedwater flow rate are not perfectly accurate. Even small errors in measured flow rates add up over time, leading to one of two undesirable extremes. The drum can fill with water and put water into the steam system, or the liquid level can drop, exposing the boiler tubes, which can damage them. As a result, neither feedback nor feedforward are effective by themselves for this case. In general, feedforward-only controllers are susceptible to measurement errors and unmeasured disturbances, and, as a result, some type of feedback correction is typically required.

Figure 15.54c shows a combined feedforward and feedback controller for the control of the level in the steam drum. Note that the feedforward controller provides most of the required control action by responding to the measured steam usage. The feedback controller can be a relatively low-gain controller, since it needs to compensate only for measurement errors and unmeasured disturbances.

A lead-lag element is usually used to implement feedforward control. A lead-lag element has four tuning parameters: the gain (K_{ff}), the lead (τ_{ld}), the lag (τ_{lg}), and the deadtime (θ_{ff}). The gain indicates the change in feedforward control action for a change in the measured disturbance. The lag indicates how quickly the feedforward control action should approach its steady-state level. Whether the lead is greater or less than the lag determines the general shape of the feedforward action. The deadtime indicates how long it takes to make a correction after a measured change in the disturbance.

15.5.4.1 Tuning

Tuning a feedforward controller involves selecting the values of K_{ff}, τ_{ld}, τ_{lg}, and θ_{ff}. The following field tuning procedure is recommended:

1. Make initial estimates of K_{ff}, τ_{ld}, τ_{lg}, and θ_{ff} based on process knowledge.
2. Under open-loop conditions, adjust K_{ff} to minimize deviation from setpoint after a disturbance has had its steady-state effect on the process. Figure 15.55a shows the dynamic response of a feedforward controller for a step change in the disturbance based on initial feedforward controller settings and after K_{ff} has been adjusted to eliminate offset.
3. By analyzing the dynamic mismatch, adjust θ_{ff}. The direction of the deviation should indicate whether the feedforward correction is applied too soon or too late, causing dynamic mismatch. Figure 15.55b shows the feedforward control performance after θ_{ff} is tuned.
4. Finally, adjust ($\tau_{ld} - \tau_{lg}$) until approximately equal areas above and below the setpoint result. Figure 15.55c shows the results after ($\tau_{ld} - \tau_{lg}$) is adjusted. It is recommended to adjust the difference between τ_{ld} and τ_{lg}, since this difference (the relative dynamics of

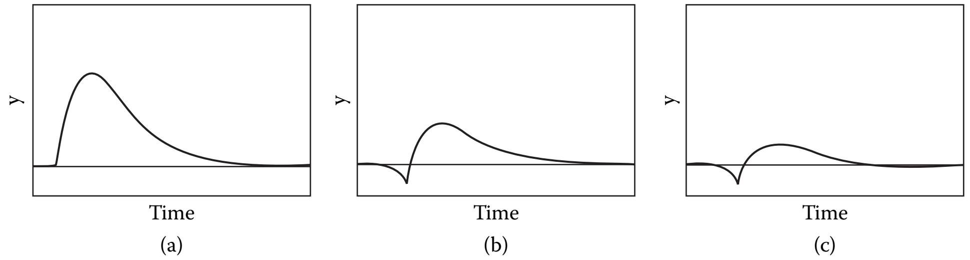

FIGURE 15.55 Tuning results for a feedforward controller for a step change in the disturbance. (a) Results for initial settings with correct feedforward gain, (b) results after deadtime tuned, and (c) final tuning results.

the process to manipulated variable and disturbance changes) has a profound effect on the shape of the response.

15.5.4.2 Overview

Table 15.8 summarizes the advantages and disadvantages of feedforward and feedback control. Note that feedforward and feedback control are complementary, i.e., each can overcome the disadvantages of the other so that together they are superior to either method alone. Feedforward control does not offer a significant advantage for fast-responding processes, because a feedback-only controller can usually absorb disturbances efficiently for these cases. But for slow-responding processes or processes with significant deadtime, by the time a feedback-only controller starts to respond to the effects of a disturbance, the process can already be severely upset. For these cases, the disturbance can cause the controlled variable to change significantly from its setpoint, resulting in relatively large process parameter changes (K_p, τ_p, and θ_p). In some cases, this can lead to closed-loop instability. When feedforward is added to a slow process or a process with significant deadtime, the deviation of the controlled variable from setpoint can be significantly reduced, resulting in smaller process parameter changes. Therefore, feedforward can provide significantly more reliable feedback control performance when the feedforward control compensates for a major disturbance to the process. In general, feedforward is useful when (1) feedback control by itself is not satisfactory, i.e., for slow-responding processes or processes with significant deadtime, and (2) the major disturbance to a process is measured on-line.

Feedforward control provides a linear correction and therefore can provide only partial compensation to a nonlinear process. Nevertheless, feedforward control can be effective when properly implemented, since it can reduce the amount of feedback correction required. When tuning a feedforward controller for a nonlinear process, care should be taken to ensure that the feedforward controller is tuned with consideration to both increases and decreases in the disturbance level.

Figure 15.56 shows the effect of the ratio of τ_{ld}/τ_{lg} on the dynamic response of a lead/lag element. When τ_{ld}/τ_{lg} is greater than 1, overcompensation is used. That is, when the process responds faster to the disturbance than to the controller output, larger than steady-state changes in the controller output are required to compensate for dynamic mismatch. On the other hand, when τ_{ld}/τ_{lg}

TABLE 15.8
Comparison of Feedback and Feedforward Control

Advantages	Disadvantages
Feedback	
1. Does not require a measurement of the disturbance.	1. Waits until the disturbance has affected the process before taking action.
2. Can effectively reject disturbances for responding process.	2. Susceptible to disturbances when the process is slow or when significant deadtime is present.
3. Simple to implement.	3. Can lead to instability of the closed-loop system due to nonlinearity.
Feedforward	
1. Compensates for disturbances before they affect the process.	1. Requires the measurement of the disturbance.
2. Can improve the reliability of the feedback controller by reducing the deviation from setpoint.	2. Does not compensate for unmeasured disturbances.
3. Offers noticeable advantages for slow processes or processes with significant deadtime.	3. Since it is a linear-based correction, its performance deteriorates with nonlinearity.

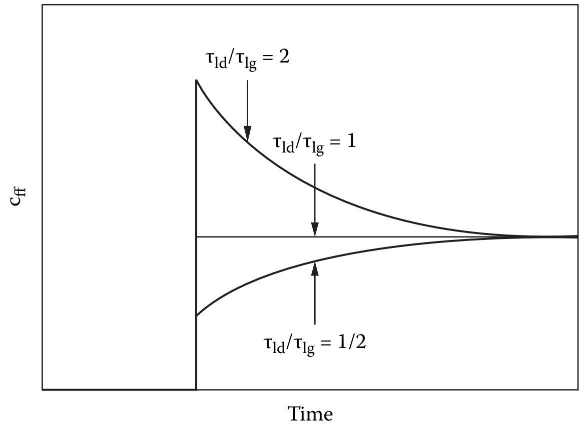

FIGURE 15.56 The effect of the ratio of τ_{ld} to τ_{lg} on the dynamic response of a lead/lag element; c_{ff} is the output from the feedforward controller.

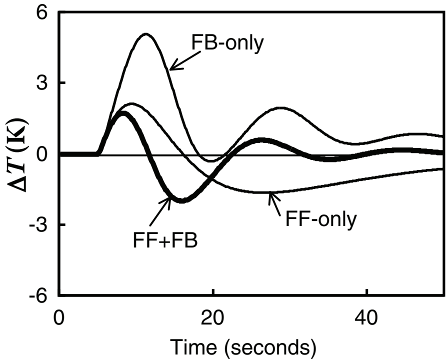

FIGURE 15.57 Comparison among feedforward (FF-only), feedback (FB-only), and combined feedforward and feedback (FF + FB) for a disturbance upset.

is less than 1, the application of the controller output is more gradual, eventually approaching its steady-state level.

Figure 15.57 shows a comparison between a feedback-only controller, a feedforward-only controller, and a combined feedforward and feedback controller. The feedforward-only controller significantly reduces the initial deviation from setpoint compared to the feedback-only controller but is sluggish in returning to the setpoint. The combined feedforward and feedback controller uses the feedforward action to reduce the initial deviation from setpoint and the feedback action to quickly settle at the setpoint.

15.5.5 Inferential Control

Up to this point, it has been assumed that the sensor in a control loop provides a direct measurement of the controlled variable. In fact, the output of the sensor only correlates with the value of the measured variable. A thermocouple exposed to a process stream at a specific temperature generates a millivolt signal that correlates strongly with the temperature of the process stream. In this section, it is shown that easily measured quantities, such as pressures, temperatures, and flow rates, can be effectively used to infer quantities that are more difficult to measure, such as compositions, molecular weight, and extent of reaction. Then, the inferred value of the controlled variable can

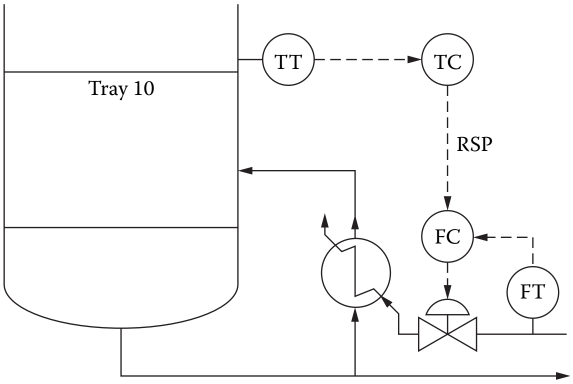

FIGURE 15.58 Schematic for inferential control of the bottoms product composition of a distillation column.

be used as the value of the controlled variable in a feedback control loop, greatly reducing the associated measurement delay.

There are three main reasons for using inferential measurement of a controlled variable: (1) Excessive analyzer deadtime undermines the performance of the feedback loop. (2) The total cost (i.e., the purchase price and maintenance cost) of an on-line analyzer can be excessive. Since inferential measurements are typically based on temperature, pressure, and flow measurements, they are much less expensive to install and maintain. (3) An on-line analyzer may not be available. In that case, an inferential measurement may be the only option for feedback control.

For an inferential control to be effective, the inferential measurement must correlate strongly with the controlled variable value, and this correlation should be relatively insensitive to unmeasured disturbances. The following are several examples that illustrate how inferential measurements can be effectively applied in the CPI.

15.5.5.1 Inferential Temperature Control for Distillation

Tray temperatures correlate very well with product compositions for many distillation columns; therefore, inferential control of distillation product composition is a widely used form of inferential control. Figure 15.58 shows the arrangement for inferential temperature control of the bottoms product composition for this column. Note that the tray temperature controller is cascaded to a flow controller.

15.5.5.2 Inferential Reaction Conversion Control

Consider an adiabatic fixed-bed reactor. For a single irreversible reaction, $A \rightarrow B$, the macroscopic energy balance assuming no phase change is given by

$$X_A C_{A_{in}} \left(-\Delta \mathrm{H}_{rxn}\right) = \rho C_P \left(T_{out} - T_{in}\right)$$

where X_A is the fractional conversion of reactant A, $C_{A_{in}}$ is the inlet concentration of A to the reactor, ΔH_{rxn} is the heat of reaction, ρ is the average density of the process stream, C_P is the average heat capacity of the process stream, T_{out} is the temperature of the outlet stream from the reactor, and T_{in} is the temperature of the inlet stream to the reactor. Rearranging the previous equation,

$$X_A = \frac{\rho C_P}{C_{A_{in}} \left(-\Delta H_{rxn}\right)} \left(T_{out} - T_{in}\right)$$

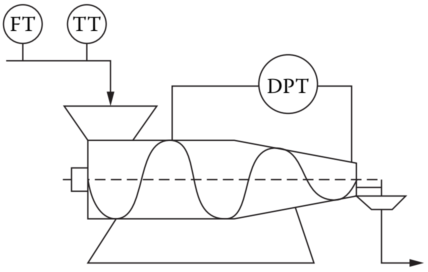

FIGURE 15.59 Schematic of a polymer extruder.

Note that this relationship is not affected by changes in the feed rate, although feed rate affects T_{out} and thus X_A. In an industrial reactor, there are heat losses, side reactions, and variations in the physical parameters; therefore, the assumed inferential relationship is

$$X_A = a\left(T_{out} - T_{in}\right) + b$$

A plot of the experimental data for a reactor (X_A, T_{out}, and T_{in}) can be used to determine *a* and *b* as well as check the validity of this functional form. For this approach to be effective, the temperature difference across the reactor needs to be large enough that temperature measurement noise does not significantly affect the results of the measured temperature. Once *a* and *b* are identified, the inlet temperature, T_{in}, can be adjusted to maintain a fixed reaction conversion, X_A. Periodically, composition measurements for the product leaving the reactor can be made and the results used to update the value of *b* in the previous equation, since *a* is less likely to change significantly compared with *b*.

15.5.5.3 Inferential Measurement of the Molecular Weight of a Polymer

Figure 15.59 shows a schematic for a polymer extruder. The procedure for estimating the molecular weight of a polymer is as follows. First, the flow rate, *F*, temperature, and pressure drop across the extruder, ΔP, are measured. Next, a fluid dynamic relationship is used to calculate the corresponding viscosity of the polymer melt at the prevailing temperature, $\mu(T)$. Then, the viscosity is corrected for temperature so that the viscosity of the melt is calculated at a standard temperature, T_o. Finally, a correlation between $\mu(T_o)$ and the molecular weight of the polymer melt is developed using laboratory measurements of the molecular weight (M_{wt}) for a range of $\mu(T_o)$ values. Therefore, from measurements of the flow rate of the polymer melt, the pressure drop, and the temperature, the molecular weight of the polymer can be estimated online. This value can be used by a feedback controller to make adjustments to the polymer reactor to control the molecular weight of the polymer product. Without this inferential estimator, samples of the extruded polymer have to be tested in the laboratory requiring in the range of 10 hr to perform each test. Since the residence time of the reactor/extruder process can be less than 1 hr, a 10-hr analysis deadtime makes feedback molecular weight control extremely difficult, if not impossible. The samples, which are taken one to three times per day, are used to make corrections to the correlation functions used to infer molecular weight.

15.5.5.4 Soft Sensors Based on Neural Networks

In electric power generating stations, restricting the NO_x (nitrogen oxide compounds) emissions from the flue gas to acceptable levels is important, because NO_x compounds contribute to air pollution. Typically, on-line analyzers are used to measure the NO_x in the flue gas from the boilers.

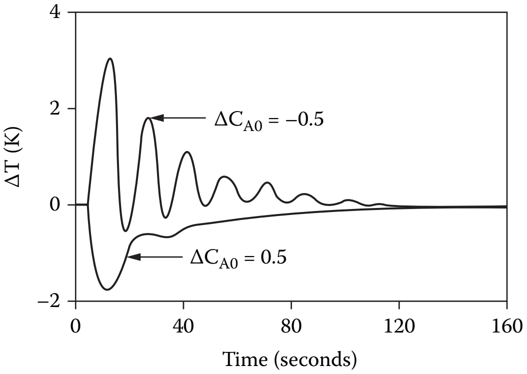

FIGURE 15.60 The effect of feed composition upsets on the PI feedback behavior for an endothermic CSTR.

Occasionally, the NO_x analyzers on a boiler fail. If the NO_x level is not measured, the power companies must pay a fine for emissions. Instead of installing additional on-line NO_x analyzers, which are quite expensive, some power companies have applied a type of inferential estimator to predict the NO_x level in their flue gas.

Instead of using one or two process measurements, all the measured process conditions (e.g., fuel feed rate, oxygen in the flue gas, heating value of the fuel, ambient air temperature, and so on) have been empirically correlated to predict the NO_x concentration in the flue gas. The empirical correlation is based on training an artificial neural network to predict the flue gas NO_x concentration from all the available data.

15.5.6 Scheduling Controller Tuning

In Section 15.4.5, it was demonstrated that nonlinear process behavior can result in a controller becoming unstable in certain situations; in others, it can become extremely sluggish (see Figure 15.60). Tuning PID controllers for the case with the largest process gain can eliminate unstable operation, but at the expense of largely sluggish performance. For some processes, certain measurements directly indicate whether the process parameters have increased or decreased and by how much; therefore, scheduling of the controller tuning based on process measurements can often compensate for process nonlinearity. The controlled variable and the feed rate are examples of such key process measurements that typically can be used to schedule the controller tuning.

Consider a heat exchanger used to heat a process stream with steam as the heating medium. As the feed to the heat exchanger flows through the tube bundle, it is heated by steam condensing on the shell side. As the feed rate changes, the residence time of the feed in the tubes exposed to the steam changes. Figure 15.61 shows the open-loop responses for three different feed rates for a step change in the setpoint of the steam pressure controller. The feed rate is represented by the average fluid velocity (v) in the tubes. Both the gain and the dynamic response change as the feed rate is changed. Table 15.9 lists the FOPDT parameters for each flow rate. Note that the gain and the deadtime each change by a factor of about 2.5. Using these FOPDT parameters, the controller settings for each flow rate are also listed in Table 15.9. Note that the controller gain changes by a factor of 5, but the reset time changes are more gradual. It is clear from these results that it is not reasonable to expect one set of PI controller settings to work effectively for significant changes in the feed rate to this heat exchanger. For example, if the temperature controller for the outlet of the heat exchanger were tuned for v = 7 ft/s, when the feed rate is reduced to v = 4 ft/s, the controller becomes unstable. Conversely, if the controller were tuned for the low flow rate condition, it would perform sluggishly for the high flow rate conditions. Figure 15.62 shows results with and without scheduling of the controller tuning based on feed rate for a step decrease in the feed rate corre-

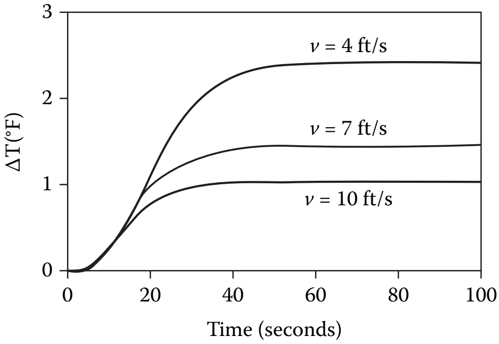

FIGURE 15.61 Open-loop response for a heat exchanger for different feed rates.

TABLE 15.9
FOPDT and PI Tuning Parameters for Heat Exchanger Case as a Function of Feed Rate

	v = 4 ft/s	v = 7 ft/s	v = 10 ft/s
K_p	0.25	0.15	0.11
τ_p	10.7	9.9	10.0
θ_p	10.2	5.8	4.0
K_c	4.2	10.8	21.3
τ_I	12.0	8.8	7.3

sponding to a change in the velocity through the tubes from 7 to 4 ft/s. Note that the controller without scheduling was tuned for a feed rate corresponding to v = 7 ft/s.

15.5.6.1 Nonstationary Behavior

Consider a wastewater neutralization process. If the titration curve of the wastewater and the other process parameters remain fixed, the process is referred to as *stationary*. On the other hand, if the titration curve changes, the process is *nonstationary*. In the case of this pH control example, changes in the titration curve can have an overwhelming effect on the process gains. There are many more

examples of nonstationary behavior that results in much more gradual process gain changes. The following are several examples of such behavior in the CPI: (l) catalyst deactivation, (2) heat exchanger fouling, (3) fouling of trays in a distillation column, and (4) feed composition changes that affect the process parameters (K_p, τ_p, and θ_p).

These effects can be large enough that controller retiming is required. If an overall tuning factor, F_T, has been used, one can adjust F_T in a straightforward manner to compensate for the nonstationary behavior. Control methods that adjust controller tuning to adapt to nonstationary behavior are referred to as *adaptive control techniques*. Adaptive control techniques can be effectively applied for processes that vary slowly. A number of commercially available adaptive controllers are referred to as *self-tuning controllers* and can usually be installed on a DCS. While a range of approaches are used for self-tuning controllers, they are generally limited to processes that vary in a gradual, consistent manner.

15.5.7 Override/Select Control

Constraints are a natural part of industrial process control. As processes are pushed to produce as much product as possible, process limits are inevitably encountered. When an upper or lower limit on a manipulated variable is encountered, or when an upper or lower value of a controlled or output variable from the process is reached, it can become necessary to apply different control loops from those previously used. That is, effective industrial controller implementation requires that safeguards be installed to prevent the process from violating safety, environmental, or economic constraints. These constraints can be met using override/select controls.

Consider the furnace-fired heater shown in Figure 15.63. Under normal operating conditions, the fuel flow rate is adjusted to control the exit temperature of the process fluid. As the feed rate of the process fluid is increased, the furnace tube temperature increases. At some point, the upper limit on furnace tube temperature (an operational constraint) is encountered. The fuel flow rate to the furnace must be adjusted to keep the furnace tube temperature from exceeding its upper limit, at which point damage to the furnace tubes results. Figure 15.63 shows that the output of both control loops (the temperature controller on the process fluid and the temperature controller on the furnace tube temperature) are combined, and the lower fuel feed rate is actually applied. The "LS" symbol in Figure 15.63 is called a *low select* and indicates that the lower fuel feed rate is chosen. When the feed rate is sufficiently low that the temperature of the process fluid can be controlled

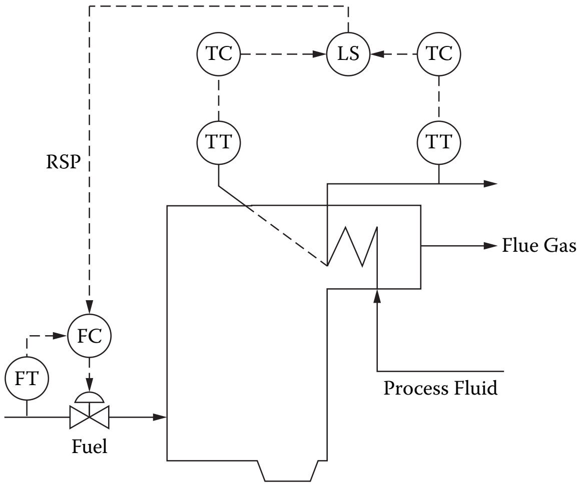

FIGURE 15.63 A schematic of a furnace-fired heater with low select firing controls.

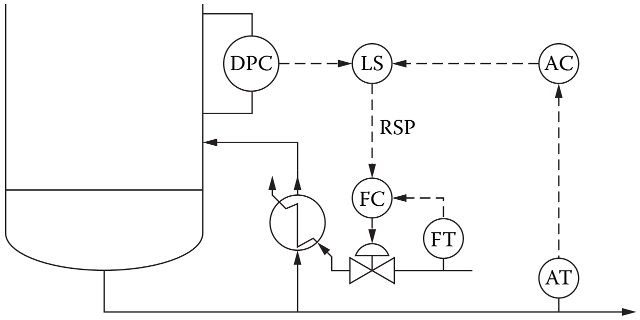

FIGURE 15.64 Schematic of the stripping section of a distillation column with override/select control to maintain bottom product purity when a maximum reboiler constraint is encountered.

to setpoint, the output of the process fluid temperature controller is selected, since it is lower than the output of the tube temperature controller. Likewise, when the tube temperature approaches its upper limit, the output of the tube temperature controller is selected.

Figure 15.64 shows a distillation column that reaches an upper limit on the reboiler duty. When the remote setpoint for the steam flow rate to the reboiler is consistently greater than the measured steam flow, an override controller switches to using the column feed rate as a manipulated variable to keep the bottom product purity on specification. When the column feed rate is adjusted back to its normal level and the control valve on the steam to the reboiler is no longer saturated (i.e., fully open), the control configuration is changed so that the reboiler duty is manipulated to control the bottom product purity.

15.5.8 Computed Manipulated Variable Control

In certain cases, the desired manipulated variable for a particular process cannot be directly adjusted. Distillation columns can be particularly sensitive to sharp changes in ambient conditions due to weather fronts or thundershowers, since both of these cases can cause significant increases in the reflux subcooling. Equating the heat lost by the condensing vapor to the heat required by the subcooled reflux results in the following equation:

$$C_p F_{ex}\left(T_{oh} - T_r\right) = \Delta F_{int}\,\Delta H_{vap}$$

where C_p is the heat capacity of the reflux, T_{oh} is the overhead temperature, T_r is the subcooled reflux temperature, F_{ex} is the external reflux flow (the setpoint for the flow controller on the reflux), ΔF_{int} is the change in the reflux caused by the condensing vapor, and ΔH_{vap} is the heat of vaporization of the vapor. ΔF_{int} combines with the external reflux to form the internal reflux. Then, the equation for the internal reflux flow rate (F_{int}) is given by

$$F_{int} = F_{ex}\left(1 + C_p\left[T_{oh} - T_r\right] / \Delta H_{vap}\right)$$

This equation can be rearranged to calculate the external reflux that maintains a specified internal reflux control (F_{int}^{spec}), i.e.,

$$F_{ex} = \frac{F_{int}^{spec}}{1 + C_p\left(T_{oh} - T_r\right) / \Delta H_{vap}}$$

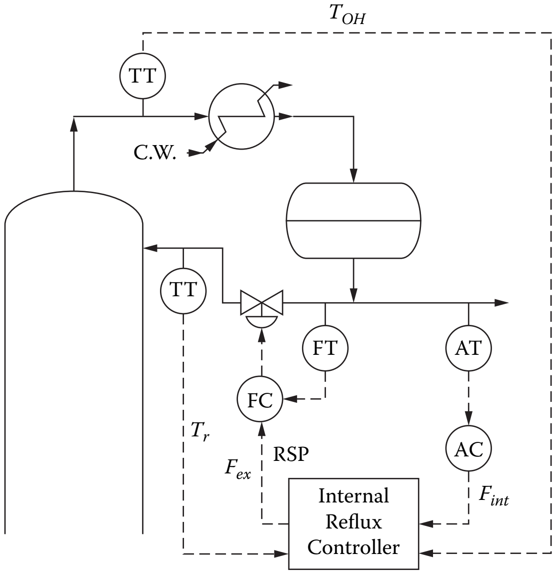

FIGURE 15.65 Schematic of an internal reflux controller applied for composition control of the overhead of a column.

This approach, called *internal reflux control,* is shown schematically in Figure 15.65. Note that the composition controller outputs the internal reflux flow rate, and the internal reflux controller calculates the external reflux flow rate, which is used as the setpoint for the flow controller on the reflux.

15.5.9 Antiwindup Strategies

Figure 5.17a shows the manipulated and controlled variables for a standard PI controller for which the manipulated variable reaches its upper limit, i.e., the control valve is fully open or fully closed, which is referred to as a *saturated control valve.* This can occur when a large disturbance enters the process. Since the manipulated variable cannot be increased further, the PI controller is unable to return the controlled variable to its setpoint. As long as there is an error between the controlled variable and its setpoint, the integral term in the PI controller [Equation (15.1)] continues to accumulate, which is referred to as *reset windup* or *integral windup*. After some time, the disturbance level returns to its original value. At this point, integral windup in the PI controller keeps the manipulated variable at its maximum level, even though the value of the controlled variable is now above its setpoint. In effect, before the process can return to steady state, an equal area above the setpoint must be generated to compensate for area "A" shown in Figure 5.66a.

This behavior occurs because the integral is allowed to continue accumulating after control of the process has been lost (i.e., the manipulated variable saturates). Figure 5.66b shows the same case as Figure 5.66a except that, when the manipulated variable saturates, the integral is not allowed to accumulate (windup). Note that when control returns to the process (i.e., when the manipulated variable is no longer saturated), the controlled variable moves directly back to its setpoint and does not exhibit prolonged deviations from setpoint as before. Because the integral action was turned off when the manipulated variable became saturated, the PI controller does not have to generate an area equivalent to area "A" above the setpoint.

Antireset windup can be implemented by simply not allowing the integral to accumulate when the manipulated variable is saturated. The manipulated variable is saturated when the control valve on the line supplying the manipulated variable is either closed or fully open. A saturated control valve can be identified when there is sustained offset between the manipulated variable level

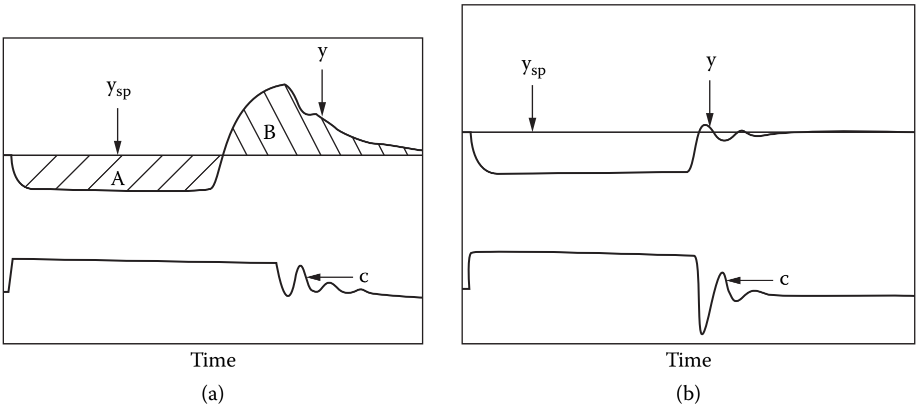

FIGURE 15.66 Response of a feedback system to a saturated manipulated variable. (a) Conventional PI controller and (b) PI controller with antireset windup.

requested by the flow controller and the actual flow rate of the manipulated variable. Modern DCSs have built-in provisions for preventing windup.

15.5.10 Bumpless Transfer

Figure 15.67 shows the process behavior with and without bumpless transfer. Without bumpless transfer, if the controller is turned on when the controlled variable is far removed from setpoint, the controller takes immediate action and drives the process to setpoint in an underdamped fashion. In certain cases, the controlled variable can be far enough away from setpoint, and the process can be sufficiently nonlinear that the control loop becomes unstable. Even if the control loop does not become unstable, the abrupt action of the feedback controller can significantly upset other control loops in the process. As a result, operators find that the behavior of a controller without bumpless transfer is generally unacceptable, particularly for key loops such as composition and temperature control loops.

For bumpless transfer, there are two types of setpoints: the true setpoint, which corresponds to the desired operating point, and the internal setpoint, which is used for bumpless transfer. When a control loop is turned on, the setpoint used by the controller is actually different from the true setpoint when applying bumpless transfer. When the controller is turned on, the internal setpoint

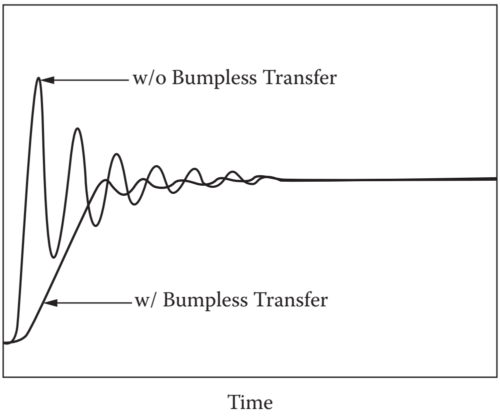

FIGURE 15.67 The startup response of a feedback system without bumpless transfer and with bumpless transfer.

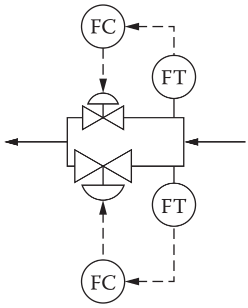

FIGURE 15.68 Schematic of a split-range flow controller.

is set equal to the current controlled variable value; therefore, there is no change in the manipulated variable level. After this, the internal setpoint is ramped toward the true setpoint, and the process gradually begins moving toward the true setpoint. After the internal setpoint reaches the true setpoint value, it remains constant. By selecting a proper setpoint ramping rate, smooth and consistent startups for control loops result.

15.5.11 Split-Range Flow Control

Consider a wastewater neutralization process with a titration curve for the wastewater that exhibits a high gain at neutrality. To control the pH to ±1.0 pH units at a setpoint of pH 7, the base flow rate must be metered accurately to within ±0.5%. A single-flow control loop with a control valve with a positioner can meet this metering precision. But if the total flow rate of base were to range from 0.1 to 10 GPM, one flow control loop could not meter the base flow rate to within ±0.5% at both 0.1 and 10 GPM.

Two flow control loops that work together can meet this requirement, as shown in Figure 15.68. At low flow rates, the large control valve is closed, and the flow control loop with the smaller control valve can accurately meter the low-flow operation. As the total flow increases, the smaller control valve begins to approach saturation. Before this happens, the flow control loop with the larger control valve comes into service. At large flow rates (>1 GPM), the small control valve is completely open, and the flow control loop with the larger valve is accurately metering the base flow rate. This is an example of split-range flow control, which is used when accurate flow control is required over a wider operating range than one control valve can provide.

15.5.12 MIMO Process Control

A multiple-input/multiple-output (MIMO) process has two or more inputs and two or more outputs. A two-input/two-output system is shown schematically in Figure 15.69. Note that both c_1 and c_2 affect both y_1 and y_2. When both inputs affect both outputs, the process is referred to as a *coupled process*. MIMO processes are frequently encountered in the chemical processing industries.

This section considers the application of PID controllers to coupled MIMO processes. A key issue when applying PID controllers to MIMO systems is deciding which manipulated variable should be used to control which controlled variable. This is referred to as choosing the manipulated/controlled variable pairings [(c, y) pairings] or the control configuration. The factors that affect the choice of (c, y) pairings are analyzed here.

15.5.12.1 SISO Controllers and (c, y) Pairings

Figure 15.70 shows two single-loop PID controllers applied to a two-input/two-output process (2 × 2 system). Applying single-loop PID controllers to a MIMO process is called *decentralized*

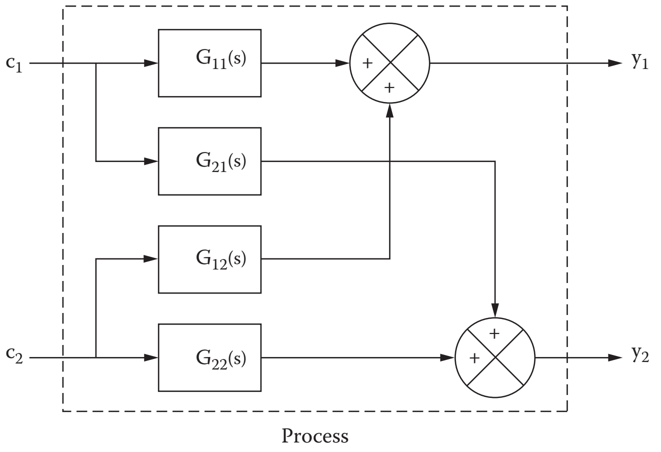

FIGURE 15.69 Block diagram of a two-input/two-output process. Note that G represents an input/output function.

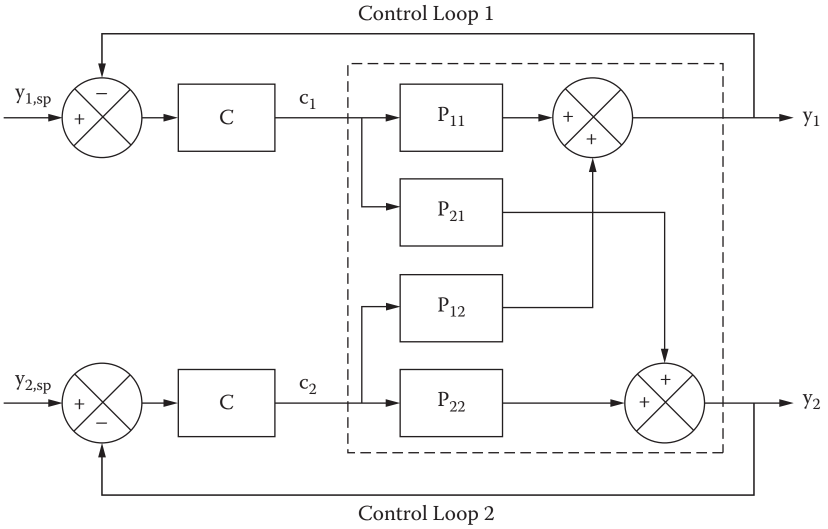

FIGURE 15.70 Block diagram of a 2 × 2 process with single-loop controllers applied (decentralized control). Note that C represents a controller and P represents an input/output function.

control. Note that the coupling in this 2 × 2 system causes the two control loops to interact. That is, while control loop 1 adjusts c_1 to keep y_1 at its setpoint, it upsets control loop 2. Likewise, the operation of control loop 2 can act as an upset for control loop 1. Figure 15.71 shows schematically the coupling effect of control loop 2 (indicted by heavy lines) as an additive disturbance to control loop 1. For this 2 × 2 example, when tuning control loop 1, the effects of control loop 2 must be taken into account, and vice versa. When tuning single-loop PID controllers applied to a MIMO process, one must take into account the effects of coupling.

The selection of pairings for a decentralized controller can have a dramatic effect on the resulting overall control performance. Three factors determine the best pairings for a MIMO process: coupling, dynamic response, and sensitivity to disturbances. Process control engineers typically rely on their understanding of the process and their experience when selecting a control configuration for a MIMO process.

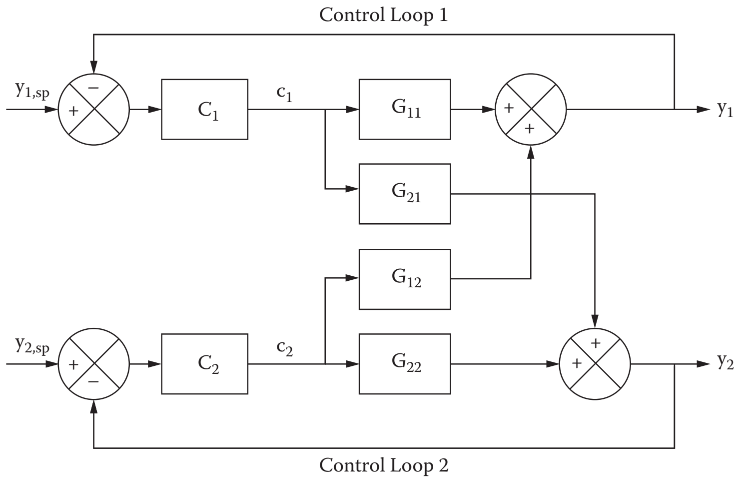

FIGURE 15.71 A block diagram of a 2 × 2 process with single-loop controllers showing the coupling effect of loop 2 on y_1 for changes in c_1. Note that C represents a controller and P represents an input/output function.

Example 15.4 Configuration Selection for a C_3 Splitter

Problem statement. Evaluate the configuration selection problem for a C_3 splitter. A C_3 splitter separates a feed mixture primarily composed of propane and propylene into polymer-grade propylene (<0.5% propane) and a fuel-grade propane (approximately 2% propylene).

Solution. The nomenclature used here refers to a particular configuration as (c_1c_2), where c_1 is assumed to be the controller output that is used to control the overhead composition, and c_2 is the controller output that is used to control the bottoms composition. If we limit ourselves to controlling the overhead composition with *L, D,* or *L/D* (the reflux ratio) and the bottoms composition with *V, B,* or *V/B* (the boilup ratio), there are a total of nine possible configurations. Here we limit the discussion to the following configurations: (*L, B*), (*L, V*), (*L/D, V/B*), and (*D, V*).

The steady-state *RGA*s for each of these configurations are listed below:

Configuration	***RGA*[1] (λ_{11})**
(*L*, *B*)	0.94
(*L*, *V*)	25.3
(*L/D*, *V/B*)	1.70
(*D*, *V*)	0.06

Based on these results, the (*L*, *B*) and (*L/D*, *V/B*) configurations appear to be the most promising.

The dynamics of distillation columns can be understood by recognizing that product composition changes result from changes in the internal vapor/liquid traffic in the column. On the other hand, changes in *B* and *D* must depend on the level controllers to change the vapor/liquid traffic of the column; therefore, the dynamic response of the product compositions is significantly slower when *B* and *D* are changed, compared with changing *L* and *V*. The dynamic response to changes in *L/D* and *V/B* are intermediate between *L* and *V* on the fast side and *B* and *D* on the slow side. Based on this analysis, (*L, B)* is expected to perform better for the overhead composition control than for the bottoms, but there is no clear winner between the (*L*, *B*) and the (*L/D*, *V/B*) configurations with regard to the overall dynamic response.

Table 15.10 shows the relative changes in each manipulated variable for a change in feed composition. This table is based on steady-state results in which the product compositions are maintained at a constant level. A lower relative change for a manipulated variable indicates a reduced sensitivity to feed composition changes for that manipulated variable. Note that *L*, *L/D*,

TABLE 15.10
Relative Changes in the Manipulated Variables to Maintain the Product Purities for a 5-Mole % Increase in Feed Composition

Manipulated Variable	Percentage Change
L	4.2
D	7.4
L/D	−3.0
V	4.4
B	−16.8
V/B	25.5

TABLE 15.11
Control Performance (IAE) for a Step Change in Feed Composition

Configuration	IAE for Overhead	IAE for Bottoms
L,B	0.067	1.49
L,V	0.250	13.3
L/D,V/B	0.095	2.00
D,V	0.098	1.91

and *V* show the least sensitivity to feed composition changes.Table 15.11 lists the integral absolute error (IAE) for each configuration for each product for a feed composition upset. A lower IAE value indicates closer control to setpoint. Note that the (*L*, *B*) configuration provided the best overall control performance, especially for the overhead product. This is consistent with the observation that *L* is dynamically fast and relatively insensitive to feed composition changes coupled with the relatively moderate steady-state coupling as indicated by the *RGA*.

The (*L*, *V*) configuration has the advantages of fast overall dynamics and insensitivity to feed composition upsets. These advantages are negated by the extreme degree of steady-state coupling as indicated by its steady-state *RGA* value. The control performance of the (*L*, *V*) configuration is the poorest of the four configurations listed in Table 15.11. The (*L/D*, *V/B*) configuration has a good steady-state *RGA* and dynamic characteristics, but is particularly sensitive to feed composition upsets for the bottom composition control loop. The steady-state *RGA* value of the (*D*, *V*) configuration indicates that this configuration does not function properly, but it is quite reasonable, i.e., the IAEs for the (*D*, *V*) configuration were only about 30% larger than those for the (*L*, *B*) configuration, which is not substantial in this case.

For complex configuration selection problems, such as distillation columns, the previous analysis is helpful but does not always guarantee that the best configuration will be identified. The performance differences between reasonable configuration choices and the best configuration can be substantial. Therefore, in these cases, the use of detailed dynamic simulations for the analysis of the control performance of feasible configurations is recommended wherever possible.

15.5.12.2 Tuning Decentralized Controllers

The recommended tuning procedure for a single PID loop can be extended to tuning the single-loop PID controllers applied for decentralized control of a MIMO process. The first step in tuning

a decentralized controller is to apply ATV tests for each manipulated variable/controlled variable pair. While an ATV test is applied to one loop, the other loops should be maintained in an open-loop condition.

Next, determine if any of the loops are significantly faster responding than the other loops. This can be done by comparing the values of the ultimate periods, P_u, obtained in the ATV tests. If the smallest value of P_u is at least five smaller than the next larger P_u, that loop alone should be implemented first, before tuning the other loops. It can be tuned as a single PID loop as discussed in Chapter 3. Next, ATV tests on the remaining loops should be rerun with the tuned fast loop in service (closed-loop operation). Then, the remaining control loops can be tuned using the following procedure.

Assume that it is required to tune PI controllers on a 2 × 2 MIMO process. The ATV results are used to select the controller gain and reset time based on, for example, Zeigler–Nichols tuning. Then, a single tuning factor, F_T, is applied to the tuning parameters for both control loops:

$$\left.\begin{aligned} K_c &= K_c^{ZN} / F_T \\ \tau_I &= \tau_c^{ZN} \times F_T \end{aligned}\right\} \text{First control loop}$$

$$\left.\begin{aligned} K_c &= K_c^{ZN} / F_T \\ \tau_I &= t_I^{ZN} \times F_T \end{aligned}\right\} \text{Second control loop}$$

F_T is adjusted until the proper dynamic response is obtained. While tuning, if the closed-loop response is sluggish, decrease the value of F_T. Likewise, if the controller exhibits periods of ringing, increase the value of F_T.

After F_T has been adjusted to tune the set of decentralized PI controllers, fine tuning of the controller settings should be used. For example, if one observes that one of the control loops is slow to settle at setpoint in a manner similar to Figure 15.3a, an increase in integral action for that loop should be tested. If one of the loops exhibits ringing, derivative action should be tested to determine if it improves the feedback control performance of that loop. In the latter case, derivative action should be tuned in the manner that was described in Section 15.3.

15.6 MODEL PREDICTIVE CONTROL

This section covers model predictive control (MPC). It describes what it is, how to design it, how to install it, and how to make it work. This work is both fun and useful, but there is one rule: *Understand the process.* This section contains tips and clues about how to analyze and learn process behavior.

15.6.1 What Is MPC?

There are many ways to control plant operations. Among these are the following.

Batch control is used to produce batches of material to specification. For example, certain polymer reactors fall into this category.

Programmable logic controllers (PLCs) are typically used to control very high-frequency equipment such as steel mill rolls or compressors.

PID (the old standby of continuous control) is largely dedicated to controlling a single variable, such as flow in a pipe.

Neural networks are relatively new and are used in nonlinear multivariable situations where a rigorous process model is unavailable or unsuitable for traditional implementation. Neural networks are used where traditional identification techniques are not well suited for the problem due to nonlinearities.

Model predictive control (MPC), the subject of this section, is sometimes referred to as *multivariable control or MVC*.

A short definition of MPC is: a way to control many variables simultaneously, using a plant model to manipulate more than one variable to produce improved plant operations.

Some other useful definitions are as follows:

Controlled variable (CV). Controlled variables are those that you want to control.
Disturbance variable (DV). A DV affects the process in a known way but cannot be manipulated.
Feedforward (FF) variable. Same as DV.
Input. See MV.
Linear program (LP). A linear economic optimizer.
Model plant model. Normally dynamic and linear, often described in matrix notation as *A*.
Manipulated variable (MV). Manipulated variables are those moved by the controller.
Output. See CV.

Referring to the above definitions, a model predictive controller has at least one CV, more than one MV, and possibly DVs. It can be used to optimize the plant in an economic sense with an LP. With today's technology, the model, *A*, is linear and dynamic, and it describes the approximate relationships between the CVs and MVs (and DVs). In this section, we will assume that the process being controlled is continuous (as opposed to batch or discrete).

In the step response model, a change in MV of size u causes a corresponding change in the CV, y. In matrix notation, this is described as

$$y = A\Delta u \tag{15.16}$$

where y and u are vectors, and A is a matrix. A prediction of the CV's future value, $\tilde{\mathbf{y}}$, can be calculated using the plant model and previous changes in the MVs. By including future changes made in the MVs, a prediction of the future response of the CV with control $\tilde{\mathbf{y}}_{\mathrm{C}}$ at each discrete time interval, k, can be made:

$$\tilde{\mathbf{y}}_{\mathrm{C}}(k) = \tilde{\mathbf{y}}(k-1) + A\Delta u(k-1) + \mathbf{d}(k) \tag{15.17}$$

where $\mathbf{d}$ is a disturbance that may effect the plant. The objective of MPC is to have the CVs reach their targets, y_T, or setpoints, y_{sp}, in the most efficient manner by a certain time. The move sizes to be made are calculated by minimizing the error, e, between the CV target (y_T) and the predicted CV ($\tilde{\mathbf{y}}_{\mathrm{C}}$) while the MVs are being moved. This unconstrained solution is formed as

$$\begin{gathered} \mathbf{e}(k) = \mathbf{y}_{\mathbf{T}}(k-1) - \tilde{\mathbf{y}}_{\mathrm{C}}(k-1) \\ \min_{\Delta \mathbf{u}} \mathbf{\Phi} = [\mathbf{e}(k)]^2 \end{gathered} \tag{15.18}$$

At each time step, the first step (k) of the calculated moves is then implemented, and the calculation proceeds again (see Figure 15.72).

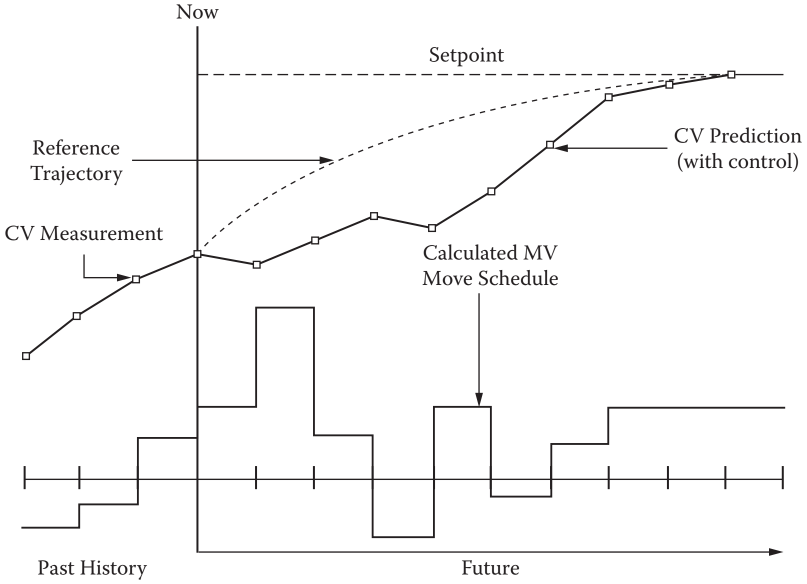

FIGURE 15.72 Representation of CV prediction and scheduled MV moves at each calculation step for MPC.

15.6.2 History of MPC

Industrial model predictive control (MPC) is based on algorithms that were developed many years ago. They share several common traits:

They are based on discrete linear dynamic models.
The algorithm for identifying linear dynamic models is derived from plant data.
The algorithm for calculating on-line control actions is based on plant models.

They have been refined and applied successfully over the past 40 years. Currently, DMC is the predominant industrial MPC.

15.6.3 When Should MPC Be Used?

Because MPC requires significant investments in software and time, it is best to observe certain considerations:

There is significant economic payout. A typical MPC takes about a man-year to build. Software costs are typically about one third of the investment in engineering time.
The process is interactive. This means that a single MV affects more than one CV.
There are significant process constraints.
The plant must have suitable infrastructure, particularly skilled engineers and operators, as well as modern and well-maintained instrumentation.
All of the necessary final control elements must exist and be able to work properly.

One should not to use MPC if

The problem is easily solved with one or two PID controllers or other standard control blocks. This happens when the process is naturally decoupled, i.e., either there are few

process interactions or very fast-acting parts of the process are naturally separated from very slow-acting parts.

Special logic is required, for example, safety shutdown systems.

15.6.4 General Method for Designing a Multivariable Controller

There is a well-defined methodology for designing MPCs. It is quite general and can be applied to almost any situation where a MPC is required. In summary, the method is as follows:

Understand the process
Design the plant test
Conduct the plant test and collect data
Structure the controller and analyze the data
Tune the controller
Commission the controller
Post audit

15.6.4.1 Understand the Process

15.6.4.1.1 General

Process control is a blend of different disciplines, including mathematics, chemical engineering, computer science, economics, and process understanding. These skills are not equally weighted. Process understanding accounts for about 70 to 80% of the total knowledge required to install a successful MPC application; the other skills make up the remaining 20 to 30%. The lesson is clear: you must understand the process before proceeding. The following are things you can do to better understand the process:

Read and understand process flow drawings (PFDs).
Read and understand the piping and instrumentation diagrams (P&IDs).
Spend a few hours in the control room and talk to operators.
Interview plant engineers.
Interview plant economic planners.
Run a simple steady-state simulation of the process if one is readily available.
Read the plant operating manuals.
Cultivate a thorough understanding of such things as
  Why does this plant exist, i.e., what is the purpose of this facility?
  Where does the feed come from, and how much does it cost?
  Where do the products go, and how much are they sold for?
  How much flexibility is there in the feed supply and the product demand?
  Are there any seasonal operations?
  What are the top three or four constraints that operators worry about?
  Where is energy used and how much does it cost?
  What are the important plant specifications?
  What are typical plant daily operating orders?

The following is a good equation to keep in mind:

Probability of MPC success (%) = completeness of process understanding (%)

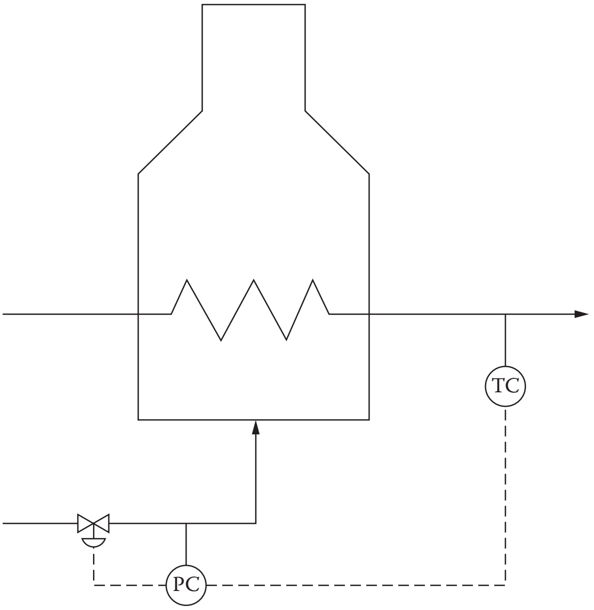

FIGURE 15.73 Fired heater outlet temperature control in the DCS.

15.6.4.1.2 Regulatory Control Strategy

Early in the project, learn which variables to keep in cascade, automatic, or manual modes. This is commonly referred to as the *state of the plant.* Normally, you want the PID loops to do as much work as possible, allowing the MPC to focus on higher-level functions.

The following are situations in which you probably want to leave the PID loops closed:

Fired heater outlet temperature control
Drum level control (see exceptions later)
Controls on rotating equipment
Properly functioning distillation tower temperature controls

The fired heater in Figure 15.73 shows the outlet temperature in the DCS. One reason for leaving this loop closed is that disturbances in these systems are usually very high in frequency and are rejected well by simple PID loops in the DCS.

Situations in which you may want to break the PID loops in the DCS, taking them out of cascade, or possibly putting them in manual, include the following:

Distillation columns with temperature controllers on both overhead and bottom
Process lines with two control valves in series (e.g., flow/level or flow/flow)
Loops with very long dynamics (e.g., composition loop with an hour or more of deadtime)

Consider a distillation column that has a temperature controller on the overhead and one on the bottom as well. Usually, this configuration leads to instability, variable saturation, or both. The best solution is to break one of the temperature loops (put in manual) in the DCS before beginning the plant test. Leave the one closed at the end of the column, where composition matters the most.

In general, think very carefully about the state of the plant before doing plant tests. If you choose incorrectly, you can always repeat the tests, but this will cost you many weeks of engineering time and a loss of credibility with the plant operators.

15.6.4.1.3 Inventories and Process Decoupling

Drums (tanks) are common in process plants. Every drum represents inventory, which in some cases can be usefully exploited to decouple the plant. This is especially useful in plants with significant heat integration.

For example, let us assume that the overhead stream from a main fractionator is condensed, enters the overhead accumulator (inventory), and then feeds a gas plant downstream. Assume also that the main fractionator has pumparounds lower down the tower that are used to supply reboiler heat to the same gas plant. This is an example of a heat-integrated plant.

In such a plant, the following can happen. Imagine that a big rainstorm causes increased condensing of the main fractionator overhead product. Assuming that the overhead accumulator is on level control, product flow to the gas plant increases, affecting the gas plant. The gas plant reboilers (being on temperature control) call for more heat, which results in increased main fractionator heat removal (via the pumparounds). This heat imbalance in the main fractionator again affects the overhead product flow, which again affects the gas plant, and so on. This whole chain of events can take a day or so to subside.

By breaking the main fractionator overhead level control loop, the vicious cycle described above can be avoided, because many of the heat integration imbalances simply show up as fluctuations in the overhead accumulator level. MPC will do a very good job of controlling overhead drum level so as to keep the gas plant stable.

Pay attention. Carefully determine which level loops should be broken before conducting plant tests.

15.6.4.2 Design the Plant Test

The plant test is the most important part of designing and installing MPC. Normally, a plant test consists of making changes to an MV and watching how the rest of the plant (CVs) responds. Usually, a single MV is moved while all others are held constant. In some situations, more than one MV can me moved simultaneously—for example, in different parts of a plant that are not significantly coupled. Although it is theoretically possible to move all MVs simultaneously in a carefully constructed plant test, such tests are nearly impossible to conduct in commercial plants and therefore are not recommended.

The following are requirements for a good test:

- At least 5 moves per MV are required, and 15 moves would be better.
- The signal (MV movement) must be as random as possible so as to minimize the chance that it correlates in time with some other variables in the plant.
- The MV movement must be large enough to elicit a process response (1% of current MV value is a good minimum, and 10% of current MV value is a good maximum).
- At least some of the moves in the MV must be held long enough that the plant comes to steady state.
- Use a series of steps in the MVs. Other waveforms are possible (e.g., sinusoids) but are much more difficult to analyze visually.

Before you conduct the test, make a detailed list of which MVs you want to move and when you will move them. Discuss the move sizes with the plant operations people—they will let you know how big the moves can be. (Often, you can start with conservative move sizes and, as the test progresses, increase the move sizes to get better information.)

Above all, make sure you understand what the product specifications are and where important equipment and environmental constraints are located. You must accept responsibility for keeping the plant in a safe and economic operating condition during the plant tests. A law of nature is that

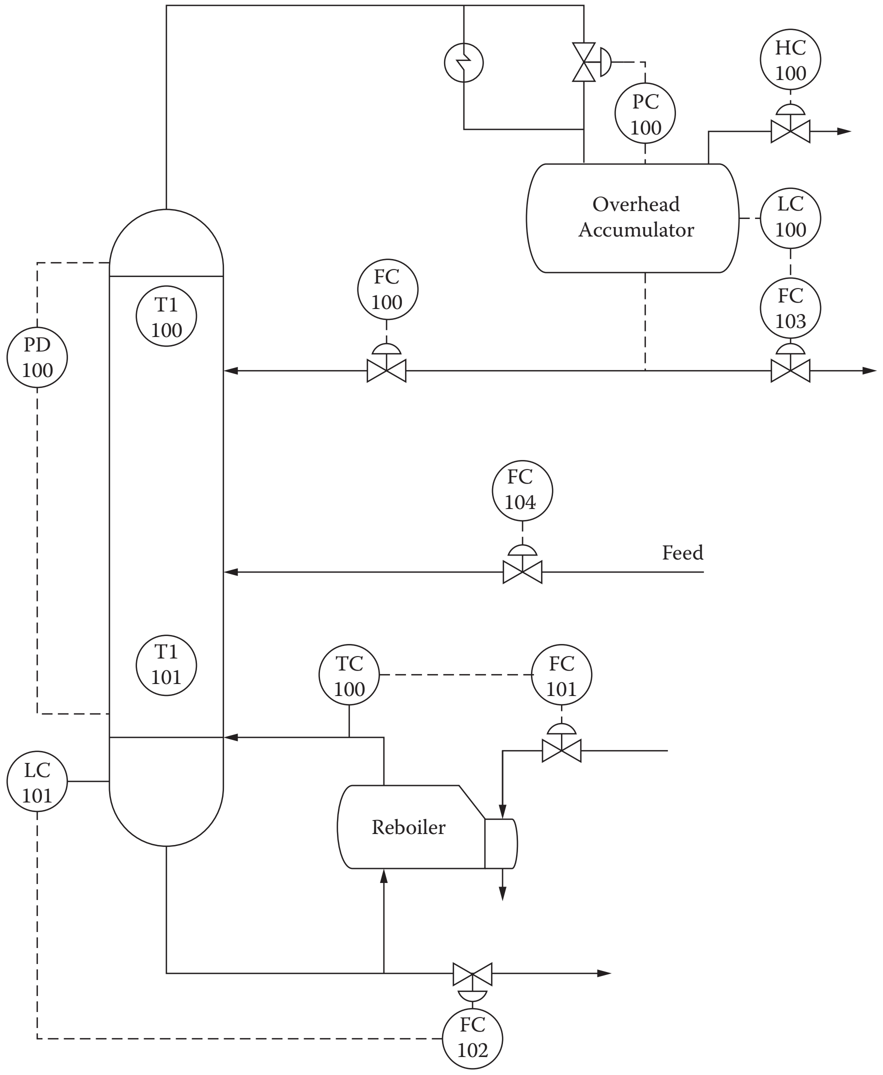

FIGURE 15.74 A distillation column with temperature control on the reboiler return.

as soon as a problem occurs in the plant, you will be blamed because you are doing something new. Be prepared, and don't let that happen.

For example, assume that you want to perform tests on the plant, represented by Figure 15.74. The plant is a simple distillation column with overhead accumulator pressure controlled by moving the hot vapor bypass, bottoms level maintained by bottoms product draw rate, and the overhead accumulator level controlled by adjusting the overhead product draw rate. Reflux is on flow control, and the reboiler is on temperature control. Typical move sizes for this plant are shown in Table 15.12.

15.6.4.2.1 Designing a Good Input Waveform

There are many ways to make moves to independent variables during a plant test. The most practical approach is as follows:

Use a series of step changes in a single variable.

Move only one independent variable at a time. If you move more, the resulting test data often become difficult to analyze visually.

TABLE 15.12
Typical Move Sizes for the Plant Shown in Figure 15.73

Tag	Description	Nominal Value	Typical Move Size
FC100	Tower reflux	2000 BPH	20–200 BPH
TC100	Reboiler Return temp.	200°F	2–5°F
HC100	Vent to fuel	5%	0.1–0.5%
PC100	Overhead accum. pressure	200 PSIG	2–10 PSIG

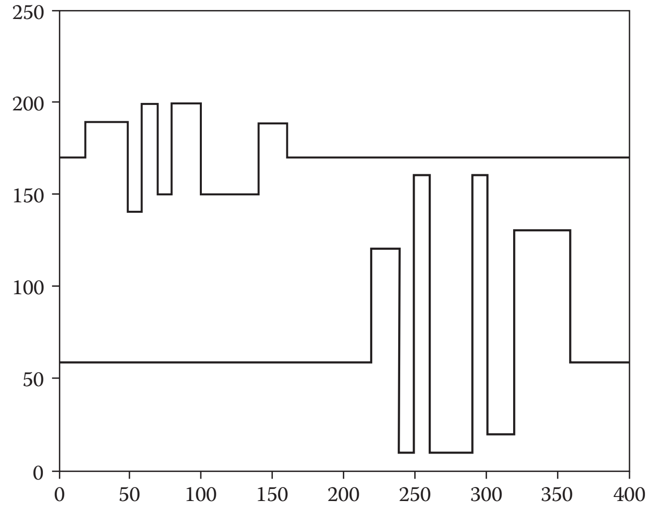

FIGURE 15.75 Plot of two unconnected step tests (good step test).

Make sure the input series is pseudorandom. This means that the behavior of the input variable being moved is not correlated with itself (no autocorrelation).

Figures 15.75 and 15.76 are examples of good and poor testes, respectively, being plots of input vs. time.

15.6.4.2.2 Set Up the Data Collection

15.6.4.2.2.1 Sample interval

The normal data collection in use today is one minute. If you are dealing with a really fast process, you may need to sample as often as every few seconds. If the plant is extremely slow, consider one sample every five minutes. There is nothing to prevent you from sampling either faster or slower, but you need to consider the trade-off between increased time resolution (good) and increased data set size (bad). Also, you should consider the dynamics of the system that you are dealing with—there is no point in sampling a system every ten seconds when the time constant is eight hours.

15.6.4.2.2.2 Collecting the Right Instrument Tags

In addition, you need to carefully define which data to collect. With modern digital instrumentation systems, it is tempting to collect all of the tags in a plant. Instrument tags contain the identification numbers assigned to process measurements. In a typical process unit, the number of tags is between 1000 and 3000, so keep in mind that if you collect them all, you will pay a price later in terms of the raw time it takes to handle the data.

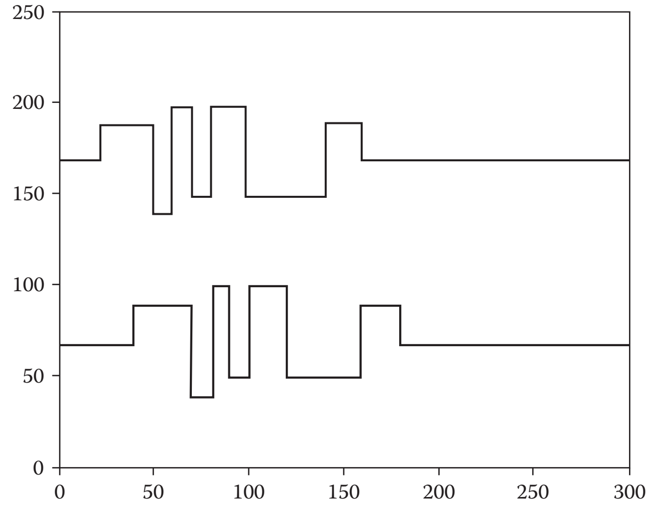

FIGURE 15.76 Plot of two correlated step tests (poor step test).

There are two theories of data collection:

1. Be cautious and collect everything. This minimizes the chance that you will forget something, but it maximizes the chance that you will acquire too much data to deal with later. This approach is a bit like packing five suitcases for an overnight trip.
2. Be practical and collect only what you need. If you carefully determine which data to collect, you minimize the data-processing problem but run the risk of missing useful data. This is like spending an hour to pack a small suitcase but forgetting your comb.

15.6.4.2.2.3 Laboratory Data

You need to identify which stream samples to collect during the plant test. Later, you will analyze the sample data to build inferred properties. Make sure you agree with the plant operations people about how much lab data you will need, for which streams, and how often it should be collected. Finally, remember that lab analyses are very expensive, so be careful to take just enough, but not too many, samples (30 to 60 samples per stream is about right). A good rule of thumb is to take at least ten data samples for each inferred properties coefficient being modeled. For a simple inferred property with 3 coefficients, at least 30 samples should be taken; e.g., $Y = a_1 x_1 + a_2x_2 + a_3x_3$, where a_i = the coefficients.

15.6.4.3 Conduct the Plant Test and Collect the Data

15.6.4.3.1 Preparation

The objective of doing a plant test is to get *good* data. The requirements of getting good data include

The instrumentation must work properly.
The PID controllers must be properly tuned.
Control valves must be properly sized and functioning correctly.
The process equipment must be in a normal state.

Before investing the time to conduct a plant test, you should spend a few days making sure that everything in the plant works properly. Move the setpoints to the main controllers to verify that the PID loops and final control elements work as they should. Look at the heat, mass, and

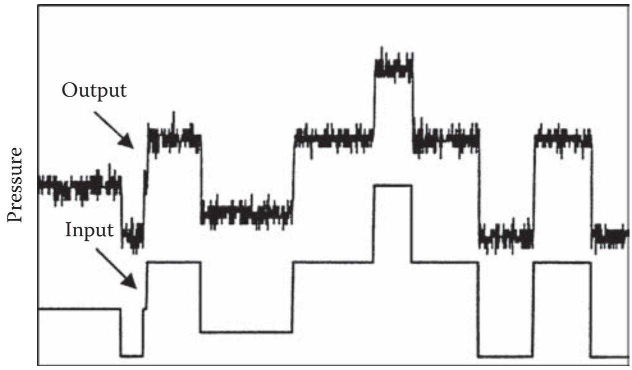

FIGURE 15.77 A good test.

composition balances on the unit to track down problems in process equipment. Check all of the major equipment and make sure that it is actually operating. For example, make sure that compressors, turbines, pumps, and furnaces are operational and running well.

In summary, first look at the big things, such as major actuators and major equipment, and make sure they are all in working order. You can do it first, or you can do it after investing three months of work and discovering that the big power generation expander, which makes most of the money in the plant, has been shut down for maintenance during the entire plant test.

15.6.4.3.2 Plant Test

Conducting a proper plant test is probably the most important step in a multivariable control project. A checklist for conducting a successful plant test follows:

- Meet with plant operators at the start of each shift and explain what you are doing and why. The meeting should take five to ten minutes.
- Make sure each MV move gets made on time, in the proper direction, and by the proper amount.
- Once per shift, make sure that your data collection is still running.
- Make real-time plots and try to explain all of the behavior you see. You should be doing this on a more or less continuous basis. Often, this will help you identify operating problems before the operators do, and will help to keep the plant stable during your tests.
- Make notes during the plant test. Record any unusual events, along with the time they happened.
- Talk to plant operators. Learn as much as you can about the process.
- Buy plenty of pizzas and donuts for operators. A happy operator is a cooperative operator.

When you have finished the plant test, you will have an excellent understanding of how the unit operates. If you do not have this understanding, you will have failed to achieve one of your main objectives.

Figure 15.77 shows an example of a good test. There are nine input moves. The input series is not autocorrelated (i.e., the moves are of different lengths and do not show a pattern). The move sizes are large enough to get a good response in the output.

15.6.4.4 Structure the Controller and Analyze the Data

15.6.4.4.1 How to Pick MVs, CVs, and DVs

Make sure that you select the right number of MVs; too many, and the controller is cumbersome and hard to understand, too few, and you may miss important interactions and constraints (and

TABLE 15.13
Relative MPC Controller Sizes

	MVs	CVs	Comment
Very small controller	2–4	2–10	Will likely miss important constraints and interactions.
Reasonable controller size	5–40	10–40	About the right size.
Controller is too large	40+	40+	Human operators begin to have difficulty in understanding.

	AP100	PD100	PC100.VP	FC101.VP
FC100	–	+	+	+
TC100	+	+	–	+
HC100	0	0	+	0
PC100	–	–	+	–

FIGURE 15.78 Roughed-out gain matrix for the control design of the tower in Figure 15.73.

therefore benefits). Typically, a single controller spans a large part of a process unit. Table 15.13 illustrates the concept of proper controller size.

At this point in a control project, you should have a good idea of the controller structure—which variables are MVs, which are CVs, and which are DVs. Draw a matrix with the MV and DV tags as rows and the CV tags as columns (or vice versa). Using your newly gained knowledge of the process, write in a "+" or a "–" for each MV/CV pair (or DV/CV pair) where you expect to see a positive response and where you expect to see a negative response, respectively. Tape the matrix to your wall and look at it from time to time just to make sure you are on track as you proceed with more detailed analyses.

Be sure to look for patterns in your roughed-out matrix. For example, if two blocks have no common interactions, you may be able to divide it into two smaller controllers. Keep this in mind as you progress with the detailed analysis. See Figure 15.78 for an example.

15.6.4.4.2 Designing for Closed-Loop Optimization

Today's multivariable controllers are mainly linear algorithms. Depending on the process, there can be significant advantages to optimizing the process using a nonlinear model. Most nonlinear models today are steady-state, rigorous, heat and mass balance models and are built separate from the multivariable controller.

Even at this early stage in designing your controller, keep in mind that some of its targets may be set by a nonlinear optimizer. It is useful to decide which CVs or MVs will have their targets set by an optimizer. This becomes important later, particularly when tuning the controller.

15.6.4.4.3 Building the Power Model for the MPC Controller

Contemporary model building methodology is well established. Essentially, it is a matter of identifying which plant test data are usable; which variables should be CVs, MVs, or DVs; and what

is the best controller frequency. Different software packages vary in which steps are involved, but when all is said and done, the designer has a few important decisions left:

Is the controller structure correct? Have the correct variables been chosen for MVs, CVs, and DVs?
Do the resulting models make sense? Are the process gains the correct sign? Should some models be zero? Are the gains roughly the correct magnitude?
Does the controller contain parallel CVs or MVs (singular matrix)? If yes, is this the best design, or can the controller be simplified to remove the parallel variables? (This is an important issue, because parallel variables usually result in some form of unacceptable controller behavior.)
Is the scope (size) of the controller correct? Are all of the right interactions and constraints present?
Will the plant operators understand the final controller, or is it too complex to understand?

Model building is a very important step. Get this part right, and the rest follows fairly easily. Get it wrong, and you will be in for a rough time later.

Extensive information is available on how to use modern MPC modeling software. Most of this takes the form of training courses and material supplied by the various technology vendors. This software does a regression between MVs and CVs and produces linear dynamic models as shown in Figure 15.79.

For those who are unfamiliar with these models, here is a brief explanation. The matrix represents the distillation tower shown earlier in Figure 15.74. The rows of the matrix are the MVs,

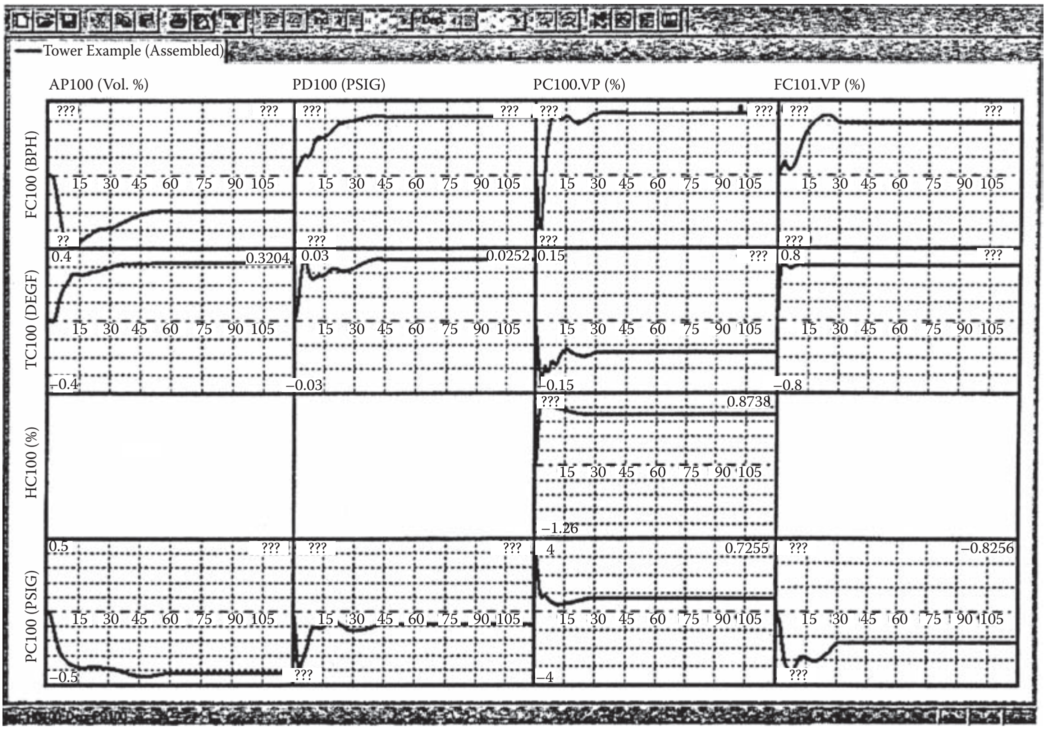

FIGURE 15.79 Calculated controller matrix for the control design of the tower in Figure 15.73. DMCplus® was used to create this matrix.

TABLE 15.14
Economic Data for Distillation Column in Figure 15.74

Tag	Description	Cost	Units
FCl0l	Steam flow	0.003	$/lb
FC102	Bottoms product	12	$/BBL
FC103	Overhead product	20	$/BBL

TABLE 15.15
Process Gains for Distillation Column in Figure 15.73

	FC101 Steam (lb/hr)	FC102 Bottoms (BPD)	FC103 Overhead (BPD)
FC100 (reflux, BPD)	1090	0.2	–0.2
TCI 00 (reboiler, Dee F)	2800	–10	10

and the columns are the CVs. At the intersection of each row and column is a single model (blanks indicate that no relationship exists between a given MV/CV pair).

15.6.4.4.4 Plant Economics

Many multivariable control algorithms include a built-in optimizer that can be used to drive the plant in a better economic direction. To tune this part of the controller, reasonable economic data are required. These are often combined with process or simulation data to put them in a form that can be used by the controller.

The plant economics almost always end up as costs on controller CVs or MVs or both. They tell the controller which variables to minimize and which ones to maximize to achieve the proper objective (e.g., increased profit, reduced cost, reduced environmental cost, and so forth).

Let us use an example to illustrate. Imagine that you are designing a controller based on the distillation tower shown in Figure 15.74. The overhead product flow is measured by FC103, the bottoms product flow is measured by FC102, and the steam flow is measured by FC101. The controller manipulates reflux flow FC100, bottoms temperature TC100, fuel gas vent HC100, and tower pressure PC100. There are measured constraints, but for the time being we will generally ignore them and aim to maximize profits; we want plant conditions that maximize production of the more valuable product. To figure out how to make the controller push the plant in the correct direction (optimization), you will need the information in Table 15.14. Your job is to find a way to get this economic information into the controller so that it makes more overhead product, while attempting to save steam.

Since none of the economic variables in Table 15.14 appear in the controller, it is necessary to transform this information somehow to include it indirectly. To do this, you will need information on what effect the manipulated variables FC100 and TC100 have on plant economics. To do this, you will need more information. Fortunately, this is given in Table 15.15. These process gains were derived during plant tests. They represent the change in the economic variables that result from changes in the manipulated variables.

So, combining the information in Tables 15.14 and 15.15, we can compute the economic costs to be included in the controller as in Table 15.16. Note that one cost is positive and the other negative. The positive cost for reflux will cause the controller to reduce reflux flow. The negative cost for reboiler temperature will cause the controller to increase reboiler temperature. In practice,

TABLE 15.16
Final Controller Economics

	Cost	Units
FC100 (reflux)	4.87	\$/BPD
TC100 (reboiler)	–71.6	\$/°F

the controller will reduce reflux and increase reboiler temperature until a constraint is encountered. As conditions change, the controller will continue to push the MVs in this direction, thus increasing profit, while always respecting constraints.

15.6.4.5 Tune the Controller

The next step after building controller models is to tune the controller. This involves using the dynamic model to simulate the plant and then tuning the controller against that. Even though every commercial algorithm is slightly different, you need to get three types of behavior right before installing the controller in the plant:

Economics
Constraints
Dynamics

15.6.4.5.1 Controller Tuning—Economics

Most MVC algorithms have a way to impose an economic solution on the controller. This approach will drive the controller to a most favorable operating point (when there are degrees of freedom available). Once you have derived appropriate plant economics (see Section 15.6.4.4.4), the next step is to run the plant/controller simulation many times with different combinations of MVs and CVs at constraints while making sure that the controller pushes the plant in a direction that makes sense.

15.6.4.5.2 Controller Tuning—Constraints

The next important aspect of tuning a multivariable controller is to determine what happens when different constraint sets become active. For example, assume that you have designed a distillation tower controller with constraints on overhead composition, bottom composition, and tower ΔP. The MVs are reboiler duty and reflux rate. The following are examples of the types of constraint trade-offs that you need to consider:

Which constraint is more important: overhead composition or tower ΔP?
What should the controller do when all three constraints are active (since the controller has only two MVs, it must give up on one of the CVs).
When the reboiler is at the maximum limit, which constraint should be dropped last?

The plant/controller simulation should be exercised many times, with many different combinations of active constraints. For each constraint combination, it is important to make sure that when constraint violations are unavoidable (more active constraints than MVs), the CV violations occur in the correct order, with the highest priority given to variables related to safety.

As expected, most algorithms have a way to deal with this situation. Typically, each CV can be given a weight, with lower-weighted CVs being violated first. The most important consideration in tuning for constraints is to ensure that a representative number of different constraint combinations are tested in an off-line environment, before the controller is run in the plant.

15.6.4.5.3 Controller Tuning—Dynamics

All multivariable control algorithms include a way to tune how quickly they respond to setpoint changes or disturbances. Two general classes of tuning parameters affect the speed of response.

The first is often referred to as *reference trajectory* and can be thought of as a filter on setpoint changes. The filtered setpoint in essence becomes a trajectory—the controller attempts to move the MVs so that the CV follows their individual trajectories. Increased filtering produces slower controller action.

The second class of dynamic tuning focuses on how much the MVs move for a given disturbance (either setpoint change or unmeasured disturbance). This type of tuning parameter is commonly called *move suppression* and provides a mechanism to slow down some MVs relative to others. Move suppression is important when a given MV affects a critical piece of equipment, for example, a large compressor with many automatic overrides and shutdown interlocks.

The general procedure for tuning the dynamics of a new controller is to run the controller/simulation combination under many different combinations of setpoint changes and unmeasured disturbances. Typically, plant operators will provide valuable feedback for how much the MVs should move in different circumstances and how fast the CVs should get to setpoint and away from constraints.

15.6.4.5.4 Operator Training

In many states in the U.S.A., it is a legal requirement that all operator training take place before a multivariable closed-loop controller is activated in an operating plant for the first time. Even in places where this is not a legal requirement, common sense dictates that this step be carried out first.

Typically, the plant operators each receive an hour or two of training while working on their normal shift. In some exceptional cases, the operators receive formal classroom training. Better training leads to increased project success.

15.6.4.5.5 Watchdog Timer

A multivariable controller is expected to run continuously. Sometimes, however, the control software or control hardware fails. This situation should be detected quickly and the operator warned, normally by an alarm in the DCS.

The most common way of detecting and alarming this problem is to use a small program called a *watchdog timer* running in the DCS. The watchdog timer communicates frequently with the multivariable controller program. If the watchdog timer fails to get a response after a predetermined period of time, the watchdog forces each MV into its fallback (shed) position and writes an alarm to the operator.

15.6.4.6 Commission the Controller

After a controller has been designed, built, and tuned in an off-line environment, the next big step is to install it in the plant computing hardware and commission it. Since, at this stage, it becomes possible for the controller to directly modify how the plant is running, one must proceed methodically and with caution. Use checklists. Be observant and, at least initially, monitor all of the variables related to the controller frequently and thoroughly. Below is a good suggested procedure.

15.6.4.6.1 Use a Checklist

Installing a multivariable controller is not difficult, but, if done carelessly, it can lead to serious problems such as an off-specification product or equipment damage. To maximize the chances of a smooth installation, use a checklist. Here is a simple example.

1. Make sure that operators are trained on how the controller works. Do not proceed until they are.

2. Install software, database, and other real-time components.
   - ❑ Control algorithm installed in on-line computer.
   - ❑ Controller on-line database built.
   - ❑ Watchdog timer installed.
   - ❑ Controller definition information (models, tuning parameters).
3. Check controller data base.
   - ❑ Controller CVs, DVs, and MVs match raw DCS inputs *exactly.*
   - ❑ Controller models, tuning parameters, etc., match off-line versions *exactly.*
4. Turning controller on in prediction mode.
   - ❑ Make sure that each MV is configured correctly in the DCS.
   - ❑ Check the shed mode for each DCS.
   - ❑ All MVs out of cascade (MFC controller cannot change).
   - ❑ Controller turned on in prediction mode.
   - ❑ Watch calculated move sizes. Check that the sizes make sense.
   - ❑ Watch the CV predictions. Check that they make sense.
5. First-time MV check.
   - ❑ Narrow upper and lower limits of MVs (or rate limits).
   - ❑ Make sure the controller is running.
   - ❑ Put MVs into cascade *one at a time.* Ensure no bad behavior in DCS setpoint.
   - ❑ Make sure that the DCS setpoint changes by *exactly* (to within machine precision) the size of the calculated move.
6. Closing the loop.
   - ❑ Make sure controller is running.
   - ❑ Activate controller master ON switch (if there is one).
   - ❑ With MV limits still clamped, put one or two MVs into cascade.
   - ❑ Relax the MV bounds a little and check for good controller behavior.
   - ❑ Add more MVs gradually, making sure controller behavior is OK.

For a reasonably large controller, steps 2 through 5 should take a few days. Step 6 should take a day or so, assuming that there are no problems. From this point on, the main activity is to gradually relax the controller bounds until it is clear that the actual behavior in the plant matches the behavior that was simulated during design. Over the next few weeks, make sure that the standard deviations on the CVs decrease (normally only when they are at constraint limits), that the MVs are not moving around too much, and that the economics are driving the controller in the correct direction.

15.6.4.7 Post Audit

The last step in a properly run control project is to conduct a post audit. Collect postcommissioning data and compare them to precommissioning data. Make sure the new operating point is economically better than the old one. Check to ensure that the standard deviations of economically important CVs (often associated with product specifications) have decreased significantly. Evaluate whether the MV bounds are still set correctly. Can they be widened? Is the controller forcing the process to run at the best set of constraints most of the time?

15.6.5 Multivariable Controller Troubleshooting

A newly commissioned multivariable controller works well. Over time, the performance can deteriorate to the point at which the controller is turned off by plant operators. This section can be used to diagnose common problems that can lead to disabling a multivariable controller.

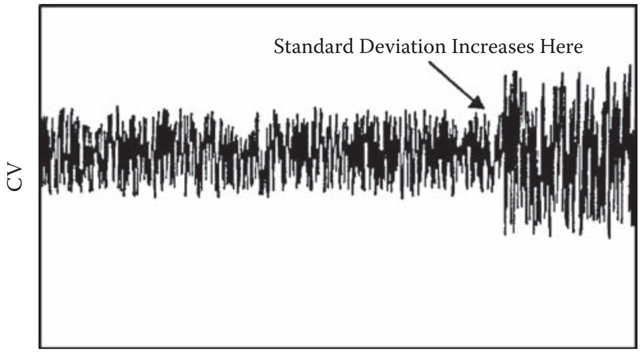

FIGURE 15.80 Standard deviation of a CV increases suddenly.

15.6.5.1 Commonsense Approach

Ninety percent of troubleshooting multivariable controllers is common sense. For example, below is a daily checklist that can be applied to diagnose the last 24 hr of operation for a MPC application.

15.6.5.1.1 Quick Screening

The first step in controller troubleshooting is to check overall controller behavior during the recent past. This quick screening is often a simple set of questions or a few simple reports. For example, here are some questions to ask each morning:

- What percent of time was the controller running?
- Which constraint set was most active?
- How many MVs are at bounds?
- How many CVs are at bounds?
- How many MVs are active (being manipulated by the controller)?
- What is the standard deviation of CVs that are at bounds?
- Is the controller pushing the plant in the right direction?
- How far apart are the MV bounds?

15.6.5.1.2 Deeper Analysis

If the quick screening turns up potential problems, deeper analysis can help narrow down the problem areas. One good way to do this is to examine time plots for all CVs and MVs for the last 24 hr. Abnormal behavior can be quickly traced to one or a few variables by this approach.

Figure 15.80 is an illustration of what happens when a multivariable controller develops a problem; in this case, a CV in the controller exhibits a sudden increase in standard deviation. Now, having narrowed the problem, an engineer can conduct even more detailed analyses.

15.6.5.2 Detailed Troubleshooting—Use a Checklist

Finally, once the problem behavior has been narrowed down, a good final step is to try to pinpoint the problem using a checklist. It is surprising how many problems can be found by running quickly through a checklist—for example,

- ❑ Controller is on, but MVs don't move
- ❑ Controller turned off by itself
- ❑ Operator turned controller off

- ❑ Controller is on, but control is poor
- ❑ General controller error
- ❑ One or more inputs is bad
- ❑ MVs are moving erratically
- ❑ Controller is on, but MVs don't move:
  - MV upper and lower bounds are the same
  - MV step bounds are very small (or zero)
  - Most CVs are turned off (removed from controller)
  - Valves are wide open or closed
- ❑ Controller turned off by itself:
  - Look at error log, check for numerical problems
  - Critical CVs are not available or bad
  - Critical MVs are not available or bad
  - Bounds on CVs or MVs do not make sense (e.g., lower bound greater than upper bound)
  - There is a hardware failure (often DCS or computer)
  - Check watchdog timer alarm—often indicates hardware problem
- ❑ Operator turned controller off:
  - Ask operator why controller was turned off
  - Are operators adequately trained?
  - Process is very upset, wait for normal behavior and turn on again
- ❑ Controller is on, but control is poor:
  - Has the process operating point changed significantly?
  - Have the controller targets changed significantly?
  - Is there a new feed?
  - Is the weather very different (e.g., snow, rainstorm, etc.)?
  - Have valves been bypassed?
  - Has new process equipment been put in service (or existing equipment taken out of service)?
  - Has a controller model been recently changed?
  - Has the multivariable controller been retuned?
  - Have PID loops been retuned?
  - Have actuators broken or been replaced?
  - Have the controller economic parameters been changed?
- ❑ General controller failure:
  - Most algorithms have diagnostics based on error number. Check error number
- ❑ One or more input is bad:
  - AI needs to be reset
  - DP cell plugged
  - FI plugged
  - LI float stuck
  - TI burned out
  - Calculated variable has error (usually, a flow has gone to zero)
  - Check software interface between DCS and multivariable controller hardware
- ❑ MVs are moving erratically:
  - Has multivariable controller tuning changed?
  - Has a new control matrix been loaded into the controller?
  - Has DCS database changed?
  - Has an instrument been reranged in the DCS?

15.6.5.3 Is the Controller Still Making Money?

In the final analysis, only one thing really matters—is the controller still making money? You should get in the habit of periodically evaluating the controller behavior; every few months is probably often enough. Check to see whether

The controller is pushing the plant in a direction that makes economic sense.
Controller economics match the current process economics.
Standard deviations of key variables are acceptable compared to a good base case.
CV and MV constraints still make economic sense and are safe.
The variable set is correct. (Should some be removed? Others added?)
The scope of the controller is still OK. (Should it be expanded? Made smaller?)
It is time to add a real-time nonlinear optimizer.
The operators are still adequately trained in the use of the controller.

Additional Reading....1436

Consult this chapter first if you need to accomplish any of the following:

- Design a piece of equipment
- Propose and design new equipment or a new process
- Evaluate a current piece of equipment or a process
- Suggest changes for equipment or a process
- Debottleneck by increasing the limiting capacity in a process
- Troubleshoot to correct faulty operation

We classify these problems as being design, process analysis and improvement, and troubleshooting.

Engineering is based on fundamentals and the dynamic balance among economic, operability, sustainability, safety, environmental, legal, ethical, and time constraints. It is *dynamic,* because the development of new technology, catalysts, and materials of construction, and the shifting economical, social, and political scenes, mean that the processes we develop, improve, and operate in the future will be dramatically different from past practice. We say it is based on fundamentals, because mass, energy, momentum, and charge will still be conserved.

The goal is a win-win balance (not a lose-lose compromise) among competing forces. Moderation and patient creative problem solving are the keys. Regrettably, plants have been built that have so many safety interlocks, so much heat integration, and such extremely minimized inventory that

they cannot be started up or operated safely. Likewise, process options with the highest economic return may not be the best. A win-win balance among apparently conflicting pressures is needed.

In this chapter, we remind you how to balance astutely the competing issues. Ideally, we would discuss this as an integrated whole. However, for quick reference, the issues and sections break down as follows:

Section 16.1: The Problem-Solving Process
Section 16.2: Problem-Solving Rules of Thumb
Section 16.3: Engineering Economics
Section 16.4: Building a Data Base
Section 16.5: Sustainability
Section 16.6: Integrating Process Control with Engineering
Section 16.7: Safety, the Environment, and Waste Reduction (see also Section 16.11 for pertinent rules of thumb)
Section 16.8: Software Options
Section 16.9: Optimization Methods
Section 16.10: Rules of Thumb for Teamwork
Section 16.11: Rules of Thumb for Selection and Sizing Equipment

16.1 PROBLEM-SOLVING PROCESS

The key to effective conceptual design, process improvement, and troubleshooting is the thinking process and how we use our basic knowledge. The process and procedure to solve any design, process improvement, or troubleshooting problems has six characteristics:

1. *The problem-solving process is systematic, organized, and cyclical*. It is systematic and organized to keep track of many details. The process is cyclical; we start by solving a very simple version of the big problem using the rules of thumb in Section 16.11. If this very simple concept seems to be satisfactory, then we repeat the cycle, spending more time and resources and using technical details given in other chapters in this handbook. This progression is illustrated in Figure 16.1. The problem-solving strategy is applied many times, as illustrated for the first phases of the hierarchical conceptual design sequence.

   We start at the top central spiral at point A and solve our initial simplified conception of the problem. Once the first cycle is completed, a person assigned the decision-making responsibility will assess the "deliverables" from this cycle. These deliverables usually include an estimate of the technical size, the total capital cost, the operating cost, the financial attractiveness (such as in terms of a measure called the *net present value*, described in Section 16.3), a summary of the legal constraints, the hazard rating, the sustainability implications, and an estimate of the control and operability. The decision being made is either to *stop (*we are no longer interested) or *go* (this idea is worth investigating in more detail). The stop-go decision is like a gate that stops the poor ideas and admits the good ideas. The process is sometimes called the "gating process," and the person making the decision is the gatekeeper. The problem is solved over and over again, in ever increasing detail and with ever increasing accuracy, provided that the idea is given a *go* at each gate (Doyle, 1980). Table 16.l illustrates this gating process from a slightly different perspective. In column 1, the general business cycle for any commodity is shown: startup, market entry, market leader, and then phaseout. The typical marketing activities are illustrated in column 2. The name and "deliverables" for the gating process are listed in column 4, with data from market research in column 3

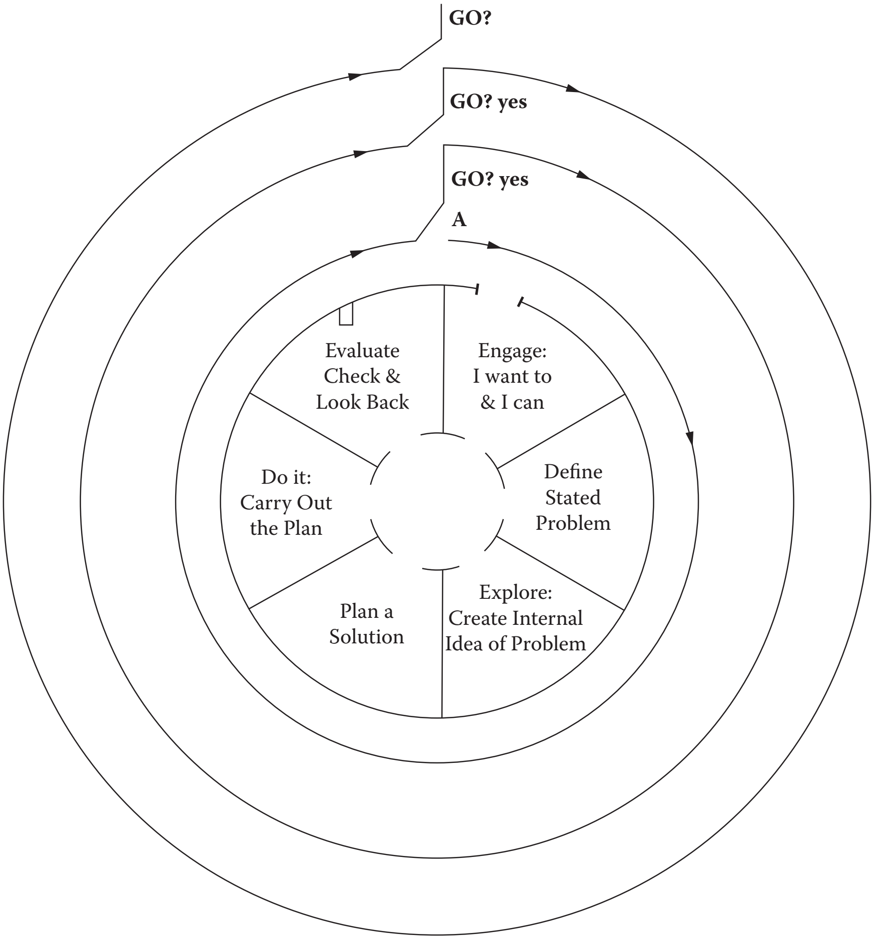

FIGURE 16.1 The problem solving strategy is applied many times in solving problems as illustrated for the first phases of the hierarchical conceptual design sequence.

suggesting the number of ideas or options considered at the different gates (Cooper, 1987). Listed in columns 5 and 6 are the different technical and economic dimensions of the overall task. Column 5 also shows when the three different types of problems (conceptual design, process improvement, and troubleshooting) are usually encountered. The "startup phase" includes conceptual design through construction.

2. The problem-solving process applies to design, process improvement, and troubleshooting. To manage the process, we usually consider the problem in a hierarchical series of cycles that reflect the systematic evolution of our ideas. For conceptual design, these stages in the cycle are listed across the top of Table 16.2 (based on Douglas, 1988). The constraints are usually (1) the production capacity, the purity of the products, and the anticipated disturbances; (2) economic (amount of capital available and the projected return); (3) time (when); (4) the budget, time, and resources for the design process; and (5) the potential for expansion.

For *process improvement,* the cyclical stages and criteria are as illustrated in Table 16.3. The constraints are usually (1) the existing plant, equipment, and layout, and (2) the existing feedstocks (although one might allow different trace contaminants) and economic constraints of budget and profitability. For process improvement and waste

TABLE 16.1
Relating the Business Cycle, the Gating Process, and Engineering and Marketing Activities

Business Cycle	Marketing	Illustrative Number of Options	Gating Process: Levels of Decision Making	Technical Engineering	Economic Dimension of Engineering and Expected Accuracy in Economic Values
Period 1: Startup		50	**0.** Idea		
	Preliminary market assessment	20	**1.** Preliminary evaluation	**Order of magnitude** using rules of thumb	Use ratios ± 50% or scale-up of process cost correlations
	Concept identification & market study	10	**2.** Concept generation: produce *Business plan*	**Conceptual design,** flowsheet development and rules of thumb sizing of equipment. Use of the hierarchical stages illustrated in Table 16.2.	Equipment costs using flowrate correlations ±25 to 40%
	Develop market plan	4	**3.** Development: budget authorization	**Preliminary Engineering design** Flowsheeting; semi-detailed design of the major pieces of equipment.	No quotations; detailed factor method used ±15 to 30%
	Prototype	2	**4a.** Pilot plant, prototype	Confirm key data; revise detailed design as needed	Recalculate based on new data
	Finalization of market plan	1	**4b.** Finalized design	**Defined equipment design** details of equipment but estimated piping	Vender quotations, ±6%
			Select the contractor	**Detailed contractor bid design** detailed takeoffs done; bid documents	Detailed takeoffs and bid documents, ±3%
	Implement market plan	1	**4c.** Construct, produce, and launch	Manage construction, authorize modifications	Manage budgets; authorize changes
Period 2: Market entry	Search for new markets		Annual *Balance sheet and Income statement*	Startup **trouble shooting** Use of hierarchical stages illustrated in Table 16.4	
Period 3: Market leader	Strategies for price reduction and increased functionality		Gating process for improvements; Annual *Balance sheet and Income statement*	**Continual process improvement** Use of the hierarchical stages illustrated in Table 16.3. And trouble shooting	Economic justification
Period 4: Phase out	Identify new user needs		Annual *Balance sheet and Income statement*	Search for new opportunities	

TABLE 16.2
Full Problem-Solving Cycle Is Applied to Each of the Hierarchical Stages in Conceptual Design

	Hierarchical Stages in Conceptual Design						
Criteria	**I. Batch versus Continuous**	**II. Gather the Data for Inputs and Target Outputs; Set Goals**	**III. Preliminary Scouting of the Reactor**	**IV. Explore Mass Recycle**	**V. Explore Separations**	**VI. Explore Energy Integration**	**V. Polish**
Technical feasibility	Use when difficult to scale up; identify as multiproduct, general multipupose, or campaign operation of multipurpose.	Define product amount, purity, and range of production rates	Reaction conditions: Excess reagent? Heat removal method? Shift equilibrium? Add diluent? Combine reactor-separator?	Buildup of trace materials? Overall mass balance? Changes in corrosion?	Prefer not to add agents	Pinch technology	
Economic feasibility	< 2,500 Mg/a <0.1 kg/s	Use cost correlation to estimate investment; estimate product cost using %. Define risk and expected return; Define tax and insurance impacts			Use cost correlation based on flowrate		Minimum cost may not give minimum waste
Sustainability		TNS: renewable resources? Bioassimilimlation of feedstock, product, byproducts, intermediates, and wastes					

Control and operability		Setpoint and random, seasonal and gradual disturbances should be specified	Heat removal, runaway reactions?	Control purge? Monitor and measure wastes, increased scaling of heat exchangers? Reduced reliability because of intimate interdependence	Sufficient surge volume?	Thermal disturbance because of recycle? Add trim heaters/coolers? Reduced reliability because of intimate interdependence; additional startup-shutdown equipment?	Increased fugitive emission for each valve added;
Hazard: safety, environmental, waste minimization		Remove impurities in feed	Heat removal? Runaway reactions?	Recycle waste to eliminate reversible reaction production?	Impact of adding agents		Fugitive emissions: sampling: monitor and measure wastes
Legal and ethical		Know the law; know patents	Ethical: sustainability? Legal: hazard	Loss of water rights			
People	Teams of key people; bring members together early to increase ownership; seek operator input	Few design errors occur because of technical incompetence. Most result from poor communication. Use e-mail. Use rules of thumb for effective teams, given in Section 16.10.					

TABLE 16.3
Full Problem-Solving Cycle Is Applied to Each of the Hierarchical Stages for Process Improvement

	Hierarchical Stages in Process Improvement							
Criteria	**I. Better Inventory; Reduce Fugitives**	**II. Identify Realistic Needs for Process Units**	**III. Optimization of Reactor/ Separation**	**IV. Cycle Time Optimization; Improved Control**	**V. Process Modifications to Debottleneck: Simple Switch**	**VI. Process Modifications to Debottleneck; Redesign, Equipment Replacement**	**VII. Recycle Management; Heat and Mass Exchange Networks**	**VIII. Substitute Raw Materials, Reagents, Solvents, and Additives**
Technical feasibility	Minimum risk with greatest economic potential	Realistic specifications for products, utilities;	Focus here because usually raw material cost predominates: consider issues from design		Relocate feed, replace internals, vertical condenser to horizontal condenser		Pinch technology	
Economic feasibility	Incremental analysis							
Sustainability			Purity of feedstocks: renewable? and bioassimilation?					
Control and operability	Minimum surge volume needed to damp out disturbances	Four levels	Better sensors, relocate sensors	Shift to statistical process control?	Impact on control	Impact on control, startup		
Hazard: safety, environmental, waste minimization	Main focus here!	Consider zero discharge; guidelines for acceptable risk	Minimize waste production		Minimize holdup	Increase in fouling? Increase in corrosion?		
Legal and ethical: social/political	Ethical concern for community; legal requirements							
People								

TABLE 16.4
Full Problem-Solving Cycle Applied to Each Hierarchical Stage When Applied in Trouble Shooting

	Hierarchical Stages in Trouble Shooting				
Criteria	**I. Prioritize the Trouble**	**II. Problem Definition, Hypothesis Generation**	**III. Gather Data and Identify Cause**	**IV. Correct Cause**	**V. Prevent Reoccurrence of Cause**
Technical feasibility		Focus on changes? or on fundamentals?			
Economic feasibility	Third priority		Use inexpensive detectors		
Sustainability					
Control and operability			Put on manual control		
Hazard: safety, environmental, waste minimization	Top priority: safety, environmental impact		Ensure system is safe		
Legal and ethical	Legal: accidental spill or discharge top priority		Follow internal procedures		
People			Use Jungian typology to identify preference on the P-J dimension; avoid fixation and pseudodiagnosticity		

management, our sequence of issues to consider is approximately the reverse of the order used for design: better inventory practices, scrutiny of operating practices and procedures, reduction of fugitive emissions, optimization of reactor and separation operating conditions and control of operations, recycle management plus energy and mass exchange networks, and substitution of raw materials.

For *troubleshooting*, the cycles and criteria are as listed in Table 16.4. The constraints are usually safety and time: A process often operates 25 to 28 days per month to cover costs. On the remaining days, it is making a profit. We need to keep the process operating. The tests, changes, and remedy should be safe, environmentally acceptable, and ethically and legally possible.

3. *The problem-solving process focuses on money.* The prime concern of the gatekeeper is "will this idea be profitable for the company?" Without profit, companies fold. The feasibility criterion is economic feasibility: The financial investment should provide a return commensurate with the risk.
4. *Throughout the problem-solving process, we consider a host of "feasibility" criteria other than money.* These include (1) market feasibility (the product provides customers with benefits they want and are willing to buy), (2) technical feasibility (the process must work, the desired amount and purity of the target product must be produced), (3) sustainability (the process should use our world's resources wisely so that we evolve toward sustainable development), (4) operability and controllability, (5) minimal hazards,

(6) satisfaction of all legal and ethical concerns, and (7) providing the company with a good corporate image. More is given under "Qualitative Measures" in Section 16.3 and in Sections 16.5 through 16.7.

5. *The problem-solving process uses all available current computer assists such as flowsheeting, the Web, data sourcing, and data-processing techniques.*
6. The problem-solving process is usually a team effort, with many people contributing.

16.2 RULES OF THUMB FOR PROBLEM SOLVING*

Below are 18 rules of thumb about the process of problem solving.

1. Be aware. Be able to describe the thought processes being used and to identify where in the process you are.
2. Know the systematic stages for each cycle of the problem-solving process (as illustrated in Figure 16.1).
3. Focus on accuracy. Check and double check.
4. Actively write things down. Make charts and raw diagrams, write down goals, list measurable criteria, and record ideas in brainstorming.
5. Monitor and reflect. Mentally keep track of the problem-solving process and monitor about once per minute.
6. Be organized and systematic. Use an organized strategy such as those illustrated in Figure 16.1 and in Tables 16.2 to 16.4.
7. Define the "real" problem by creating a rich perspective of the problem. See it from many different points of view. Be willing to spend at least half the total available time defining the problem. Ask many "what-if" questions. Try to bound the problem space. "Swim with the data" to see how they respond. Identify the real problem by asking a series of "why" questions to generalize the situation. In Figure 16.l, this activity of identifying the real problem is called the *explore* stage and is the heart of the problem-solving process.
8. Be flexible.
9. Use your creativity effectively. Defer judgment; be succinct; list 50 ideas in 5 min; create a risk-free environment; encourage free and forced association of ideas; piggyback on previous ideas; use triggers, such as those listed in Table 16.5, to maintain the flow of ideas; don't be discouraged—in the last 2 min of a 5-min brainstorming session, over 85% of the ideas are impractical—but spend time to identify the treasures among the 15%. Use impractical and ridiculous ideas as steppingstones to innovative, practical options.
10. Critically assess the knowledge and data used. Too often, we hope that the data are applicable. A colleague, in designing a petrochemical plant, was unable to locate the physical properties of the organics. He decided to assume that they were the same as water and hoped that this would work out. Just a short time spent in critical assessment of this assumption would have saved six months of wasted work. Too often, we accept

TABLE 16.5
Checklist of Triggers for Brainstorming

Name of Trigger to Change Point of View		Elaboration of How It Is to Be Used	Comments
To be used for objects "How to improve *ion exchange resin*"	Function	What is the function of this object? How else can we achieve this function? What function **can** it **not** do?	Objects for engineers are "products" and hardware. Usually engineers deal with situations. However, these triggers are needed to help apply triggers for situations.
	Physical uses	What are its physical properties and characteristics? What are they **not**? How else might we obtain or use these physical properties?	Probably the most useful perspective; use first. The negative view is often extremely illuminating.
	Chemical uses	What are its chemical properties? How can these be exploited? What are they **not**?	Easy for us to use; use second after physical uses.
	Personal uses	What personal uses can we make of the this object?	These three give a unique perspective that is often overlooked.
	Interpersonal uses	What interpersonal uses can be made?	
	Aesthetic uses	How can we create pictures? music? artistic creations with the object? sculpt? weave?	
	Mathematical or symbolic properties	What are the mathematical or symbolic uses? What can they not be used for? What are they often confused with?	Only applicable for certain objects or ideas.
Situations "I need to design an ion exchange unit." "The reformer is not functioning; fix it."	Checklist	Of the many checklists published, SCAMPER is probably the most effective: **S**: substitute who? What? Other processes? Other places? **C**: combine purposes? Ideas? Appeals? Uses? **A**: adapt what else is like this, new ways? **M**: modify, maximize, minimize? **P**: put to other uses, other locations **E**: eliminate **R**: reverse, rearrange	Effective for objects and some situations. Try each viewpoint. Easy to do.
	Wildest fantasy	Think of the craziest idea and use	Need to establish self-confidence and group confidence before really outlandish ideas are presented. Build confidence in the merit of this approach by later bridging to unique ideas. Brings laughter and tension relief.
	How nature does it	Identify the situation and then think of how nature fulfills this function. Bridge to engineering reality.	Great potential; depends on the situation. Successful in designing new bridges; new bog machines.
	What if? In the extremes	Extrapolate from the unfamiliar to a simplified version	Extension of problem-solving skill in defining simple problems. Relatively easy to apply.
	Boundary exploration	Identify the constraints and remove them	Much easier for some to do than for others.

Continued

TABLE 16.5 ***(Continued)***
Checklist of Triggers for Brainstorming

Name of Trigger to Change Point of View	Elaboration of How It Is to Be Used	Comments
Functional analogy	How else is the function achieved?	
Appearance analogy	How else might we get the appearance of this situation?	
Morphology	Break the problem situation into a series of parts. For each part list 10+ options. Then, systematically combine one option from each part and ask why not?	More mechanical; easy to computerize; most of the work is in setting up the parts and the options; fun and surprising to see some of the results.
Symbolic replacement	Replace the original problem by an interesting idea generated in the session; refocus.	Occurs naturally in many brainstorming sessions. Add this trigger explicitly if needed.
Juxtaposition	Bring in three completely random words and bridge to current situation. Example: "refrigerator, light switch, clock."	Very effective. Don't fake it by using words "you think will help." Use random words.
Personal analogy	Imagine yourself as part of the situation. Describe your feelings and what you are experiencing. Be imaginative.	Tricky. Works for some people; not for others. Effective with fluid dynamic problems.
Reversal	Do the reverse.	More challenging than one thinks. Focus systematically on the reverse of different elements of the situation at a time.
Book title	Create a title for a "best selling" novel. The title should sum up the current situation. "Will exchanging bring happiness to Mary Lou?"	Interesting. Worth a try for 1 min.
Letter, word, sentence	Focus on three different levels of detail corresponding to the big view (a sentence), an intermediate view (a word in the sentence), and a letter (in a word). In ion exchange this might be "the ions, the resin, the packed bed, the separation."	Very effective for most of our problems. Consider a 5-min brainstorm at each level.

data from the published literature, yet about 8% of published data are mistakes. "The temperature into the hydrodealkylation reactor is >1150°C," states one reference. It should read >1150°F. A major handbook published an incorrect value of the heat of vaporization through several editions. Check the data coming from computer programs and simulations. Check the physical property package estimates.

11. See challenges and failures as opportunities for new perspectives.
12. Spend time where it benefits you the most. Use Pareto's principle (80% of the results can be found from 20% of the effort). Find the key 20%.
13. Be an effective decision maker. Express the goal as results to be achieved rather than as actions to be taken. Make decisions based on some criteria that are explicit and measurable. Distinguish between *must* criteria (the process must have an internal rate of return of 35%) and *want* criteria (the process might have the potential to be licensed). Reject options that do not meet the must criteria. Use a rating system to score the want criteria.

14. Be willing to take risks.
15. Manage stress well. Solving problems is stressful. When we initially encounter a problem, we experience distress because of the uncertainty. Such stress tends to immobilize us. When we successfully solve a problem, we experience the joy and exhilaration of stress (which distracts us from checking and double checking that our answer is the best). A certain level of stress motivates us. Excessive stress makes us make mistakes. Data suggest that operators with confidence and training working under high stress make one mistake in ten actions. Operators with confidence and training who receive feedback about their actions and are under low stress make 1 mistake in 1000 actions. Although these data refer to plant operators, the same trends can be extended to suggest how stress and a lack of reflection and feedback might interfere with engineering practice. High stress would be a rating of over 450 on the Holmes–Rahe scale (Holmes–Rahe, 1967).

    Ten suggested approaches to managing stress include the following: worry only about things over which you have control, include physical exercise as part of your routine, have hobbies and destimulating activities in which you can lose yourself, plan ahead, avoid negative self-talk, rename the events that are stressful to you, build a support system, be decisive, put the situation into perspective, and use role models of others who have succeeded.
16. Manage your time well. Covey (1990) offers excellent suggestions on time management. Identify problems and decisions according to their importance and urgency. Shift the important situations to being nonurgent. Learn to say "no."
17. Understand your strengths, limitations, and preferred style. See Section 16.10.1.
18. For problems involving people, use the 85/15 rule: 85% of the problems occur because of rules and regulations; 15% of the problems are because of people.

16.3 ENGINEERING ECONOMICS

Engineering economics is the critical criterion to consider early in design, process improvement, and troublshooting. In this section, we review the role of economics in financial reporting through the balance sheet and the income statement, options for measuring financial attractiveness, operating expense estimation, and capital cost estimation.

16.3.1 Role of Economics in Financial Reporting

Some basic knowledge of economics and financial reporting is essential for a professional engineer moving up the corporate ladder from a technical professional to a corporate manager. The engineer must recognize the importance of financial management and learn to speak and understand the language used by corporate management. The information in this section is beyond what one would encounter in college courses in business school economics or in engineering economics courses. A company financial report, sometimes called an annual report, contains much information. It is designed to tell the reader how well the company performed in the previous year and how this performance is measured against various standards. Two important documents in the annual report are the *balance sheet* and the *income statement*. Two ancillary documents often included are the *accumulated retained earnings* and the *changes in working capital*. As each of these documents is discussed, the reader should have Tables 16.6 and 16.7 available while reading the following sections. These are the financial documents for a fictitious chemical company, ALLCHEM, for the current year 20X6 with data for the previous year 20X5.

16.3.1.1 Balance Sheet (Anon., 1992; Couper et al., 2000)

The balance sheet is the financial status of the company on a given date. The choice of date is arbitrary and depends on the company's operations. A *consolidated* report means that all the financial data for the parent company as well as for the subsidiary companies are presented in one document. A balance sheet contains some real figures, e.g., cash and marketable securities; some estimated amounts or allowances, e.g., inventories and accounts receivable; as well as some fictitious figures, e.g., intangibles for which numbers are difficult to determine.

Two main parts of the balance sheet are the *assets,* which is what the company owns, and the *liabilities and stockholders' equity,* which is what the company owes. The total assets equal the total liabilities plus the stockholders' equity.

16.3.1.1.1 Assets

The assets of a company are divided into three categories: *current assets, fixed assets,* and *intangibles.*

Current assets are those that may be converted to cash within a year from the date of the balance sheet. The current assets include cash and money on deposit in a bank as well as *marketable securities* (e.g., commercial paper and/or government bonds) that can be easily converted to cash. *Accounts receivable* are goods sold to customers on a 30-, 60-, or 90-day basis for which full payment has not been received. An allowance is made for uncollected bills, because some customers were unable to pay. *Inventories* consist of raw materials on hand, goods in process, supplies, and finished goods ready for shipment. Raw materials are charged at cost, goods in process at raw material cost plus one half the conversion cost, and finished goods are valued at selling price. Frequently, inventory costs are carried at values slightly less than these figures to account for deterioration, decline in prices, and other factors. *Prepaid expenses* include prepaid insurance premiums as well as leases for equipment, computers, and office equipment. These expenses are listed under current assets because, although a company has paid for them, full benefit has not been received, but the company expects to do so within the year. The *total current assets* are the sum of cash and marketable securities, accounts receivable, and prepaid expenses.

Fixed assets include land, buildings, manufacturing equipment, office equipment, and so forth, that the company owns. These items are carried on the books at cost less the accumulated depreciation, except for land, which is generally entered at the same value year to year. The sum of these items is the *net fixed assets.*

Intangibles are assets that have substantial value to the company, such as patents, licenses, trademarks, goodwill, and so forth. There is no consistent way to evaluate these assets, so the company often balances both sides of the balance sheet by making this value "close" the sheet.

TABLE 16.6
Consolidated Balance Sheet for ALLCHEM, Inc.

CONSOLIDATED BALANCE SHEET*

As of December 31

Assets	20X6	20X5
Current Assets		
Cash	$63,000	$51,000
Marketable Securities	41,000	39,000
Accounts Receivable**	135,000	126,000
Inventories	149,000	153,000
Prepaid Expenses	3,200	2,500
Total Current Assets	$391,200	$371,500
Fixed Assets		
Land	35,000	35,000
Buildings	101,000	97,500
Machinery	278,000	221,000
Office Equipment	24,000	19,000
Total Fixed Assets	$438,000	$372,500
Less Accumulated Depreciation	128,000	102,000
Net Fixed Assets	$310,000	$270,400
Intangibles	4,500	4,500
TOTAL ASSETS	$705,700	$646,500

Liabilities	20X6	20X5
Current Liabilities		
Accounts Payable	$ 92,300	$ 81,300
Notes Payable	67,500	59,500
Accrued Expenses Payable	23,200	26,300
Federal Income Taxes Payable	18,500	17,500
Total Current Liabilities	$201,500	$184,600
Long Term Liabilities		
Debenture Bonds, 10.3% due in 2015	110,000	110,000
Debenture Bonds, 11.5% due in 2007	125,000	125,000
Deferred Income Tax	11,600	10,000
TOTAL LIABILITIES	$448,100	$429,600
STOCKHOLDERS' EQUITY		
Preferred stock, 5% cum		
$5.00 par value - 200,000 shares	$ 10,000	$ 10,000
Common Stock, $1.00 par value		
20X5 28,000,000 shares		
20X6 32,000,000 shares	32,000	28,000
Capital Surplus	8,000	6,000
Accumulated Retained Earnings	207,600	172,900
TOTAL STOCKHOLDERS' EQUITY	$257,600	$216,900
TOTAL LIABILITIES AND STOCKHOLDERS' EQUITY	$705,700	$646,500

* All figures are in thousands of dollars.

** Includes an allowance for doubtful accounts.

TABLE 16.7
Consolidated Income Statement for ALLCHEM, Inc.

CONSOLIDATED INCOME STATEMENT*	20X6	20X5
Net Sales (Revenue)	$932,000	$850,000
Cost of Sales and Operating Expenses		
Cost of Goods Sold	692,000	610,000
Depreciation and Amortization	40,000	36,000
Selling, General and Administrative Expenses	113,500	110,000
Operating Profit	$86,500	$94,000
Other Income (Expenses)		
Dividends and Interest Income	10,000	7,000
Interest Expense	(22,000)	(22,000)
Income Before Provision for Income Taxes	$74,500	$79,000
Provision for Federal Income Taxes	24,500	26,000
Net Profit for Year	$ 50,000	$ 53,000
ACCUMULATED RETAINED EARNINGS STATEMENT*		
Balance as of January 1	$172,900	$141,850
Net Profit for Year	50,000	53,000
Total for Year	$222,900	$194,850
Less Dividends Paid on		
Preferred Stock	700	700
Common Stock	14,600	21,250
Balance December 31	$207,600	$172,900

* All figures are in thousands of dollars.

Other assets, such as investments in affiliates or *deferred charges* for which full benefit has not been received, may be included before the total assets are summed.

Total assets are the sum of current assets, fixed assets, intangibles, and deferred charges.

16.3.1.1.2 Liabilities

The *total liabilities* are what a company owes and consist of the sum of *current* and *long-term liabilities. Current liabilities* are debts that must be paid within a year from the date of the balance sheet. The total current liabilities are the sum of the *accounts payable, notes payable, accrued expenses payable,* as well as *income taxes payable* from current assets. *Accounts payable* include such items as invoices for raw materials, supplies, and others, that a company has purchased from suppliers and for which payment is due on a 30-, 60-, or 90-day basis. *Notes payable* include monies owed to banks and other creditors as well as promissory notes. *Accrued expenses payable* include such entries as salaries, wages, interest on borrowed funds, insurance premiums, pensions, and so on. *Income taxes payable* are the debt owed to federal, state, and local governments. These taxes are usually paid on a quarterly basis and commonly isolated from other expenses.

Long-term liabilities are debts due after one year from the date of the financial report and include bonds, loans, and deferred income tax. *Bonds and loans* include *first mortgage bonds* (issued at a stated rate due in a stated year and backed by the company's property), *debenture bonds* (backed by the general credit of the company rather than by company property), and *long-term loans* from insurance companies and investment houses. *Deferred income taxes* are encouraged

by the government as a tax incentive that will benefit the economy. Accelerated depreciation, which provides the rapid write-off in the early years of the investment, is an example. The net effect is to reduce what the company owes in the early years and will be paid in the future. To smooth out wide fluctuations in a company's earnings, this entry shows what the taxes would be without accelerated depreciation write-offs.

16.3.1.1.3 Stockholders' Equity

The *stockholders' equity* is the interest that stockholders have in the business and is the *net worth* of the company, namely, total assets minus total liabilities. The *total stockholders' equity* is the sum of the *preferred stock, common stock capital surplus,* and *accumulated retained earnings.*

Capital stock is classified into two broad categories: preferred and common stock. *Preferred stock* has preference over other shares regarding dividends and/or distribution of assets. Some preferred stock is termed *cumulative,* which means that, if in any given year the company does not pay dividends, the dividends accumulate. When dividends are paid, the preferred stockholders receive these dividends before common stockholders. Preferred stockholders, however, do not normally have a voice in company affairs or voting rights unless the company fails to pay them dividends. Preferred stock is carried on the books at the stated par value. For *common stock,* there are no requirements that dividends be paid. If the company's earnings are high, dividends may be paid, but, if the earnings are poor, dividends may not be paid. Common stock is valued at a stated par value.

Common stock capital surplus is the amount of money the stockholders paid for the stock over and above the par value of the stock.

The *accumulated retained earnings* or *earned surplus* are calculated by subtracting the dividends paid to stockholders from the net profit. If the profits in any year are not distributed, they are retained by the company and added to the next year's earnings. They may be used for research and development activities and/or the purchase of capital equipment.

16.3.1.1.4 Total Liabilities and Stockholders' Equity

The sum of the total liabilities and stockholders' equity is what the company owes. It must equal the total assets for the balance sheet to "balance."

16.3.1.2 Income Statement (Anon., 1992; Couper et al., 2000)

The *income statement*, sometimes called the *earnings statement,* displays the operating activities for the year and may be an indication of how well the company is doing. A typical statement will show the numbers for the current year and at least one year previous. Frequently, an annual report will have a five- or ten-year summary near the end of the report. Table 16.7 is an example of an income statement.

16.3.1.2.1 Net Sales

Net sales is the amount of money received for the goods sold less the amount for returned goods and allowances for reduction in prices, e.g., allowing freight on goods shipped. Some income statements use the term *net revenue,* which is the income from all sources such as net sales, income from patents and licensing technology, and others.

16.3.1.2.2 Cost of Goods Sold and Operating Expenses

This item includes all expenses in converting raw materials into finished product, including cost of goods sold; depreciation; and sales, administration, research, and engineering (SARE) expenses.

The *cost of goods sold* represents the cash operating expenses for raw materials, labor, utilities, supplies, maintenance, waste disposal, plant indirect expenses, and so forth.

The *depreciation, amortization,* and *depletion* are paper transactions. The federal government allows a company to charge off a portion of an asset due to wear and tear as well as obsolescence

each year as an operating expense. This *depreciation* is not a cash item. *Amortization* is the decline in useful value of a tangible asset, such as a patent. *Depletion* is the diminution of a natural resource, such as a coal mine. All of these paper allowances appear as one item in most income statements.

The *SARE expenses* are expenses associated with the maintenance of sales offices, paying corporate officers and their staffs, and research and engineering expenses not attributable to a specific project.

16.3.1.2.3 Operating Profit (Operating Income)

This entry is the difference between net sales or net revenue and all operating expenses.

Other income may be derived from dividends or interest received by the company from other investments, income from patents, licenses, and so forth. When other income is subtracted from the operating profit, the result is *income before provision for federal income taxes.*

Every company has a basic federal income tax rate that it must pay. However, the actual *federal income taxes* paid may be less than the basic rate, due to tax incentives, tax credits, depreciation write offs, capital gains, and so on.

16.3.1.2.4 Net Profit for the tear after Income Taxes

This entry is obtained by subtracting the provision for federal income taxes from the income before provision for federal income taxes.

16.3.1.3 Accumulated Retained Earnings

Accumulated retained earnings is an important part of the financial report and is often found along with the income statement. It shows how much money the company has retained for growth and how much was paid out as dividends to stockholders. When the accumulated retained earnings increase, the company has more value. The balance of the accumulated retained earnings at the end of one year is the opening balance on January 1 of the next year. To that figure, the net profit after taxes for that year from the income statement is added, giving the total for the year. From the total for the year, the dividends paid to the preferred and common stockholders are subtracted, and the remainder is the balance of the accumulated retained earnings at the end of the year on December 31.

16.3.1.4 Changes in Financial Position

Scrutiny of the balance sheet and the income statement reveals how much money flowed through the company; how much profit was made; how the funds provided by the net profit, depreciation, sale of common stock, and other items were used; and how the cash generated affected the company operations. The changes in financial position show how the company managed its funds.

16.3.1.5 Other Financial Terms of Significance

Working capital, which allows a company to carry on day-to-day operations, is determined by subtracting current liabilities from current assets. (See also item 20 in Section 16.3.4.2.) *After-tax cash flow* is defined as the net profit after taxes plus depreciation. It is essential to have adequate cash flow to operate the company. *Earnings per share* interests common stockholders and stockbrokers. It is found by dividing the net profit after taxes by the number of shares of common stock.

Depreciation methods in use today are *straight-line* or *accelerated* depreciation. In the former method, the cost of the asset is divided by the asset's life. Accelerated methods were introduced in the 1950s to stimulate capital spending. In the intervening years, there have been many changes to the tax laws as well as how depreciation is handled. The net effect of accelerated depreciation was to provide a larger amount of depreciation in the early years of a venture, thereby increasing the cash flow when the plant is coming on stream and the market for a product is being established.

The current depreciation system is the Modified Accelerated Cost Recovery System (MACRS), and chemical industries are in the seven-year life category. The rates for years one through eight are 14.29, 24.49, 17.49, 12.29, 8.93, 8.92, 8.93, and 4.46, respectively. The depreciation is spread over an eight-year period for a seven-year asset. It is assumed that, during the first year of the life of the asset, full benefit will not be received from the asset. Therefore, a half-year convention is adopted, and the remaining recovery is made in the eighth year.

16.3.1.6 10K Report

The federal government requires a public company to submit annually a 10K report to the Securities and Exchange Commission. It contains many more financial details than the annual reports discussed above.

16.3.1.7 Concluding Comments

When reading an annual report, one should be cognizant of the following:

- The independent accountants certification, which states that the financial statements have been prepared in accordance with generally accepted practices, and the auditing steps meet the accounting world's approved standards of practice.
- In reading an annual report, one will find numerous notes referring to the balance sheet and/or the income statement. These notes indicate any litigation pending and generally how some numbers in the report were obtained. The notes often alert the reader to potential financial problems.

16.3.1.8 Financial Ratios (Couper et al., 2000)

Four classes of financial ratios are useful measures of a company's performance: liquidity, leverage, activity, and performance ratios. They are of particular interest to financial analysts, investment bankers, and corporate executives. As one reads this section, it is advisable to look at the financial ratios for ALLCHEM, Inc. in Table 16.8.

16.3.1.8.1 Liquidity Ratios

Liquidity ratios measure a company's ability to pay its short-term debts when due.

Two measures of a company's liquidity are the *current ratio* and the *cash (quick) ratio*. The current ratio is defined as the current assets divided by the current liabilities, which is a measure of the firm's ability to meet its current obligations from current assets. A "comfortable" level of 1.5 to 2.0 is considered adequate. (*Note*: Numbers presented here are typical as of the date of publication, but they will vary depending on a company's style of management.) The cash ratio is the ability of a company to cover bills from its assets in an emergency. It is the cash plus marketable securities divided by current liabilities. A typical figure is about 1.0.

16.3.1.8.2 Leverage Ratios

Leverage ratios measure the company's overall debt burden.

The *debt-to-assets ratio* is determined by dividing the total debt by the total assets and is usually expressed as a percentage. The industry average is about 35%. Another measure is the *debt-to-equity ratio*, also expressed as a percentage. Both of these ratios are measures of the amount of debt that a company maintains. The higher the ratios, the greater the financial risk. In an economic turndown, it might be difficult for a company with high ratios to meet creditor's demands. The *times-interest-earned ratio* is a measure of the extent to which profits could decline before a firm is unable to pay interest charges on debts. This ratio is calculated by dividing the earnings before interest and taxes (EBIT) by the interest charges. A comfortable figure is 7 to 8 times.

TABLE 16.8
Financial Ratios for ALLCHEM, Inc.

Liquidity

$$\text{Current Ratio} = \frac{\$391{,}200}{\$201{,}500} = 1.94$$

$$\text{Cash Ratio} = \frac{\$391{,}200 - 149{,}000}{\$201{,}500} = 1.20$$

Leverage

$$\text{Debt to Assets} = \frac{\$448{,}100 - 201{,}500}{\$705{,}700} \times 100 = 35\%$$

$$\text{Times Interest Earned} = \frac{\$74{,}500 - 22{,}000}{\$22{,}000} = 4.39$$

$$\text{Fixed Charge Coverage} = \frac{\$86{,}500}{\$22{,}000} = 3.93$$

Activity

$$\text{Inventory Turnover} = \frac{\$932{,}000}{\$149{,}000} = 6.25$$

$$\text{Average Collection Period} = \frac{\$135{,}000}{(\$932{,}00/365)} = 52.8 \text{ days}$$

$$\text{Fixed Assets Turnover} = \frac{\$932{,}000}{\$438{,}000} = 2.13$$

$$\text{Total Assets Turnover} = \frac{\$932{,}000}{\$705{,}700} = 1.32$$

Profitability

$$\text{Gross Profit Margin} = \frac{\$932{,}000 - 692{,}000}{\$932{,}000} \times 100 = 25.8\%$$

$$\text{Net Operating Margin} = \frac{\$74{,}500}{\$932{,}000} \times 100 = 7.99\%$$

$$\text{Profit Margin on Sales} = \frac{\$50{,}000}{\$932{,}000} \times 100 = 5.36\%$$

$$\begin{array}{l}\text{Return on Net Worth} \\ \text{(Return on Equity)}\end{array} = \frac{\$50{,}000}{\$705{,}700 - 448{,}100} \times 100 = 19.4\%$$

$$\text{Return on Total Assets} = \frac{\$50{,}000}{\$705{,}700} \times 100 = 7.09\%$$

The *fixed charge coverage* is obtained by dividing the income available for meeting fixed charges by the fixed charges. Some firms enter into long-term lease agreements, and these are a part of the fixed costs in doing business. The numerator of this ratio is the operating profit before deducting the interest expense, lease costs, and income taxes divided by lease costs and interest expenses.

16.3.1.8.3 Activity Ratios

Activity ratios measure how effectively a company manages its assets.

Activity ratios are based on the assumption that there are proper relationships between a company's assets and the sales and income that they generate. Most analysts compile averages from balance sheet data, which are end-of-year information. This will be used here.

Two *inventory-turnover ratios* are in common use today. The *inventory-sales ratio* is determined by dividing the sales by the inventory. Another method is to divide the cost of sales by the inventory. In either case, the industry average is between 7 and 9. The *average collection period* is the number of days that customers' invoices are unpaid. This figure is found by dividing the annual sales by 365 days to obtain the average daily sales and then dividing that figure into the accounts receivable balance. The average period for the chemical process industries is about 45 days. The *fixed assets* and *total assets turnover* indicate how well the fixed and total assets are being used. They are determined by dividing annual sales by the fixed assets or total assets, respectively. A reasonable figure for the former is 2 to 3 times, and the latter is 1 to 2 times.

16.3.1.8.4 Profitability Ratios

Profitability ratios indicate a firm's management of both income and assets.

The *gross profit margin* is calculated by dividing the gross profits by the net sales, and the result is reported as a percentage. This ratio is an indication of the effectiveness of a company's pricing, purchasing, and production policies. The *net operating margin* is equal to the earnings before interest and taxes (EBIT) divided by the net sales expressed as a percentage. This is a measure of a firm's income performance before interest and taxes. These margins vary considerably. *Profit margin on sales* is calculated by dividing net profit after taxes by the net sales, expressed as a percentage; a reasonable value is 5 to 8%.

The *return-on-equity ratio* is the net income after taxes and interest divided by the stockholders' equity. It sometimes is called the *return on net worth*, and this ratio is probably the best measure of management's performance. Returns on equity vary depending on company performance, but a figure of 15% is not unreasonable. The *return-on-total assets ratio* is the net profit after taxes divided by the total assets expressed as a percentage. It reflects the overall return that a company has earned on its assets; a reasonable value is about 10%.

In conclusion, a company's performance should be compared with the performance of companies in the same line of business, i.e., a chemical company should be compared to a chemical company, and an oil company with another oil company. Companies in the same line of business frequently use the same style of management.

Example 16.1

Use financial ratios to assess ALLCHEM, Inc. for the year 20X6.

Solution

The financial ratios calculated for the year 20X6 are given in Table 16.8. The following conclusions can be drawn about the operation of this company:

- From the liquidity ratios, the company is able to pay its short-term debts when due.
- With respect to the leverage ratios, the "fixed charge coverage" and "times interest earned" are a bit low. The debt-to-asset ratio is about average, but the company needs to reduce fixed and/or interest charges or increase the profit or income.
- The activity ratios are average for a chemical company, and it appears the company manages its assets effectively. One area that bears watching is the average collection period, lest it increase.
- The profitability is about average, although the return on total assets is low; the rest of the operating performance appears satisfactory.

In conclusion, the company overall seems to be operated by management satisfactorily, except as noted above.

16.3.2 Financial Attractiveness

In the free enterprise system, if profits are not maintained, the firm's growth might be stifled. The objective is to maximize profit on invested capital. The attractiveness of a venture is viewed by corporate officers and boards based on "quantitative" and "qualitative" measures of profitability. Although we use the term "profitability" loosely to measure a project's worthiness, it may not be a good measure. Drucker (1974) has said that "profitability is not a perfect measurement; no one has ever been able to define it, and yet it is a measurement despite all its imperfections."

16.3.2.1 Quantitative Measures

Although there are many quantitative measures of profitability, the four most commonly used are return on investment, payout period, net present value, and internal rate of return. The first two measures do not include the time value of money; however, the payout period can be modified to do so, as we shall see later.

The *return on investment* method is defined as the net profit after taxes divided by the total capital investment. Many variations on this measure have been used in the past. It does not include the time value of money but is simple enough that it can be used for simple screening purposes. The *payout period* is defined as the fixed capital investment divided by the after-tax cash flow. It indicates how long it will take to recover the fixed capital investment from the after-tax cash flow. Again, this is used for screening purposes. The payout period with interest takes into account the time value of money (Couper and Rader, 1986) but is a tedious calculation, and the results are not as informative as the net present value or the internal rate of return methods.

The *net present value* method is the most popular one in use today. An arbitrary time frame (i.e., time zero or the present time) is selected as the basis for the calculations. All investment expenditures made prior to time zero are compounded forward to time zero, and all income items are discounted back to time zero using an interest rate (or arbitrary "barrier return") set by management at a few percentage points above the *cost of capital,* depending on the project risk. The equation for determining the net present value is

Net present value (NPV) = net present value of all cash flows derived from income minus net present value of all investment items

If the NPV is positive, then the venture will earn more than the arbitrary barrier return. Conversely, if the NPV is negative, then the venture will earn less.

The *internal rate of return (IRR)* method is similar to the NPV method in principle. In the NPV method, the interest rate is stated, and the NPV is calculated. In the IRR method, an interest rate is sought by trial and error such that the NPVs sum to zero. That interest rate is the return that the venture will earn. There has been much discussion in the literature about which method is preferred (Couper et al., 2000).

16.3.2.2 Qualitative Measures

Before an investment decision is made, consideration must be given to certain qualitative factors and their impact on the decision-making process. In some cases, these may be the controlling factors. The qualitative measures or criteria are outlined in Tables 16.2 to 16.4.

The *technical feasibility* and the *control and operability* are usually accounted for in the selection of the project risk and the barrier return used in the quantitative NPV method described above.

The *environmental* issues—increasingly tighter restrictions on water, air, land, and noise pollution—have forced management to reconsider existing operations as well as future investments. It is a simple matter to determine the capital requirements to meet the current and projected future environmental standards, but the benefits are manifested in continued operation and community recognition of a company's good citizenship.

Indeed, the *company's good citizenship* or *corporate image* is a qualitative measure that considers most of the remaining criteria. How a company is perceived by the public and by its employees is an important factor in capital investment decisions. In terms of *safety and health* issues, a safe working place not only reduces the cost of operation through reduced injury and lost production but contributes markedly to employee morale. Regarding *legal* constraints, local and federal laws are intangibles that must be considered whenever an investment decision is made. A proposed venture that violates or infringes on a statute is doomed. It is essential, before locating a plant, to review the existing laws and seek advice on their influence on a site location. Most firms want to avoid litigation, as it can be costly and damage a firm's image. Regarding *product liability,* consumer advocates and the public demand a safe product. Management is wise to forego the installation of a facility until there is a high probability that the product will meet safety requirements. Management must take a responsible posture with regard to this item. Considering *plant maintenance,* a poorly maintained plant is an eyesore to the public and indicates an indifference about the locale. It may be an indication of management's sloppy attitude that may carry over in maintaining product quality and may affect employee morale. The *contributions to the community* and the *company's approach to sustainability* affect the corporate image. *Employee morale* is related directly to the efficiency of operation. If employees do not consider their jobs or working conditions to be good, surely this will affect not only the amount of material produced but also the quality of the product. Quality circles and seeking ISO designation have done much to improve workers' interest in their jobs and in their company. Employees who feel they "belong" to an organization will take more interest in it, be more content, and display high morale.

It is not possible to assign rankings to these qualitative factors, but they may be as important as the quantitative measures when making an investment decision. Attempts to present numerical criteria to rank these qualitative measures have been subjective and unsuccessful.

16.3.2.3 Cost of Capital, Minimum Acceptable Return, and Risk

16.3.2.3.1 Cost of Capital

The *cost of capital* is what it costs a company to borrow money from all sources. Three general sources of capital available are borrowed money, equity capital, and retained earnings. For borrowed capital (from investment houses, banks, insurance companies, and venture capitalists), the interest rate on loans is a few percentage points above the prevailing prime interest rate. The interest rate charged also depends on the length of the loan, size of the loan, and potential risk perceived by the lender. For equity capital, obtained from the sale of preferred and/or common stock, companies may float new stock issues or have shares of stock that may be released to secure capital funds. Retained earnings or reserves may be used to the extent of their availability.

A company must keep a balance between the cheaper "borrowed monies" and "equity capital." If too much money is borrowed, the leverage is affected: the debt/equity ratio increases, and the times-interest-earned ratio drops. If equity borrowing is relied on too heavily, the average cost of capital increases, the stock is diluted, and the stock price is reduced. Lending institutions as well as investors look at the debt/equity ratio and may become suspicious if it is too high. On the other hand, if it is too low, concern may develop that management may not be exercising good judgment.

An example of an average weighted cost of capital is presented in Table 16.9. It is based on a fictitious company. The dollar amount of the loans, bonds, and stock is multiplied by the after-tax

TABLE 16.9
Cost of Capital

Balance Sheet 12/31/20X6	Millions ($)	After-Tax Yield to Maturity (%)	After-Tax Weight Ave. Cost (%)
Long-Term Debt			
Revolving Account	5.0	4.5	0.02
4 3/8's debentures	12.0	4.0	0.05
6 1/2 DM	3.4	4.7	0.02
6 3/4 DM*	9.4	4.2	0.04
7 1/2 DM	74.5	4.2	0.30
9 3.8 DM	125.0	4.4	0.53
Other	23.2	4.4	0.10
	252.5		1.06
Deferred Taxes	67.7	0	0
Reserves	16.1	0	0
Preferred Stock	50.0	8.6	0.42
Shareholder's Equity	653.9	15.6	9.80
	1,040.2		11.28

* The after-tax weighted average cost of capital is 11.28%.

yield to obtain an after-tax weighted cost for each capital item. The after-tax weighted average costs are then summed to give the average weighted cost of capital. In the example, it is noted that the stockholders' equity is the predominate factor in the cost of capital calculation, while the bonds contribute about 10% to the cost of capital. Equity capital is an expensive way to obtain funds. The cost of capital should be reviewed periodically by the company's financial personnel because this figure is used as a basis for funding projects.

16.3.2.3.2 Minimum Acceptable Rate of Return

Every business enterprise has limitations on the amount of capital available for investment each year. A minimum rate of return or barrier rate is established by management for different projects, depending on the risk involved, the type of venture, the cost of capital, and the duration of the venture. Different styles of management often use different methods for establishing the minimum rate of return.

16.3.2.3.3 Risk

Companies release funds for capital expenditures on a quarterly, semiannual, or annual basis. Executive committees determine on a scheduled basis how the funds should be released, based on risk and measures of profitability. The riskier the project, the higher the barrier return. For the discussion here, let us assume a company has a venture classification system as follows: necessity projects, product improvement projects, process improvement projects, and new ventures.

Necessity projects are mandated by environmental, health, safety, legal, or image issues. The company must invest in these projects to stay in business and avoid fines and/or litigation. The calculation of an NPV is meaningless, as the company must comply. These projects have zero risk. *Product improvement projects* involve the addition of perhaps a processing step, requiring a low capital investment to improve quality so that more sales or increased sales price is possible. These projects are short term, and there is a low risk. The minimum rate of return for these projects is set at a few percentage points above the cost of capital.

Process improvement projects may involve some laboratory research, pilot plant, or plant studies to reduce operating expenses and to improve overall process efficiency. These projects are more expensive and of longer duration than product improvement projects. The assurance of generating a greater return is not present, so there is a higher (moderate) level of risk, and the minimum acceptable return is higher than in the previous case.

New ventures involve either the introduction of a new product to the market or an entirely new process to manufacture a product. In the domestic field, there is a risk of marketing a new product related to its potential acceptance. The number of options considered was illustrated in column 3 of Table 16.1. Research and development costs are high and require considerable technical effort. As a result, there is a chance of failure, so higher minimum barrier returns are required to satisfy management. New ventures become more risky when joint ventures are involved because of the different operating philosophies. The risk is high. Foreign new ventures are even riskier, especially joint ventures, as there are different cultures involved, time delays, market volatilities, delays in equipment deliveries, as well as potential economic crises in foreign countries. These projects are of the highest risk. The minimum acceptable rate of return for foreign projects is frequently double that of domestic ventures.

16.3.3 Operating Expense Estimation

Few methodologies have been published for the estimation of operating expense, probably because much of the information is proprietary.

Operating or *manufacturing expenses* are recurring and significantly affect profitability. Such expenses consist of the expense of manufacturing as well as of packaging and shipping, selling and distribution, and company overhead. Direct expenses are those directly associated with the manufacture of the product, exclusive of raw material expenses, which are often a separate item. Indirect expenses refer to those that are not affected by the production rate, such as depreciation, local taxes, insurance, and plant indirect expenses, such as plant roads, docks, plant security, and so on.

16.3.3.1 Manufacturing Expense Sheet

A typical manufacturing expense sheet is presented in Table 16.10. On this illustrative sheet, the bottom line is the expense to manufacture a product at the manufacturing department door and excludes packaging, shipping, and overhead expenses.

This manufacturing expense sheet has four distinct parts: the heading, raw material section, direct conversion expenses, and indirect conversion expenses. The *heading* identifies the product to be made, the amount produced, the fixed capital investment, and sometimes the location, yields, operating time, and other items. The *raw material* includes the raw materials used to produce the product as well as any by-products for which credit may be received. The *direct expenses* include utilities, labor, and maintenance. The sum of these two sections is the *direct conversion expense*. The *indirect expenses* include the depreciation and plant indirect expenses, such as plant security, fire protection, roads, docks, and so forth. These expenses occur continually regardless of whether a product is produced. The sum of these expenses is the *total indirect conversion expense.*

16.3.3.2 Operating Expense Items

1. *Raw materials*. A material balance is always needed to determine the amount of raw materials and their costs. The quality grade and the form of the raw material (powder, flake, crystal, or liquid) affect the cost. Quantity discounts on large contract amounts

TOTAL DIRECT CONVERSION				1,616	
INDIRECT EXPENSE					
Depreciation				1,143	
Factory Indirect Expense				240	
TOTAL INDIRECT CONVERSION				1,383	
TOTAL CONVERSION				2,999	
TOTAL MANUFACTURING COST				6,299	

have potential savings, but storage facilities, which increase the capital investment, may be needed. The cost is also affected by the way the material is delivered—drums, leverpaks, carboys, tank trucks, tank cars, barges, or pipeline. Some raw materials may be seasonally produced, which might present a storage problem.

2. *By-products*. By-products are reported the same way as raw materials but are entered separately. The pricing of by-products depends on the current market for the material. If there is no market, then credit cannot be claimed. If by-products have a market value, they may be credited at their net value.
3. *Utilities*. The utility requirements for a process are obtained from both a material and energy balance. The unit costs for each utility may be obtained from plant expense sheets, the accounting department, or a utility superintendent. These costs often increase continually, so they should be reviewed frequently. Utilities are usually steam (high-, medium-, and low-pressure) and their associated unit costs, electricity, natural gas, cooling tower water, and treated or city water. Sometimes instrument air, demineralized water, and refrigeration are considered utilities if they come from a central source and are not tied to a given process.
4. *Labor*. Operating labor is usually the second largest expense. The most reliable way of projecting labor requirements is to prepare a table of shift, weekend, and vacation coverage. If the estimator has not had previous experience, it is advisable to seek help from operating personnel. For continuous coverage of one laborer per shift, 4.2 laborers are required, assuming a 40-hr work week. The labor rates may be obtained from the union contract or from the plant labor-relations person. In the southwest United States, a rate for a qualified operator is between $38,000 and $49,000 per year (2007). Information on labor requirements in chemical plants in the literature is meager. The Wessel Equation (1952) tends to predict high labor requirements and does not take into account increases in labor productivity.
5. *Supervision*. For preliminary purposes, use 20% of the labor expense. Some estimators consider supervision as a fixed expense at 100% of capacity operation. If a supervisory position can be identified, then a typical salary may be obtained from a plant accountant.
6. *Payroll charges*. These include paid vacations, pensions, group insurance premiums, disability pay, social security premiums, and unemployment taxes. Estimate these as 30 to 35% of the labor plus supervision expense.
7. *Repairs (maintenance)*. The best source of information about the materials and labor costs is a company's records. Little useful information is in the open literature. For preliminary estimates, the total of the materials and labor expense is 6 to 10% of the fixed capital investment per year. The higher percentages in this range should be used for processes that have a large amount of rotary equipment, and lower percentages for processes that operate at or near ambient conditions. If the repair expenses must be split into materials and labor, use 40% for materials and 60% for labor.
8. *Supplies*. This expense includes chart paper, computer paper, filter cloths, brooms, mops, and so on. Company records are the best source, but use 6% of the operating labor for preliminary estimates.
9. *Laboratory expenses*. The use of on-line analyzers and sophisticated analytical equipment often eliminates expensive and time-consuming tests. There are, however, certain tests that can be performed only in a laboratory. The charges for these services are escalating rapidly and may be between $130 and $300 per laboratory hour (2007). As an alternative, for complex processes, an estimate of 10 to 20% of the operating labor is reasonable.
10. *Clothing and laundry*. Manufacturing departments that produce a highly toxic material or a pharmaceutical or food product often provide clothing and laundry services for their operating personnel. For estimating purposes, use 6 to 10% of the operating labor expenses.

11. *Other expenses*. Technical services for troubleshooting process problems may employ a young engineer at a salary of about $50,000 to $60,000 per year (2007). Expenses for environmental control often include the costs of incineration, chemical treatment of the waste, landfill, and perhaps notification, documentation, reporting, manifesting, and labeling under RCRA legislation. The most reliable source for these figures is the environmental engineering staff in the specific plant, with some elaboration as given in Section 16.7.
12. *Total direct conversion expense*. The sum of items 3 through 11 is the *total direct conversion expense.*
13. *Indirect conversion expenses* include (a) depreciation and (b) plant indirect expenses. (a) Depreciation is the major component of indirect expenses. For estimation purposes, the annual depreciation is assumed to be straight-line and is calculated by dividing the fixed capital investment by the number of years over which the investment is to be depreciated. (Accelerated depreciation is not normally entered into the manufacturing expense sheet but is used in cash flow analyses after backing out straight-line depreciation from the manufacturing expenses.) (b) Plant indirect expenses include many items such as *ad valorem* and real estate taxes, insurance, maintenance of yards, docks, and roads, cafeterias, fire protection, and security. Plant accounting departments often compile factors to be applied for each plant site. To estimate this expense, use 2 to 4% of the fixed capital investment per year.
14. *Total indirect conversion expense* is the sum of depreciation and plant indirect expenses.
15. *Total manufacturing expense* is the sum of the net raw material expense, the total direct conversion expense, and the total indirect conversion expense.
16. *Packaging, loading, and shipping expenses*. The packaging expense includes the container and the labor to package the product. The loading expense may entail moving the product from the manufacturing department to a centralized storage facility before shipping to a customer. Under the shipping expense may be labor charges for loading on trucks or rail cars and any materials, such as dunnage, required to protect the product containers. Transportation charges vary widely depending on whether the product is shipped by pipeline, barges or tankers, railroad cars, or tank trucks. Companies maintain good expense control records on this item. Depending on the manner in which a product is packaged and shipped, this expense could vary between $0.013 and $0.034 per kilogram of product (2000).
17. *Total product expense* is the sum of the total manufacturing expense and the packaging, loading, and shipping expenses.
18. *General overhead expenses* refers to the expense in maintaining sales offices throughout the country, staff engineering departments, research laboratories, and administrative offices. All products are expected to share in these burdens, so an appropriate charge is made for each product. Company accounting departments frequently develop formulas or factors based on sales. The charge is highly dependent on the amount of customer service provided. A factor between 6 to 15% of the annual sales revenue may be assessed. The former figure is for established commodity products, and the latter for new specialty or fine chemicals.
19. *Total operating expense* is the sum of the total product expense and the general overhead expense.

Example 16.2

The Acme Specialty Company is considering manufacturing Plasticizer M. The engineering department has estimated that a fixed capital investment of $8 million will be required to produce 7.5 million kilograms of product per year. The product is expected to sell for $1.24 per kilogram.

The net raw material expense is $0.44 per kilogram. It is estimated that three operators per shift will be required. The process is semicontinuous and is assumed to operate at 90% stream time. Other costs and usages are

Utilities	Usage/kg Product	Cost
Steam	4.0 kg	$7/Mg
Electricity	2 MJ	1 cent/MJ
Cooling water	40 L	1 cent/1000 L
City water	40 L	8 cents/1000/L

Maintenance—6% per year of the fixed capital investment
Average operating labor expense—$35,000 per year
Supervision—$3,000 per month
Payroll charges—45% of labor plus supervision
Supplies—$250 per month
Clothing and laundry—$500 per month
Laboratory charges—40 hours per month at $75 per hour
Packaging, loading, and shipping charges—1 cent per kg of product
Other direct expenses—$1,000 per month
Depreciation—straight-line for seven years
Plant indirect expenses—3% of the fixed capital investment per year
General overhead expense—6% of the annual net sales

(a) Prepare an annual manufacturing expense sheet based on full production.
(b) Calculate the total annual operating expense.

Solution

Table 16.10 has been filled in with the data from this example. Below are the details of the calculations:

Basis: One year of operation
Annual sales: 7,500,000 kg/yr × $1.24/kg = $9,300,000
Manufacturing expense sheet:
Net material expense: 7,500,000 kg/yr × $0.44/kg = $3,300,000
Direct conversion expenses:
Utilities:
Steam: 7,500,000 kg product × 4 kg steam/kg product × $7/Mg steam = $210,000
Electricity: 7,500,000 kg product × 2 MJ/kg product × $0.01/MJ = $150,000
Cooling water: 7,500,000 kg product × 40 L/kg product × $0.01/1,000 L = $3,000
City water: 7,500,000 kg product × 40 L/kg product × $0.08/1000 L = $24,000
Total utilities: $387,000
Labor: 4.2 operators × 3 operators per shift × $35,000 = $441,000
Supervision: $3,000/mo × 12 mo/yr = $36,000
Maintenance: 0.06/yr × $8,000,000 = $480,000
Payroll charges: 0.45 × ($441,000 + $36,000) = $215,000
Supplies: $250/mo × 12 mo/yr = $3,000
Clothing and laundry: $500/mo × 12 mo/yr = $6,000
Laboratory charges: 40 hr/mo × 12 mo/yr × $75/hr = $36,000
Other direct expenses: $1,000/mo × 12 mo/yr = $12,000
Total direct conversion expense: $1,616,000

Indirect conversion expenses:
Depreciation: $8,000,000/7 yr = $1,143,000
Plant indirect expenses: $0.03/yr × $8,000,000 = $240,000
Total indirect conversion expenses: $1,383,000

Total manufacturing expenses: $6,299,000 (answer a)

Packaging, loading, and shipping expense: 7,500,000 kg product × $0.01/kg = $75,000
General overhead expenses: $9,300,000 × 0.06 = $10,000

Total operating expenses: $6,984,000 (answer b)

Actual operating expense reports, given in Table 16.10, form the basis for information needed for the income statement, Table 16.8, such as the cost of goods sold, depreciation, amortization and depletion, and general overhead expense. This information would be used in the quantitative measures of financial attractiveness.

16.3.4 Estimation of Fixed and Total Capital Investments

The fixed capital investment is the cost to build the manufacturing facility. Corresponding to the different levels in the gating process given in Table 16.1 are methods of cost estimation that have different levels of accuracy. Here we describe estimation methods for the conceptual design stages that use process cost correlations (which are usually accurate to ±40 to 50%) and the "bare module" factor method (±30%). Some estimation methods provide improved accuracy but require vendor quotations; detailed estimates of material costs of piping, valves, and insulation; and estimates of installation labor hours and the mix of labor rates. Such methods are beyond the scope of this chapter.

The methods described here work well if clear definitions, unambiguous terminology, and correct methods to account for alloys, inflation, and location are used, and if care is taken to include all of the cost contributions.

16.3.4.1 Definitions and Terminology

Battery limits cost (BL). This includes the cost of the process itself and excludes the costs of utilities, storage, and services unless these are required only for this process.

BL cost estimation. The simplest and least accurate method uses a correlation of the cost with the capacity of final product. When more accuracy is needed, the process equipment is costed, and costs are attributed to all the components needed to convert the equipment items into a complete working BL process. Many different methods have been developed, depending on the accuracy needed.

Outside battery limits or *offsite costs*. Factory-site (as opposed to process-specific) facilities such as (a) access roads, rail spur lines, paving, unloading and loading facilities; (b) utilities facilities

such as boiler houses, electrical transformer stations, water supplies, cooling towers, and oxygen or nitrogen supply systems; (c) water treatment facilities; (d) environmental impact facilities for wastewater, air, solids, odors, and noise; (e) storage, including bulk storage for feed, products, and by-products; and (f) support facilities such as administration buildings, laboratories, cafeterias, gatehouses, maintenance shops, and firefighting, communication, purchasing, and safety facilities.

Grass roots or green field cost. This accounts for the all of the facilities needed to convert a grass field into a complete working plant site: BL plus offsites.

Main plant items (MPI). These include all "major" process- and utility-related equipment. "Major" includes pumps, fans, in-line filters, and installed spare equipment but excludes valves, piping, fittings, pipe hangers, heat tracing, lighting, vents, hoists, interlocks, breakers, and starter panels. Skid-mounted packages are considered to be one MPI.

FOB cost. The cost of the crated, fabricated equipment loaded onto a carrier at the location of fabrication (or another specified location). The acronym FOB stands for "free-on-board," meaning the equipment has been placed on board the carrier without an additional loading charge, e.g., FOB Pittsburgh. Such a cost does not include tax, duties, freight, and delivery costs. The term "purchase cost" is ambiguous.

Bare module cost (BM). A BL process is divided into a collection of *modules* for each type of MPI: reactor module, heat exchanger module, and membrane module. The boundary for a module has been selected from experience so that the sum of the costs of all modules for all MPIs for the process equals the cost of the whole process. In general, the *module* boundary is about 2 m from the outside of the equipment. Thus, the cost of a "pump" module would include the FOB cost of the pump plus the material and labor costs for the yard work, sewers, piping, electrical, instruments, concrete, structural steel, a section of the pipe rack through the module, painting, and electrical plus the cost of inspection, hauling to site, attaching the baseplate to the plinth, aligning the drive and the pump, and hooking up the pump to the electrical and piping. The BM cost usually does not include offsites or buildings. The BM cost includes duties, freight and delivery charges, and taxes and expenses for the design; obtaining vendor quotes and ordering the equipment; and the field work to oversee the installation. However, it excludes contingency, contractors' fees, lawyers' fees, royalties, land, and expendables such as catalyst and solvent.

BM factor method of cost estimation. Component costs within the BM are estimated as percentages (or factors) of the FOB cost. The factors differ depending on the type of equipment in the module and the alloys. Two types of factors have been developed: (1) $L + M^*$ factors to account for the FOB cost plus the materials and labor for the supports, concrete, electrical, process and utility piping, vents and sewers, insulation, and painting, plus labor for inspection and installation but excluding instruments and instrumentation. (2) *Indirect cost factors* for home office and field expense.

16.3.4.2 Cost Contributions for One Type of MPI

For one type of MPI, 21 contributions accrue to be the total capital cost for that MPI. The sum of these for all MPIs represents the total capital cost for the process. The cost contributions are shown below.

1. *The FOB cost*. FOB costs can be obtained from correlations or vendor quotations. For most installations, the FOB cost is about one third to one fifth of the total fixed capital cost. "Delivered costs" should be separated into an FOB cost with the delivery, taxes, and duties expense to be accounted for in item 6. For larger equipment that must be fabricated in the field, the FOB for this MPI is replaced by the *field erected cost.*
2. *Direct module labor and material cost, $L + m^*$ cost, and the $L + M^*$ cost.*
   (a) *$L + m^*$ cost*. The costs for the materials, m^*, needed within the module are expressed as a factor of the FOB carbon steel equipment cost. Some illustrative values for

different takeoffs are supports (0 to 25%), concrete (5 to 10%), electrical (3 to 5%, with 10 to 15% for fans and compressors and 30 to 75% for pumps), process and utility piping, vents, and sewers, including the "local" pipe rack within about 2 m of the equipment (15 to 60%), insulation (3 to 25%), and painting (1 to 3%). For carbon steel equipment, the material cost, m^*, is usually 60 to 70% of the FOB cost for process equipment handling fluids and 20 to 30% of the FOB cost for process equipment handling primarily solids. Instrumentation costs are handled separately in item 3. The other "material" cost within the module is the FOB cost, item 1.

The costs for the labor, L, include those to receive, uncrate, inspect, haul to the site, and install the equipment, and the labor to install all materials needed to provide the local environment to operate the equipment. If the unit is a skid-mounted package, then the labor cost is 20 to 45% of the FOB cost, which represents the minimum labor cost.

The sum of $L + m^*$ accounts for materials and labor within the BM but excludes the FOB cost (item 1) and excludes freight, tax and duties, instrumentation, buildings, land and site preparation, and long runs of piping needed to connect equipment modules separated by more than the usual distance because of safety. These latter costs are site specific and are added separately.

(b) $L + M^*$. For ease in calculation, the FOB costs from item 1 are combined with $L + m^*$ costs and expressed as $L + M^* = L + m^* + FOB$. That is, $L + M^*$ cost $= FOB_{carbon\ steel} \times L + M^*$ factor. This approach would be used for the purposes of decisions made at Gate 3 in Table 16.1.

The * indicates that the instrumentation costs have been excluded from the factor, and instrumentation is estimated in item 3. Typically, $L + M^*$ factors are in the range 1.2 to 3 times, depending on the type of equipment and the number of such pieces being installed. Table 16.11 gives example values of the factors. Care is needed, because published data report $L + M$ factors but use them as $L + M^*$; others confuse $L + m$ with $L + M$. All $L + M^*$ factors are based on FOB carbon steel equipment; the $L + M^*$ factor varies dramatically with material of construction. Section 16.3.4.5 gives the details.

The $L + M^*$ can be separated into a labor cost and total materials M^* cost if the L/M ratio is known. The L/M ratio ranges from 0.15 to 0.65, with 0.4 as the usual value. Figure 16.2 illustrates how the factors interact.

TABLE 16.11
Illustrative Breakdown of Material and Labor Components

	Centrifuge			Rotary Drum Filter			Crystallizer		
	Total	**Labor, *L***	**Material, *M***	**Total**	**Labor, *L***	**Material, *M***	**Total**	**Labor, *L***	**Material, *M***
FOB	1.00			1.00			1.00		
Setting		0.101		1.104	0.104			0.076	
Piping		0.109	0.25		0.07	0.59		0.17	0.41
Insulation		0.024	0.04		—	—		0.024	0.05
Paint		0.01	0.01			0.05		0.005	0.01
Elect		0.122	0.27		0.01	0.10		0.036	0.05
Concrete		0.038	0.09		0.01	0.13		0.048	0.06
Steel		0.049	0.10		0.01	0.15		0.048	0.07
*L+M**	2.21	0.453	0.76	2.224	0.204	1.02	2.06	0.407	0.65
L/M	0.26			0.10			0.24		

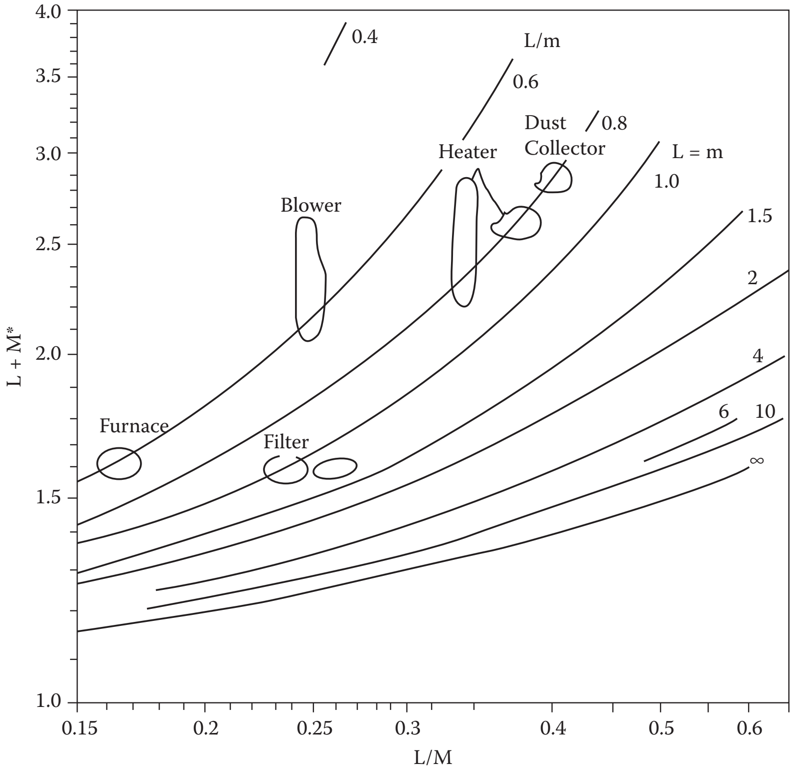

FIGURE 16.2 *L+M**, *L/m*, *L/M*.

3. *Direct L + M instrumentation cost*. Costs for instrumentation are relatively independent of the FOB cost and of the size of the equipment. Hence, the factor method described in item 2 should not be used; instead, methods given in Section 16.3.4.4 are recommended.
4. *Within BL building and housing costs.* This includes the concrete and structural steel for the building, heating, lighting, and ventilation but excludes the foundations and supports for the MPI and process piping for vents and drains that have already been accounted for in the module cost, item 2. Process buildings can be estimated based on a cost per square meter, based on methods given by Richardson (annual), Navarrete (1995), or (as a last resort) 10 to 45% of the FOB cost for fluid processing equipment or 15 to 60% of the FOB for solids processing equipment.
5. *Subtotal*. The sum of the *L* + *M** cost (item 2, which includes item 1, the FOB cost), the cost of instruments (item 3), and the cost of buildings (item 4) is called the *L* + *M module cost.*
6. *Tax, duties, freight, and insurance costs*. These typically total 15 to 25% of the FOB cost. The freight is 2 to 5% of the FOB cost, with 3% being usual. For overseas, use 5 to 10% of the FOB cost.

   Some processes (e.g., water and wastewater treatment facilities) include concrete vessels plus traditional pumps, heat exchangers, and mixers. To cost such facilities, it is more realistic to report the sum of the *L* + *M* module costs and the delivery, taxes, and duties. We refer to this cost as the *physical module (PM) cost.*
7. *Offsites*. These are usually costed separately (Woods et al., 1979) or, as an approximation, allow 1 to 5% of FOB for small modification of the offsites, 5 to 15% of FOB for restructuring the offsites, and 15 to 45% of the FOB cost for a major expansion of the

offsites. For grassroots plants, this is about 45 to 150% of the FOB cost, but the costs should be determined separately for each facility.

8. *Indirects*. Engineering home office expense includes the salaries paid to design engineers, computer time, administration of the contract, records, and drawings for this piece of equipment. This is usually about 10 to 20% of *M* or 9% of the *L* + *M* cost, with larger values needed for small projects.
9. *Indirects*. Field expense includes the salaries for the onsite personnel during construction, security, and inspection during construction for this piece of equipment. This is usually about 20% of the *L* + *M* module cost or 50 to 80% of *L*.

   The total of the indirects, items 8 and 9, is 10 to 45% of the *L* + *M* module cost, with small values for large projects.
10. *Total*. The sum of items 5, 6, 8, and 9 (with an allowance for modification of the offsites as needed, item 7) is referred to as the *direct* or *bare module costs (BM).*
11. *Contractors' and subcontractors' fees.* This is usually 3 to 5% of the BM cost.
12. *Contingency* for strikes, tornados, floods, and unexpected delays in delivery. This is usually 10 to 15% of the BM cost and does not include engineering errors, engineering uncertainties in design, or uncertainties in quotations.
13. *Design contingency* for changes in the scope during construction. Allow 10 to 30% of the BM cost.
14. *Total.* The sum of items 10, 11, 12, and 13 is called the *total module cost (TM)* or the *fixed capital investment cost.*
15. *Royalties, licenses, know-how fees, and regulatory permits.*
16. *Land* and (a) the initial site preparation such as grading and drainage and (b) the special foundation costs such as pile driving and rock blasting. These costs are important for many wastewater treatment facilities, which are often located on low-grade land. This is often about 1 to 2% of the TM cost. Site development is sometimes expressed as 10 to 20% of the FOB cost.
17. *Spare parts* (these are especially important for remote factory sites). Use 4 to 8% of the FOB equipment cost for the MPI or 1 to 2% of the TM cost.
18. *Interest* during the construction period and/or the cost of borrowing capital and paying it back, as with a municipal bond. This can be estimated to be 6% of the TM cost.
19. *Legal fees.* An estimate might be 1% of the TM cost.
20. *Working capital.* This accounts for the initial charge of solvent, catalyst, heat transfer media, and initial inventory of raw materials and of product awaiting sale. For commodity and pseudocommodity products produced at a uniform rate, use 15 to 20% of the TM cost. For seasonal products such as herbicides and fertilizers, use 25 to 40% of the TM.

    For specialty products like perfumes, cosmetics, and flavors with high raw material costs and relatively low TM costs, it may be preferred to express working capital as 15 to 40% of sales, with 30% being a reasonable value.
21. *Startup expenses.* These include a living allowance for the startup team, special tests and test equipment, and computer costs until the process is producing specification product. Estimate as 8 to 10% of the TM cost. Operator training is 0 to 4% of *M*. The total startup expense is 15 to 40% of *M*.

Although the 21 items usually represent the total capital investment, different items are excluded for different purposes. For example,

- Item 20. This cannot be included as the cost of fixed assets for government depreciation purposes.
- Item 18. For a municipal waste treatment facility, the project must be self-financed, because the municipality does not have a continual reserve. Hence, the cost of capital

and paying it back must be included. The cost is called the *bonded fixed capital cost* and is about 25% larger than the usual fixed capital investment, TM cost.

- Item 15. A waste recycling facility requires permits under legislation. Although the cost of the permit may be nominal, the cost of the public hearings, consultants, and expert witnesses needed as part of the permit application increases the cost to be about $1 million (2000). For more, see Section 16.7.
- Item 8. Home office expense may be paid for by the government on certain projects such as wastewater treatment. That is, a government agency may design the facility.

In summary, the total capital investment is the sum of several dozen cost components. The challenges in estimating the costs are to include all of the needed items and not to double count, be fully aware of local and federal regulations and legislation so that appropriate items are included and excluded, use clearly defined terms, include error estimates so that the accuracy of estimate is understood, and include the currency, location, and date.

16.3.4.3 Accounting for Time and Location

16.3.4.3.1 Time

Prices change with time. However, because of the development of inflation indices specific to the process industry, capital costs from the past can be scaled to current conditions by multiplying by the ratio of inflation index values:

$$Cost_{now} = cost_{then}\ [index\ value_{now}/index\ value_{then}]$$

More than 40 capital cost indices have been developed. These include

- *Marshall and Swift, MS* (formerly Marshall and Stevens, 1926 = 100); cost compiled quarterly for U.S. conditions, primarily for insurance companies interested in the changing value of the assets of companies. A separate MS index is compiled for the overall industry and for eight process and four related industries. Published in each issue of *Chemical Engineering*.
- *Chemical Engineering Index, CE* (1957–1959 = 100); cost developed for U.S. conditions primarily as a plant construction index. Separate CE indices are published for process equipment, heat exchangers and tanks, process machinery, and for each of the cost components and for the overall weighted total for a typical process. *CE instruments* is used in Section d. Published in each issue of *Chemical Engineering*.
- *Vatavuk Air Pollution Control Cost Index* (VAPCCI; 1994 = 100); FOB vendor quotes for U.S. conditions for nine types of air pollution control equipment. Published in each issue of *Chemical Engineering*.
- *EPA-STP Treatment Plant Index* (1957–1959 = 100); fixed capital investment costs for U.S. conditions of primary and secondary wastewater treatment plants averaged monthly over 20 U.S. cities.
- *Nelson Refinery Index* (1946 = 100); fixed capital investment costs for U.S. conditions for refineries (without consideration of changes in technology). The Nelson true-cost index accounts for changes in technology. Published in the *Oil and Gas Journal*.

In addition, process industry cost indices have been published for Canada, the United Kingdom, France, India, Italy, Japan, Germany, and The Netherlands. Table 16.12 gives values of the CE and MS indices that are general and reliable for North American conditions. All data reported in this chapter have been scaled into the future using CE = 1000 or CE instruments = 1000.

Costs obtained from the current value of CE can be inflated to future times based on an estimate of the annual inflation rate.

TABLE 16.12
Inflation Indices

	CE Index (1957–59 = 100)	CE Instruments (1957–59 = 100)	MS; Process Industry (1926 = 100)	M&S Index: All Industry (1926 = 100)
1980	261.1	249.5	676	659.6
1981	297.0	287.9	744.9	721.3
1982	314.0	297.6	774.4	745.6

16.3.4.3.2 Location

Construction costs differ depending on the location, since labor costs and productivity differ. The labor component for North America can be extracted from *L* + *M** data through the *L/M* ratio data and adjusted to reflect location costs and productivity. Illustrative location indices, given in Table 16.13, compare construction costs for complete processes in U.S. dollars to the cost in U.S. dollars in a different country. Specialists in your company should be consulted to obtain pertinent data.

16.3.4.4 Estimating the *L* + *M* Cost of Instrumentation

Three options to estimate the cost are to use an average cost per MPI, cost the control elements per MPI, and cost the instrumentation for different types of equipment.

Option 1: Main Plant Items and an Average Cost for Instrument

For typical process plants, use $47,000 U.S. (CE instruments = 1000) per MPI; for highly automated batch processes, use $69,000 to $82,000 U.S. (CE instruments = 1000) per MPI. CE instruments is the *Chemical Engineering* inflation index for process instruments. Details are given in Section c and in Table 16.12. Scale the instrument cost to the correct time.

Option 2: Take-Offs for Different Types of Processes

Table 16.14, based on Navarrete (1995) and Page (1996), reports the number of different elements in the distributed control system (DCS) for the MPIs in different types of plants. The average number of field instruments decreases as the scope of the project increases.

TABLE 16.14
Number of Elements per MPI (Based on Page, 1996, and Navarrete, 1996)

	Different Types of Plants			
Elements	**Usual Overall**	**Batch Process**	**Continuous Process**	**Storage Area**
DCS Points	2	3.6	1.7	1.0
DCS wiring units	3	5.4	2.5	1.5
Field instruments	7.5–2.5	12	7	6.5
Air hookups	1	1.8	0.9	0.5

Total $L + M$ cost = DCS FOB cost + 2.1 (FOB cost for field instrumentation), where

DCS FOB, hardware including computer = \$5000 (CE = 1000)/point
FOB field instrumentation c/s equipment = \$1800 (CE = 1000)/balloon for carbon steel. The alloy cost factors are low alloy × 1.33, high alloy × 1.5.

Option 3: Costs for Instrumentation of Particular Types of Equipment

Table 16.15 lists "typical" DCS (control loops, C; alarms, A; and transmitters, T) and the types of field instruments (indicators, I, and relief valves, R) for different types of equipment and their FOB cost. For this list, we give an estimate of the installed instrument cost in Table 16.15. These results are reasonably consistent with the previous two methods.

16.3.4.5 Accounting for Materials of Construction Other Than Carbon Steel

In Section 16.3.4.2, the $L + m^*$ costs were expressed as a fraction of the cited FOB cost (which is usually carbon steel fabrication). If the equipment is made of an alloy, the FOB cost of the equipment is larger, say \$70,000 instead of \$30,000. However, the $L + m$ costs of concrete, painting, insulation, and other components in the BM remain about the same as they were for the carbon steel equipment. To account for this, we need to multiply the FOB alloy cost by an $L + M^*$ factor that is smaller than the factor reported for carbon steel. This is counterintuitive, because we intuitively may think "alloys" = "more expense for everything." The amount of reduction in the $L + M^*$ factor for carbon steel is determined from Figure 16.3.

Example 16.3

a. The FOB cost of a carbon steel pressure tank is \$70,000, CE = 400. What is the $L + M$ cost if the $L + M^*$ factor is 2.5?
b. The vessel needs to be 316 stainless steel. If the FOB alloy cost is 1.4 times the carbon steel cost, what is the $L + M$ cost?

Solution to Part a

The $L + M^*$ cost is $L + M^* \times \text{FOB} = 2.5 \times \$70,000 = \$175,000$.
Comment: In practice, a date or inflation index value and error range should be given with every cost estimate.
For preliminary estimates using FOB cost correlations and $L + M^*$ factors, the error is usually ±30%.
In addition, we need to add the $L + M$ cost of instrumentation. For a pressure tank, from Table 16.15, the $L + M$ cost of instruments is \$8300 at CE = 1000. Therefore, the cost at

TABLE 16.15
Installed Instrumentation Costs

	Different Types of Equipment										
	Reactor: Gas Phase	Reactor: Liquid	Condenser	Fired Heater	Heat Exchanger/ Reboiler	Distillation	Evaporator	Storage Tank	Pressure Tank	Intermediate Process Tank	Pump, Stage of Compressor
Flow	C	C	C	C		C, I					
Level		C, A		C, A		2C, 2A	C, A	I	I	C	
Pressure	2C, 2A R	2C, 2A R	I, R	I		3I, T, A, R	I, R	R	I, R	R	I, R
Temperature	C,A,2I	C, A, 2I	C, A	C, A	C, 2I	6I, 4C	I	I	I	I	I
Cost, US $	63,000	70,500	40,000	40,000	27,000	150,00	25,000	7,000	8,300	17,400	7,000
Cost US $ method (i)						46,000					
method (ii)	57,400	69,500	29,800	37,700	16,240	117,300	23,800	11,340	15,120	16,240	11,340

Note: CE instruments = 1000, for different process equipment (excluding control valves) based on Cran, 1981.

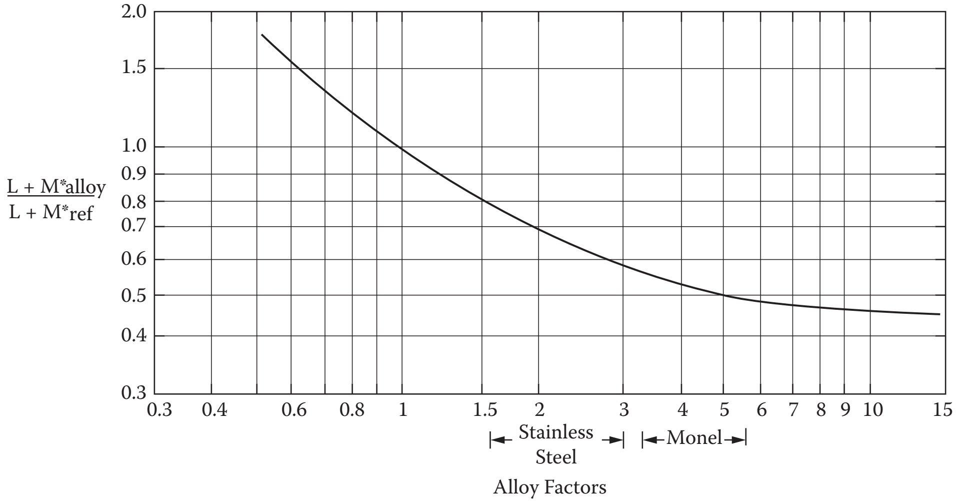

FIGURE 16.3 *L+M** and alloys (reproduced with permission from Donald R. Woods, *Rules of Thumb in Engineering Practice,* page 377, 2007, copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, ISBN: 978-3-527-31220-7).

CE = 400 would be found by the ratio of the indices = \$8300 × 400/1000 = \$3320. The *L* + *M* cost at CE = 400 is \$175,000 + 3,320 = \$178,320 or \$178,000 ± 30%.

Solution to Part b

The FOB cost of the stainless steel vessel is \$70,000 × 1.4 = \$98,000.

The *L* + *M** ratio for an alloy of 1.4 is 0.82, from Figure 16.3. The *L* + *M** factor for the alloy is therefore *L* + *M** carbon steel × correction factor = 2.5 × 0.82 = 2.05. Therefore, the *L* + *M** cost is \$98,000 × 2.05 = \$196,000 ±30% at CE = 400.

Comment: we need to add the cost of instruments = \$3320 from part a for an *L* + *M* cost = \$199,320 or 199,000 ± 30% at CE = 400.

16.3.4.6 Different Methods for Different Levels of the Gating Process

For *preliminary evaluation* (Gate 1 in Table 16.1), correlations for complete processes scaled up for capacity and for time are commonly used. For a *conceptual design* (Gate 2), FOB equipment cost correlations based on flow rate are often used and scaled up to BM cost based on *L* + *M** factors. For a *preliminary engineering design* (Gate 3), the equipment is sized more accurately; based on simple rules of thumb, the cost is estimated from FOB cost correlations related to equipment size and scaled up to BM cost based on *L* + *M** factors. The process and FOB cost correlations are all of the form

$$\text{cost} = \text{cost}_{\text{reference}} \left(\frac{\text{size}}{\text{size}_{\text{reference}}} \right)^n$$

Tables of cost data are given for the reference cost corresponding to the reference size, for example, *flow rate, annual production, filter area*, the exponent *n* (e.g., usually *n* = 0.6 to 0.7), the range of the size variable over which the correlation is valid, and the error (e.g., ± 30%). Sometimes the costs for one piece of equipment will be correlated with a different exponent, *n*, for different size ranges. For example, for flow rates 10 to 100, *n* = 0.4. For flow rates 100 to 1,000, *n* = 1.0.

That is, at flow rate 100, with $n = 1$, the cost doubles when the size doubles, and there no longer is economy of scale. Since the key size is where $n = 1$, polynomial curve-fit correlations of costs should be avoided, since the size corresponding to $n = 1$ is not obvious.

16.3.4.6.1 Process Cost Correlations

For this method, we need to know the names of the products, raw materials, process or the chemical reactions involved, and capacity. Treat with caution correlations developed from *construction boxscore* data because of ambiguity in process details.

An example correlation is BL ammonia (ex natural gas including reforming, CO converter, centrifugal compressors, methanation, low-temperature gas purification, and low-temperature/low-pressure synthesis); costs \$290 million for 400,000 Mg/annum product; $n = 0.7$ for range of 300,000 to 750,000 Mg/a ± 40% at CE = 1000.

Example 16.4

Estimate the BL capital cost of a plant to produce 600,000 Mg/annum of ammonia from natural gas. The current CE = 390; we estimate inflation to be 4% per annum and determine the cost for one year from now.

Solution

The desired production rate is within the range of the correlation. For CE = 1000, the estimated BL cost would be

$$\text{cost} = \$290 \text{ million}\left(\frac{600{,}000 \text{ Mg/a}}{400{,}000 \text{ Mg/a}}\right)^{0.7} = \$385 \text{ million US} \pm 40\%$$

Correct to the current time by using the ratio of CE values:

$$= \$385 \text{ million} \times 390/1000 = \$150 \text{ million}$$

Adjusting for one year of inflation at 4%:

$$= \$150 \text{ million} \times 1.04$$

$$= \$156 \text{ million U.S.} \pm 40\% \text{ one year from now}$$

16.3.4.6.2 Equipment Cost Correlations Based on Flow Rate and BM Factor Method

We need to know the flowsheet, the mass and energy balances, and the names and materials of construction of the processing equipment selected.

An example correlation is as follows. The FOB cost of a rotating biological contactor, including rotating mechanism, motor, and drive but excluding the basin, is \$900,000 at a design flow rate of 1000 m^3/day with exponent $n = 0.56$ valid over the range 45 to 1100 m^3/day ± 35% at CE = 1000. $L + M^* = 2$. $L/M = 0.35$.

Example 16.5

Estimate the cost at CE = 400 for an RBC for a design flow rate of 400 m^3/day day installed in an existing concrete basin.

Solution

The correlation applies. The FOB cost for CE = 1000 is

$$\text{FOB cost} = \$900{,}000\left(\frac{400}{1000}\right)^{0.56}$$

$$= \$539{,}000$$

$$\text{FOB cost at CE} = 400 = \$215{,}600$$

$$L + M^{*}\ \text{cost} = \text{FOB} \times 2 = \$431{,}200$$

Accounting for instrumentation, from Table 16.15, estimate minimal controls needed as \$8,000 at CE = 1000 or \$8,000 × 400/1000 = \$3,200. Hence, $L + M$ cost = \$431,200 + 3,200 = \$435,000 ± 35% at CE = 400.

16.3.4.6.3 FOB Equipment Cost Correlations Based on Design Size and BM Module Factor Method

For this method, the size, materials of construction, and conditions of operation for the process equipment must be known. The calculation is the same as that used in Example 16.3. The difference is an increase in accuracy for the estimate of the FOB cost because the correlation requires an estimation of *size* of the unit instead of the *flow to the unit*. For example, for a bag filter, we could use a cost correlation based on feed gas flow rate to the filter or, for increased accuracy in engineering design, use a correlation based on the bag filtration area. Since the gas flow rate/unit filter area depends on the specific application, the cost correlation based on filtration area is site specific and therefore more accurate. Cost correlations based on flow rate are usually less accurate (±25 to 40%) than those based on design size (±15 to 30%). Rules of thumb, given in Section 16.11, can be used to obtain the size.

16.4 BUILD A RELIABLE DATABASE

At the start of the project, and continuing throughout the project and for troubleshooting, we need a range of input data about the chemicals and reactions and about species used and produced in the process. Information may be supplied from chemists who have unraveled the mysteries of a synthesis or from a pilot plant or small-scale operations that provide key design data (as illustrated in step 4a in Table 16.1).

16.4.1 Input Data from Scientists

Traditionally, chemists take an approach different from that of engineers, so information needed by engineers may not be collected. For example,

Chemists Tend to:	Engineers Tend to:
Ask "Why?"	Ask "How can I use it?"
Work on small scale.	Work on large scale.
Process the chemicals "once through."	Often use "recycle" with a buildup of trace materials.
Consider a linear, once-through sequence.	Consider system.
Operate batchwise.	Operate continuously.
Neglect cost considerations.	Consider costs critical.
Use glass as the material of construction.	Use carbon steel or 316 stainless.
Work at atmospheric conditions.	Use a range of conditions.
Neglect disposal problems.	Consider waste disposal as a major concern.
Work in fume hood.	Place major interest on environment impact.
Control the process by watching & adjusting.	Use computers and control schemes to automatically control.
Focus on the yield of target product.	Need to know system information for mass and energy balances

Without good communication, scientists may collect data that are incomplete for design purposes, or engineers may infer incorrect conditions.

Example 16.6

"I crystallized the product in the usual way." Translation: crystallization was from slightly supersaturated conditions in the metastable region to promote homogeneous nucleation to yield large, easy-to-filter crystals. Scratching the inside of the glass vessel was needed to start the crystallization. The crystals were removed by filtration. No record was made of the volume of filtrate. The crystals were dissolved in pure solvent and then recrystallized. This was done three times until the crystals appeared pale. Engineers might infer that crystallization occurred in the labile region by seeding and that high purity and high yield of crystals were obtained after one cycle. They might infer that the crystals obtained were pure, robust, and easy to filter.

16.4.2 Minimize Uncertainty in Input Data through Experimentation: Principles of Scale-Up

Some process information is unknown or uncertain. To minimize the uncertainty, in step 4a, Table 16.1, we can gather data on a smaller scale. For the information to be valuable and transferable, the small-scale experiment should be geometrically, mechanical, thermally, and chemically the same as the proposed large-scale operation.

Geometrical similarity. Two bodies are geometrically the same when to every point in one body there exists a corresponding point in the other. *For example, a laboratory Florence flask reactor should be changed to a reactor of the same shape as visualized in the plant.*

Mechanical similarity. Similar bodies deform geometrically similarly when subjected to constant stress or when fluid tracers exhibit geometrically similar patterns on both scales for static,

kinematic, and dynamic conditions. To achieve this, the dimensionless numbers are kept the same for small- and large-scale operations. *For example, a mix in the lab should not be done with a magnetic stirrer, because this does match geometrically the large-scale operation from, say, a propeller agitator. For mechanical similarity, for some operations, operate at the same impeller Reynolds numbers for small- and large-scale equipment.*

For drops, bubbles, particles, or catalysts, we cannot scale down, because the area, volume, and surface/volume ratio change. For this situation, we often use the "element" strategy in which the small scale consists of a small slice of the real situation that contains the real size of the drops, bubbles, packing, or catalyst. Recurring sources of scale-up problems include (a) the inability to have similar equipment shape; (b) faulty accounting for the batch vs. continuous operation and the scale of operation; (c) changes in the surface/volume ratio that cannot be appropriately accounted for; (d) unexpected flow patterns; (e) flow instability and mixing characteristics, (f) wall, edge, and end effects; (g) materials of construction; (h) trace impurities; and (i) heat removal from gaseous, highly exothermic catalytic reactions.

16.4.3 Units of Measurement and Communication

My calculations for the first plant I designed were 10% too small. That is because I was working in *short* tons (2000 lb), whereas my supervisor in this UK-based company assumed I was using *long* tons (2240 lb). The definitions of such terms as ton, yard, inch, gallon, and barrel vary around the world. Fortunately, the SI (Le Systeme International d'Unites) eliminates most ambiguity, and the use of the time unit of seconds and length unit of meters allows simple determination of force and energy without additional factors. However, care is still needed. Some engineers and texts use metric units instead of SI and assume they are using SI. Examples include the archaic use of mm mercury, bar, torr, and kg/ cm^2 for pressure instead of Pa; the use of calorie instead of joule; and the use of minutes, hours, or days instead of the standard use of second.

Concerning powers, often the SI prefixes work well *provided* everyone knows the definitions. A common error is to use lowercase "m" or "MM" instead of capital "M" to represent 1000 kg. Care is needed to distinguish between gauge pressure and absolute pressure; it is recommended that all pressures (except for differences in pressure) be reported as kPa-g or kPa-a.

16.4.4 Gather Input Data from Databases for Design and Process Improvement

Data needed include expected variations in conditions; costs of materials, labor, equipment, and utilities; disposal limitations; sources; legal definitions and restrictions; environmental impact measures; and numerical values for the criteria. For all the species involved in the process, we need physical and thermodynamic data, and such reactivity and safety properties as flammability, corrosivity, abrasiveness, and propensity for dust explosions of solids, stability, environmental persistence and health indicators such as the LD_{50}, carcinogenicity, mutagenicity, and toxicity and those listed in Table 16.16.

TABLE 16.16
Definitions of Key Terms

ACGIH threshold limit value	American Congress of Governmental Industrial Hygienists threshold limit, see TLV.
Autoignition	Temperature above which a flammable mixture is capable of extracting enough energy from the environment to self-ignite. AIT. Benzene, 560°C; toluene, 480°C.
BLEVE physical explosion	Boiling liquid expanding vapor explosion is an explosion that occurs when a liquid stored above its boiling point is released into the atmosphere. Such a release immediately causes a shock wave; if the liquid is flammable, it can create a VCE. Example: A propane tank ruptures during a fire and causes a BLEVE followed by a VCE.
Carcinogenic	Risk of inducing cancer in humans or to increase its incidence.
Deflagration	An explosion caused by a very rapid chemical combustion in which the shock wave moves slower than the speed of sound. A deflagation proceeds by transport processes from the reaction front to the unreacted front. Contrast with *detonation*.
Detonation	An explosion caused by a very rapid chemical combustion in which the shock wave moves faster than the speed of sound. A detonation proceeds by a shock wave. Contrast with *deflagration*.
Dow rating	Hazard ratings are based primarily on flammability.
Dust explosion	Rapid combustion of fine solid particles. Upper and lower concentration limits of the dust explosion conditions are available.
Explosion	A rapid expansion of gas resulting in a rapidly moving pressure or shock wave. Three types of explosions are mechanical, thermal chemical, detonation, and deflagation. A mechanical explosion is caused by the pressure difference causing a vessel to rupture. A thermal chemical explosion has no reaction front separating unreacted from reacted materials: the rate of heat generated exceeds the rate of heat removal. In a chemical explosion, a reaction front separates reacted from unreacted materials. If the shock wave travels at less than the speed of sound, the explosion is referred to as a *deflagration*. If the shock wave speed is greater than the speed of sound, the explosion is called a *detonation.*
Fire point	Lowest temperature at which a vapor above a liquid will continue to burn once it is ignited; fire point > flash point.
Flammability limits	Upper and lower concentrations of combustible material in air that bound the region for combustion or explosion. Benzene in air at 298K and 101 kPa: 1.2 and 8.0% v/v respectively; toluene, 1.2 to 7.1% v/v, respectively. Increased temperature and/or pressure tends to lower the lower limit and raise the upper limit.
Flash point of a liquid	The temperature at which the vapor in equilibrium with the standard atmosphere above a pool of that liquid is at the lower flammability limit. Reported as open-cup or closed-cup. For materials that vaporize rapidly, the two values are about the same. For materials that vaporize slowly, the closed-cup temperatures are always less than open-cup data because of the conditions of the test. Benzene: –11.15°C; toluene: 4.0°C.
Hodge–Sterner toxicity classes	Rates 1 to 6 based on amount orally taken that causes death. Rating: 1, practically nontoxic, (15 g/kg) to 6, supertoxic (<5 mg/kg).
HON	Hazardous organic NESHAP (National Emissions Standards for Hazardous Air Pollutants). Rating of emissions and their impact on the environment. Subpart F denotes species as hazardous.
IDLH	Immediately dangerous to life and health concentrations are the maximum concentrations from which one could escape within 30 min without experiencing escape-impairing or irreversible health effects.
LD_{50} lethal dose	Administered orally or by skin absorption will cause death 50% of the time within 14 days. This can also be used as a crude index of biological activity or for an impact on the environment (Hushon et al., 1984, p. 95). Example: LD_{50} for 1-2 dichloroethane for rats for 30-min exposure is 12,000 ppm. For humans, the critical anesthesia limit is probably about 20,000 ppm.

Continued

TABLE 16.16 ***(Continued)***
Definitions of Key Terms

LC_{50} lethal concentration	Administered via 4-hr inhalation will cause death 50% of the time within 14 days.
LEL	Lower explosive limit, the minimum concentration of combustible material that will support combustion.
Light liquid	One that contains a liquid compound to the extent >20% w/w that has a vapor pressure greater than 0.3 kPa at 20 C.
Light liquid petroleum	One that has >10% evaporate at 150°C.
MAK	Maximale Arbeitsplatzkonzentration or maximum workplace concentration.
Mond rating	Ratings are based primarily on flammability.
Mutagenic	Risk of hereditable genetic defects.
NFPA	National Fire Protection Association. System gives a qualitative rating for health, flammability, and spontaneity. These values range from 0 to 4, with 4 being the most hazardous. These can be used for an initial screen to sensitize engineers to the potential hazard. Quantitative values are published elsewhere for each separate issue: health (TLV, STEL, IDLH); flammability explosivity (upper and lower explosive limits).
OSHA	Rating of employee exposure and working conditions.
Overpressure	Pressure exerted on an objective from an impacting shock wave.
PDEP corrosion index	Process Design and Engineering Practice qualitative rating on the corrosivity of pure components contacting carbon steel, copper, and 316 stainless steel. These can be used for an initial screen to sensitize engineers to the potential hazard (Woods, 1994).
PEL	Permissible exposure limits; typical worker can be exposed to this time-weighted average concentration of the substance for 8 hr per day, five days per week for a working lifetime, without ill effects.
RCRA	Resource Conservation and Recovery Act (U.S.). Legislation dealing with licenses, fees, and accountability for the processing of hazardous wastes.
STEL	Short-term exposure limit, a 15-min time-weighted average concentration. Example: TLV-STEL for monochloroethane is 1250 ppm or 3250 mg/m^3.
Teratogenic	Risk of subsequent nonhereditable birth defects.
TWA	Time-weighted average.
TLV-STEL	Threshold limit values as measured by short-term exposure. A typical worker can be exposed to this time-weighted average concentration of the substance for 15 min without ill effects. (UK based on 10-min TWA), benzene, 50 ppm.
TLV-TWA	Threshold limit values as measured on a time-weighted average (sometimes referred to as the ACGIH permissible limit values). Typical worker can be exposed to this time-weighted average concentration of the substance for eight hours per day, five days per week for a working lifetime, without ill effects. Example: TLV-TWA for monochloroethane is 1000 ppm or 2600 mg/m^3; benzene, 10 ppm.
UFL UEL	Upper explosive limit; the maximum concentration of combustible material that will support combustion.
VCE	Vapor cloud explosion; occurs when a cloud of combustible material is within the flammable or explosive limits.
VOC	Volatile organic compound.

Data from each of the HON, OSHA, NFPA, Dow, and Mond hazard ratings should be gathered. Example 16.7 highlights the disadvantages of using only one type of hazard indicator and the importance of knowing the legal ratings.

Example 16.7

Acetophenone is on the HON and HON Section F list (defined in Table 13.16) as a hazardous chemical. Thus, legally we must monitor and minimize emissions from vents, storage vessels, and transfer racks, and discharges to wastewater, and minimize leaks from rotating shafts, sampling, and

valves. On the other hand, the NFPA rating for *acetophenone* indicates only a modestly high flammability rating (Health 1, Fire 2, and Stability 0). Contrast this with *ethane,* which is not on the HON list and has a higher NFPA rating (defined in Table 13.16) of Health 1, Fire 4, and Stability 0.

16.4.4.1 Checklist for Reactivity

The key data to identify the reactivity of species include the following:

1. The *heat of decomposition*, ΔH_d, of the products in the absence of oxygen. The reaction is considered very hazardous, with potential for deflagration if $\Delta H_d > 0.2$ to 0.3 MJ/kg (AIChE, 1995), but the absolute value varies. King and CHETAH (King, 1990) cite $\Delta H_d > 1.25$ MJ/kg as being hazardous with $\Delta H_d > 2.9$ MJ/kg being likely to explode when subjected to mild heat or shock.
2. *Potentially hazardous reactants.* Spontaneous polymerizations with exothermic heat generation include styrene, substituted styrene, vinyl chloride, vinyl pyridine, acrylonitrile, butadience, isoprene cyclopentadience, and methyl isocyanate; reactions involving peroxides as illustrated in Table 16.17, azides, perchlorates, or nitro compounds; and decompositions, nitrations, oxidations, alkylations, aminations, combustions, condensations, diazotizations, halogenations, or hydrogenations.
3. The *exothermic heat of reaction* of the target and the by-product reactions gives an adiabatic temperature rise of >100 to 200°C (AIChE, 1995). Table 16.18 suggests some ranges for heats of reaction.
4. *Potential reactions between the process chemicals and the utilities*: water, air, coolants, lubricants, and oxidizers, for example. Table 16.19 lists materials that react strongly with water.
5. The *spontaneous stability* of the species: a high value of the NFPA value, i.e., those with an impact sensitivity of <60 J for solids and <10 J for liquids (AIChE, 1995).
6. The *explosive limits* for atmospheric and for reactor conditions. For example, for the oxidation of acetaldehyde to acetic acid, explosive conditions occur outside the operating window. However, for some processes during startup, the reactor passes through the explosive conditions to reach the operating window.
7. The *rate of temperature rise*, *dT/dt*, is a useful measured value for active control.
8. *Explosive conditions for dusts,* especially if the particles are <200 μm.

16.4.4.2 Checklist for Chemical Persistence

Table 16.20 gives example data for chemicals and their persistence in the environment. If such data are not available, such as from the database of Mackay and colleagues (1992 to 1997) or from Allen and Shonnard (2002), then we need to estimate the "ecological half-life" by estimating (1) the natural distribution in the environment and (2) the bioassimilation in the dominant compartment.

Step 1. *Natural distribution of a species* among the compartments (air, water, soil, and biota) can be estimated from its solubility in water, vapor pressure, and octanol-water partition coefficient. Use Figure 16.4 for estimation purposes. Species with a high ratio of vapor pressure/solubility and a low ratio of K_{OW}/solubility are likely to reside in the air. Species with lower values of the vapor pressure/solubility and higher values of the ratio of K_{OW}/solubility are likely to be in the sediments and concentrate in the biota. In Figure 16.4, the numeral in brackets is the ppm concentration in biota; a high value implies that the species would move up the food chain. The octanol-water partition coefficient, K_{OW}, suggests the ease with which a species is absorbed across a cell membrane and thus is a measure of the potential uptake of the target chemical up the food chain.

TABLE 16.17
Bonds That Are Potentially Hazardous

Type	Examples		
Vinyl	–CH=CH2	Styrene, vinyl chloride, ethyl acrylate	Exothermic polymerizations
	>C=CH–CC–	Vinyl acetylene	Contains peroxidisable hydrogen with potential for explosion
Congugated double bonds with carbon, nitrogen, and oxygen atoms	–CH=CH–CH=CH–	Butadience, isoprene, chloroprene, cyclopentadience	Exothermic polymerizations
	–CH=CH–CH=O	Acrolein, crotonaldehyde	Exothermic polymerizations
	–CH=CH–C=N	Acrylonitrile	Exothermic polymerizations
Adjacent double bonds	–CH=C=O	Ketene	Exothermic polymerizations
	–N=C=O	Methyl isocyanate, toluene diisocyanate	Exothermic polymerizations
Three-membered rings	O / \ –CH–CH2	Ethylene and propylene oxide, epichlorhydrin	Exothermic polymerizations
	NH / \ –CH–CH2	Ethylene imine	Exothermic polymerizations
Aldehydes	–CH=O	Acetaldehyde, buyraldehyde	Exothermic polymerizations: contains peroxidisable hydrogen with potential for explosion
	>CH–O–	Acetals, ethers, oxygen heterocycles	Contains peroxidisable hydrogen with potential for explosion
Isopropyl compounds	–CH2 >CH– –CH2	Isopropyl compounds, decahydronaphthalenes	Contains peroxidisable hydrogen with potential for explosion
Allyl compounds	>C=C–CH2–	Allyl componds	Contains peroxidisable hydrogen with potential for explosion
Haloalkenes	>C=CH–X		Contains peroxidisable hydrogen with potential for explosion
Dienes	>C=CH–C=CH<		Contains peroxidisable hydrogen with potential for explosion

TABLE 16.18
Heats of Reaction

Classification	Heat per Mass of Total Reactants Solvents and Diluents Fed to the Reactor, MJ/kg [King, 1990, 174]	Heat per Mol of Target Reactant, MJ/kmol	Examples
Extremely exothermic	>3	>150	Direct oxidation of hydrocarbons with air, chlorination, polymerization of ethylene without diluent
Strongly exothermic	>1.2 but < 3	100 to 130	Nitrations, polymerizations of propylene, styrene and butadiene
Moderately exothermic	> 0.6 but < 1.2	30 to 90	Condensation or polymerization reactions of species of molar mass 60 to 200
Mildly exothermic	>0.2 but < 0.6		
Thermally neutral	> –0.2 but < 0.2		Esterifications
Endothermic	< –0.2		Cracking

TABLE 16.19
Materials That React Aggressively with Water (Based on King 1990)

Solid Species	Gas, Liquid, Solid	Reacts with Water	To Produce
Acetic anhydride (liquid)	L	Moderately	steam
Acetyl chloride	L	Vigorously	steam and acid fumes
Alumina, activated	S	Moderately	steam
Aluminum alkyls	L	Vigorously	alkanes
Aluminum alkyl halides	L	Vigorously	alkanes
Aluminum chloride	S	Vigorously	steam and acid fumes
Aluminum phosphide	S	Moderately	phosphine
Calcium	S	Moderately	hydrogen
Calcium carbide	S	Moderately	acetylene
Calcium hydride	S	Vigorously	hydrogen
Calcium oxide	S	Vigorously	steam
Calcium phosphide	S	Moderately	phosphine
Ethyl aluminum dichloride	L	Vigorously	alkanes
Fluorine	G	Vigorously	oxygen and ozone
Lithium	S	Moderately	hydrogen
Lithium hydride	S	Vigorously	hydrogen
Molecular sieves, activated	S	Moderately	steam
Phosphorus pentoxide	S	Vigorously	steam and acid fumes
Phosphorus trichloride	L	Vigorously	steam and acid fumes
Potassium	S	Explodes	hydrogen
Potassium hydroxide	S	Moderately	steam
Silica, activated	S	Moderately	steam
Silicon tetrachloride	L	Vigorously	steam and acid fumes
Sodium	S	Vigorously	hydrogen
Sodium hydroxide	S	Moderately	steam
Sodium peroxide	S	Moderately	oxygen
Sulfur trioxide	S	Vigorously	steam and acid fumes
Sulfuric acid	L	Vigorously	steam and acid fumes
Thionyl chloride	L	Vigorously	steam and acid fumes
Titanium tetrachloride	L	Vigorously	steam and acid fumes
Zinc alkyls	L	Vigorously	alkanes

TABLE 16.20
Fate of Chemical Species: Distribution among Compartments and Degradation Rate within Each Compartment (Mackay and Paterson, 1991)

		Rate of Assimilation within a Compartment		
Synthetic Chemical Species	Illustrative Amount in the Compartment or Distribution among Compartments	Degradation Rate Constant, h^{-1}	Comments	Net Overall Rate of Assimilation in the Ecosphere
Benzene	air [2500 ng/m^3]	8.6×10^{-4}	partitions mainly to the air	about 50 to 200 h depending on the atmospheric temperature
	soil [0 01 µg/kg]	0		
	water [290 ng/L]	0.0048		
	biota [0.002 mg/kg]	0		
	suspended solids			
	sediment [0.5 ng/g]	0		
Benzopyrene	air [3.0 ng/m^3]	0		
	soil [0.04 mg/kg]	3.5×10^{-5}		
	water [11 ng/L]	3.5×10^{-5}		
	biota [0.26 mg/kg]	0		
	suspended solids			
	sediment [190 ng/g]	0		
Hexachlorobiphenol	air [1.4 ng/m^3]	0.		> 8 years
	soil [0.04 mg/kg]	1.5×10^{-5}		
	water [5 ng/L]	1.5×10^{-5}		
	biota [0.2 mg/kg]	1.0×10^{-6}		
	suspended solids			
	sediment [80 ng/g]	1.5×10^{-5}		
Hexachlorobenzene	air [0.2 ng/m^3]	0.0144		> 10 years
	soil [0.0009 mg/kg]	1.9×10^{-5}		
	water [1.3 ng/L]	0		
	biota [0.01 mg/kg]	0	high bioconcentration potential	
	suspended solids			
	sediment [7 ng/g]	0		

Example 16.8

Mackay and Patterson (1981) estimated that 79% of DDT would end up in sediments, 98% of benzene in the air, and 61% of p-cresol in water. Hence, the biodegradation of most interest would be for DDT in sediments, for benzene in air, and for p-cresol in water.

Step 2. *Estimate* the *bioassimilation* of the species in the dominant compartment.

16.4.5 Gather Data for Troubleshooting

The general principles are as follows:

1. Believe the facts and be cautious about the inferences. For example, the pressure gauge reads 230 kPa-g is a fact; an inference is that the pressure is 230 kPa + 110 = 340 kPa.
2. Be sensitive to your own style in collecting data and interpreting data. Those dominant J personalities in Jungian typology (MBTI) often prefer to act rather than collect data to determine a cause, whereas dominant P personalities may prefer to gather extensive data before deciding on a corrective action.
3. Beware of "pseudo diagnosticity," a fixation on one cause and a refusal to change even when data prove the cause to be faulty.
4. Prioritize: consider safety first, then short-term choices, and finally long-term options. An option might be to live with the "trouble."
5. If pertinent, focus on gathering data about *changes* that occurred.
6. Test both positive and negative parts of the hypothesis.
7. Use the general problem-solving guidelines from Section 16.2.

16.5 SUSTAINABILITY FROM THE START

Robèrt's (1992) program, The Natural Step (TNS), is preferred to such options as life cycle, ecological footprinting, and green engineering. The four principles of TNS are as follows:

1. Substances extracted from the core, mantle, and crust of the Earth (such as oil and fossil fuels, metals, and other minerals) must not systematically accumulate in the ecosphere. The rate of mining from the Earth's crust must not be at a pace faster than the extracted species can be redeposited and reintegrated into the crust. The rate of extraction can be reduced by recycling or by substitution. Table 16.21 lists minerals and compounds present in the lithosphere that are deemed to be economically extractable based on today's best practice. Also shown is the ratio of annual rate of mining to the rate of natural weathering. All abundant minerals (except iron) have values < 1. However, all scarce metals have values > 1. For the sources of energy given in Table 16.22, shift toward renewable resources.
2. Substances produced by society must not systematically increase in the ecosphere. Yet some synthetic substances are produced at rates faster than they can be broken down and integrated into the cycles of nature.
3. The physical conditions for productivity and assimilation within the ecosphere cannot be systematically diminished. Forests, wetlands, prime agricultural land, and natural plants and animals cannot be systematically diminished. The assimilative capacity of the ecosystem must exceed any rates of pollution so that nature can regenerate itself. The rates of use of renewable resources do not exceed their rates of regeneration. Table 16.23 illustrates the net rate of natural regeneration.
4. Since we have limited resources and a human population with needs, the basic human needs must be met with the most resource-efficient methods possible. The satisfaction

TABLE 16.22
Energy Sources (Harte, 1988)

Source of Energy	Estimated Reserves, EJ	Energy Usage, EJ/annum
Renewable		
Solar	—	
Wind	—	
Wood and dung combustion	—	30
Water	—	6.1
Nonrenewable		
Petroleum [43 GJ/kg]	10,000	135
Natural gas [50 MJ/kg]	10,000	60
Coal [29GJ/kg]	250,000	90
Tar sands	>2,000	0
Oil shale	2,000,000	0
Uranium [83 TJ/kg]	20,000	6.3
Thorium & uranium	10,000,000	0
Deuterium and lithium in seawater [250 TJ/kg]	10^{13}	0

TABLE 16.23
Some Example Biosystems and Their Net Rates of Productivity (Harte, 1988)

	Area, 10^{12} m^2	Mean Plant Biomass, kg (Carbon)/m^2	Net Primary Productivity, kg (Carbon)/m^2/annum
Forests			
Tropical	24.5	18.8	0.83
Temperate	12	14.6	0.56
Boreal	12	9.0	0.36
Woodland and scrubland	8.0	2.7	0.27
Savanna	15.0	1.8	0.32
Grassland	9.0	0.7	0.23
Swamp and marsh	2.0	6.8	1.13
Cultivated land	14.0	0.5	0.29

of the basic needs must take precedence over the production of luxuries. Furthermore, the focus should be on increasing efficiency rather than on increasing quantity.

16.5.1 Impact of Sustainability on Design

TNS principle 1 applies to Stage II in Table 16.2 and suggests that using renewable resources as the feedstocks (e.g., fuel derived from the fermentation of corn, *gasahol*) shifts the raw material from nonrenewable to a renewable resource. TNS principles 1, 2, and 4 are satisfied if the hydrocarbon raw materials are obtained from fermentation instead of from fossil fuels. TNS principles 1 and 4 suggest that aluminum be used instead of copper in electrical applications. TNS principle 4 suggests the use of electric motors instead of internal combustion engines.

16.5.2 Impact of Sustainability on Process Improvement

As engineers debottleneck, upgrade, and improve processes, The Natural Step criteria provide a convenient, and sometimes unsettling, set of guidelines.

16.6 OPERABILITY AND CONTROL CONSIDERED THROUGHOUT

Chemical processes must be controlled to make them operable, profitable, safe, and environmentally friendly. Issues of control affect process design, process improvement, and troubleshooting.

16.6.1 Control and Design

Control is the heart of process design; how to control the plant effectively should be in the designer's mind right from the very beginning of the design process.

16.6.1.1 Design: Impact of Control on the Initial Design Statement

The initial design statement usually identifies the target product, amount, and purity. However, the initial design goal should also include the base case conditions, the expected setpoint changes, and the likely process disturbances.

16.6.1.1.1 Range of Setpoints

The range in production modes is determined by *setpoint*:

- Production rate (processes typically operate at 80% design capacity).
- Product specifications and the distribution among products on multiproduct processes.
- The range in product purity. The product purity has a major impact on both capital investment costs and operating costs. For example, for distillation, increasing the purity specifications by 1% may increase the energy requirement by about 10%. For sulfur removal from waste gases, for the same volume of gas treated, the fixed capital investment triples when the sulfur removal is changed from 90 to 99%.
- The different grades of a product customers want and may want in the future, for example, the grades of acid.

16.6.1.1.2 Range of Anticipated Process Disturbances

Anticipated disturbances include the range in feedstock composition, the range in expected utility properties (summer and winter temperatures of the cooling water and of the air), the slow drift in reaction kinetics, the gradual deactivation of the catalyst, and the gradual fouling of heat exchangers. Downs and Vogel (1993) provide a good example of a well-defined problem with the setpoint specifications in Table 7 and the disturbances in Table 8 in their paper.

16.6.1.2 Design: Impact of Control on the Evolving Flowsheet

Major issues include surge volume, recycle, and the control system:

Surge volume. As the flowsheet design progresses, sufficient (but not excessive) surge volume must be provided. The trade-off is between a steady-state and a safety viewpoint, in which the surge volumes are eliminated to minimize the capital cost and the volumes of hazardous

material stored in intermediate surge vessels, and the control viewpoint, in which surge volumes provide sufficient liquid inventory to reduce the effects of changes in inlet stream flow rate and properties.

Recycle. Self-regulation must be provided for components and energy in recycle loops. Recycling of material can recycle disturbances if the control is, for example, based on level control. Disturbances in the heat balance can be recycled if extensive heat integration is used. Add trim heaters and coolers to damp out thermal disturbances.

Control system. For subsequent selection and sizing of pumps and compressors, we need to map out the number and location of the control valves. Since the number of control valves is related to the number *of control degrees of freedom*, identify the *control degrees of freedom*. For example, a typical hydrodealkyllation process with a reactor, furnace, vapor-liquid separator, recycle compressor, two heat exchangers, and three distillation columns has 23 *control degrees of freedom* (Luyben et al., 1997). This requires 23 control valves whose location affects the rest of the design and the safety and hazards (see Section 16.7).

Provide fast feedback dynamics for control: include an adjustable bypass around slow processes, inject cooling material to quench fluid streams, adjust flows that more directly affect the key controlled variable rather than flows that affect the process environment slowly. Select fast manipulated variables, even when costly, because they can provide a "trim" to slower, less costly manipulated variables.

16.6.1.3 Design: Impact of Control on the Type of Equipment Selected

Identify the process operating equipment constraints, conditions for reliable operation, and shutdown limits. For example, reactor operating temperatures should be 25°C less than the maximum temperature of the catalyst.

16.6.1.4 Design: Impact of Control on the Sizing of Equipment

For transportation equipment: Controllability affects the sizing of pumps and compressors. In determining the system resistance, the appropriate anticipated variation in flow and pressure (from both setpoints and disturbances) and the location and pressure drop across the control valves must be included. Ensure enough pressure drop across the control valves to provide good control. Although the rules of thumb vary, the general guideline is to allow 50% of the system frictional resistance or 140 kPa. The available net positive suction head (NPSH) used in the design affects the selection of the pumps for liquids.

For energy exchange equipment: Supply sufficient excess of heat transfer area in reboilers, condensers, cooling jackets, and heat removal systems for reactors to be able to handle the anticipated upsets and dynamic changes. Sometimes extra area is needed in overhead condensers to subcool the condensate to prevent flashing in the downstream control valves. Too frequently, overzealous engineers size the "optimum heat exchangers" based on an economic minimum based on steady-state conditions and produce uncontrollable systems.

For distillation columns: Add sufficient trays to account for disturbances and anticipated expansion of production. The expected turndown ratios affect the choice of internals in a distillation column with a large turndown ratio, suggesting the use of bubble caps; a low turndown ratio may point to structured packings. At the same time, safety and hazard analysis indicates that we want a minimum of liquid holdup in the system.

16.6.1.5 Design: Impact of Control on Issues beyond Conceptual Design

As the process design moves through the gating process of Table 16.1, attention to the details of piping layout is crucial for reliable control. Minimize process delays because of piping and large

time constants, minimize sensor dynamics (especially sample systems for analyzers), and provide the required upstream and downstream lengths of straight pipe for flow meter and sensor reliability. Prevent maldistribution of flow in parallel systems. The selection and location of steam traps and air vents are important.

Consider using statistical process control, reexamine the types and locations of sensors, and use the four basic levels of control: (1) basic process control system, (2) alarm system, (3) safety interlock system, and (4) relief system. Consider active/passive controls. Active controls include sensors to detect hazardous or unsafe conditions; for example, a flame sensor that is used to shut down the fuel supply if no pilot flame is present and sensors for trace impurities that trigger deflagration. Passive controls (or self-regulating control systems) include fail-open and fail-shut valves, safety relief valves, and bursting disks to release pressure; large solvent or heat transfer fluid heat sinks to absorb heats of reaction should the cooling system fail; and the addition of a cold shot or reaction inhibitor. Prevent overheating by limiting the steam pressure; use tempered water instead of steam to ensure that the heating medium cannot overheat sensitive reactants. Include process conditions that have a negative temperature coefficient on reaction conditions. Self-limiting reactor configurations could be used. Marlin (2000) provides details.

16.6.2 Control and Process Improvement

To improve processes and remove bottlenecks, one of the first areas of focus is control. For batch processes, consider installing surge volumes to smooth out variations and make overall batch operations more efficient. Add the four levels of control.

The location and type of sensor can greatly affect controllability, safety, and on-time reliability. Controllability can also be improved when a different type of sensor is used. For example, a temperature sensor might be used to infer composition. Such a sensor is easy, robust, and accurate in measuring the temperature. However, the new specifications for the purity have shifted the composition to a range where temperature measurements are no longer sensitive to the composition. Refractive index measurements should be used.

Control can often be improved by using statistical process control. Montgomery and Runder (1994, Chapter 14) and Kourti and MacGregor (1996) describe this approach.

16.6.3 Control and Troubleshooting

When trouble occurs, one of the first steps is to put the system on manual control and see if the trouble disappears. Other suggestions are given in Section 16.11.1.1 on rules of thumb for process control.

16.7 CONSIDER SAFETY, WASTE MINIMIZATION, AND ENVIRONMENTAL SENSITIVITY THROUGHOUT

Safety, waste minimization, environmental concerns, and health hazards should be considered together because of their commonality in impact and in the database, and because if we solve one problem, say in waste reduction, we often solve problems in the related areas such as safety and environment. Minimizing waste, environmental impact, and unsafe conditions are not always consistent with the minimum cost. The criteria given in Tables 16.1, 16.2, and 16.4 do not always agree.

16.7.1 Step 1: Target Opportunities

Know the legal and economic contexts and identify the opportunity.

16.7.1.1 Know the Legal and Economic Contexts

Consider each in turn.

16.7.1.1.1 The Legal Context

Engineering decisions must comply with laws related to hazards, the environment, wastes, recycling, and occupational health and safety. Federal, state, and community agencies regulate source reduction, waste reduction, pollution prevention, and hazardous materials. The legal definitions may be counterintuitive to traditional engineering ideas. To illustrate, the legal definition of "in-process recycling" may be *recycling unreacted feedstock to the reactor* whereas, from an engineering point of view, we might incorrectly think it to be immaterial whether *unreacted feedstock is recycled to a reactor in this process or in another*. The legal definition affects whether reporting is required.

In 1996, for example, a Pollution Prevent (P2) plan was required if >1 Mg/month of hazardous waste was generated. P2 plans were also needed for storage volumes that exceed legally defined volumes if regulated substances were used in quantities exceeding the thresholds, and if toxic pollutant discharges required NPDES permits.

16.7.1.1.2 The Economic Context

The economic context is that the use of designated species will usually add operating and capital expenses. Typically, annual overhead costs for processes using "hazardous species" can range from $400 to $200,000 per annum (2000) for notification, documentation, reporting, manifesting, and labeling required by law under the Resource Conservation and Recovery Act (RCRA). Annual general liability and insurance cost for wastes could be $600 to $1000 (2000) per Mg of waste. For some facilities, an RCRA permit may be needed, adding an additional cost to be included in item 15 for the capital cost estimation (Section 16.3.4). The initial permit fee could range up to $3 million (2000), with most of the cost resulting from public meetings, consultants, and expert witnesses.

16.7.1.2 Identify the Opportunity

Identify hazardous chemicals from databases as discussed in Section 16.4.4 and from local legal regulations. Identify the potential for hazards from the checklist for reactivity (in Section 16.4.4) and from HAZOP-type studies or fault-tree analysis (Crowl and Louvar, 1990). In HAZOP studies, use checklist key words as triggers to systematically analyze the impact of changes to *flow rate, temperature, pressure, composition, level, viscosity, heat transfer, reaction,* and *conditions* and the potential for *barrier failure* and *startup* and *shutdown* to cause hazards.

Identify the amount of wastes from mass and energy balances.

Use checklists, such as given in Table 16.24, to identify potential waste reduction and safety opportunities. Identify opportunities by challenging the nominal specifications.

16.7.2 Steps 2 through 5: Move from "Eliminate" to "Isolate" during the Design Process

Guidelines for inherent safety, environmental protection, or waste minimization can be summarized in the following five steps that move from elimination to isolation.

16.7.2.1 Step 2: Eliminate the Source

Eliminate the source at the reactor and elsewhere in the process.

16.7.2.1.1 At the Reactor: Eliminate, Substitute, and Recycle

Eliminate

Eliminate reactants that pose problems with sustainability, the environment, and the hazard.

Substitute

Modify the reaction pathway, the operating conditions, the heat management system, and the reactor configuration.

Change the reaction pathway. Select reaction pathways between the raw material and the desired product to eliminate the use of hazardous intermediaries.

Change the operating conditions. Alter the reaction conditions to eliminate the hazards or production of toxic waste. Waste by-products from the reactor can be eliminated if the reaction to produce the by-products is reversible (as for biphenyl production in the hydrodealkyllation process).

Change heat management systems. Substitute sources of thermal energy and provide active and passive control. For example, for the catalytic liquid-phase oxidation of a substituted acetophenone to produce carboxylic acid operating at 80°C, the reaction is very exothermic (–920 MJ/kmol acetophenone) and poses great potential for temperature runaway. Temperature runaway can be prevented by the use of a catalyst that deactivates at 100°C.

Change the reactor configuration to minimize hazard.

Recycle

Recycle by-products until the rate of production of the by-product equals its rate of consumption.

16.7.2.1.2 Elsewhere in the Process: Eliminate, Substitute, and Recycle.

Eliminate

Additives. Eliminate catalysts, solvents, and adsorbents. For example, use thermal hydrodealkylation instead of catalyzed hydrodealkylation.

Trace contamination. Eliminate by locating air and water intakes in pollution-free locations. For example, instrument air compressors for a plant site were incorrectly located beside ammonia refrigeration units. Throughout the plant, the ammonia reacted with the mercury to produce azides in the instruments.

VOCs. Eliminate by eliminating rotating shafts that must be sealed or by selecting a sealing mechanism that produces no emissions. Use welded pipe instead of flanges. Table 16.25 provides data for options.

The source of electrical hazards. Eliminate electric sparks and charge buildup; replace electrical with pneumatic instrumentation, replace electric-driven with steam-driven devices. Eliminate charge buildup by increasing conductance, e.g., increasing the conductivity of the atmosphere (via ionization) and increasing the conductivity of nonconductors (by humidification or additives).

TABLE 16.24
Potential Sources of Wastes and Safety Hazards

Wastes associated with the reactor (approximately 5 to 50 kg/Mg product) Unreacted feedstock Impurities in the feedstocks Undesirable by-products Startup and shutdown losses Gas purges Reactor washings Catalyst usage and losses Off-spec material from upsets; power failures; freezing	**Safety hazards associated with the reactor** (main source of hazard) Uncontrolled temperature excursion because of insufficient heat removal and/or loss of agitation (insufficient area, fouled surface, loss of solvent) Catalyst hot spot because of flow maldistribution or instabilities Accumulation of reactants Hazardous material Induced unexpected reactions because of contamination, heat, friction, or electrostatic Plugging and temperature/pressure buildup Explosive limits Incorrect sequencing of feedstocks Mischarging Corroded relief valves Corrosion and vessel failure
Wastes because of type of reactor operation Cleanout of lines between batches	**Safety hazards because of type of reactor operation** Incorrect switching sequence Hazardous residual left Single reactor for multistage reactions No tests for impurities No lockouts or interlocks
Wastes caused by operating conditions or because of equipment selected Tar bottoms from columns Filtrate washing; filter aids Interstitial purging of any packed system between cycles Coagulants Adsorbents, IX resins	**Safety hazards because of conditions or equipment** Hazardous residual left from previous cycle in batchwise adsorption, IX Flammable materials at high pressure and high temperature Flammable liquids above their atmospheric boiling temperature because of vacuum/pressure or refrigeration Operation near explosive limits (for dust or fluid systems) Processing spontaneously polymerizable materials or unstable materials. Large inventory (above critical value for each material) Unrecognized byproducts that interfere with operation: silica carry over from reactor to foul downstream heat exchanger; elemental sulfur buildup in crude oil distillation
Waste spent solvents (approximately 20 to 150 kg/Mg product) Solvent losses and purges of recycled Cross contamination with water	**Safety hazards because of solvents** Flammability and toxicity Trace cross contamination with water Trace surfactant buildup causing stable emulsion and decanter flooding/spillover Static charge buildup (especially with hydrocarbon/water flow)

Continued

TABLE 16.24 ***(Continued)***
Potential Sources of Wastes and Safety Hazards

Waste from general operation and maintenance Oils and lubricants Equipment cleaning Sampling and analytical losses Purges of internal environments at startup and shutdown	**Safety hazards from general operation and maintenance** Poor housekeeping, Electrical lines and water Maintenance done on wrong equipment Inadequate isolation of equipment; venting of atmosphere; removal of toxics Insufficient room around equipment
Safety hazards from packaging and storage Storage mass larger than safe maximum	**Wastes from packaging and storage** Packing, use of non-reusable drums Failure to use disposable liners Damage during storage Storage vessel residue Fugitive via vents
Safety hazards because of fugitive emissions	**Wastes from fugitive emissions** Seals around rotating shafts: valves, pumps, compressors, mixers Breathing from storage vessels
Safety hazard because of accidental spills	**Wastes from accidents** Incidental spills **Wastes from metal sludges** (approximately 0 to 150 kg/Mg product) **Wastes from slags and ashes** (approximately 10 to 50 kg/Mg product) **Non-chemical industrial wastes** (approximately 10 to 80 kg/Mg product)

Substitute

Mechanical gauges for mercury gauges. Nonhazardous additives: solvents, catalysts, filter aids, adsorbents, absorbents. Nonhazardous solvents can be identified by matching the Hildebrand hydrogen bond and polar solubilities parameters and the molar volumes. Example substitutions are water > nonpolar organic > aliphatics with flashpoint < 60°C > aliphatics with flashpoint > 60°C > aromatics > halohydrocarbons > polar organics > alcohols > organic acids > other oxygenates > nitrogen-bearing compounds > halogenated organics > chlorinated organics.

Recycle

Water. Caution: account for the buildup of trace amounts of other species; salts may precipitate if the concentration of salts becomes too high. Increased corrosion can occur because the recycle causes the buildup of unexpected species that enhance corrosion. Trace surfactants can build up and stabilize foams, causing foaming in distillation and stable emulsions in decanters. Although the buildup of trace species can be controlled by purging or by separation, the location of the purge stream can affect the overall performance. Purging minimizes but does not eliminate waste.

16.7.2.2 Step 3: Minimize the Source

If one cannot eliminate, one can at least minimize.

TABLE 16.25
VOC Release from Various Equipment Options

Source: Equipment Option		Rate, mg/s [King, 1990]	Rate, mg/s [Allen and Rosselot, 1977]
Pump shaft seals	Regular packing with external lube sealant	140	Industry average for light liquid: 5–30. Industry average for heavy liquid: 2–6
	Regular packing with lantern ring oil-injection	14	
	Grafoil packing	14	
	Single mechanical seal	1.7	
	Double mechanical seal	0.006	
	Bellows seal, diaphragm pump, canned	Nil	
Valve stems excluding pressure relief	Rising stem regular packing rating < 4 MPa	1.7	Industry average for gas: 1–7. Industry average for liquid: 0.05–3
	Rating > 4 MPa	0.03	
	Non-rising stem	0.005	
Pressure relief valves	Without upsteam protection by bursting disk	2.8	Industry average for gas: 29–50. Industry average for liquid: 2
Compressors	Reciprocating: single rod packing	45	Industry average: 60–175
	Reciprocating: double rod packing	3.6	
	Rotary: labyrinth seal	45	
	Rotary: mechanical	Same as pumps	
	Rotary: liquid film seal	0.006	
Agitators	[pump seal data x shaft speed [m/s]]/1.91		Industry average: 5–30
Piping and flange connections	Open ended pipe	0.63	Industry average: 0.5–6
	Flange with asbestos gasket: 2–4 MPa	0.056	Industry average: 0.07–0.3
	Flange with asbestos gasket: > 4 MPa	0.056	
	Threaded connection	0.056	
	Welded connection	Nil	
Sampling connections	General		Industry average: 2.7

Intensify

Use lower volumes in all process vessels. This has probably the most dramatic effect on both safety and cost. For example, *minimize the inventory*. Use smaller storage, eliminate surge drums, use packing instead of plate trays, reduce the interim storage, use thermosyphon reboilers instead of kettle reboilers, use plate exchangers instead of shell-and-tube models, keep transfer lines to a minimum length, transport as a gas instead of a liquid, and consider pumping at higher velocities to keep holdup volume in the line less. *Eliminate storage* by making the hazardous materials *in situ*. An example is the *in situ* production of hydrogen selenide for microelectronics production; this innovation eliminates the need to store this toxic material under high pressures. *Combine or segregate equipment*. Combine equipment: use reactive distillation, membrane reactors. Segregating the reaction into a series of separate reactors for each reaction in a multiple reaction sequence creates a safer environment. *Segregate and concentrate waste streams* to minimize the volume of waste, recycle, concentrate the wastes to minimize the volume, and manage containers; use the smallest equipment. *Eliminate the accumulation of reactants*. In a liquid-liquid mass transfer controlled reaction system (for example, nitration), an increase in agitation will increase the mass transfer, and reduce buildup of reactants and decrease the potential of a runaway reaction. *Minimize the amount produced* by using closed-loop sampling instead of once-through sampling.

TABLE 16.26
Dust Emissions from Various Equipment Options

Source	Description of Equipment Option	Emission Rate, mg/s [King, 1990]
Vibratory screens	Open top	5.5 times top surface area in m^2
	Closed top with open port access: 15 cm diam. port	0.11
	20 cm diam. port	0.21
	30 cm diam. port	0.44
	Closed cover, no ports	Nil
Bag dumping	Manual slitting and dumping	3
	Fully automatic with negative pressure	Nil
Bagging machines	No ventilation	1.5
	Local ventilation	0.01
	Totally enclosed with negative pressure	Nil

Substitute

Employ less-hazardous species. *Use less-hazardous additives* (solvents, catalysts, filter aids, adsorbents, and absorbents) if nonhazardous ones are not available.

Attenuate or Minimize

Use equipment, seals, and valve stems that leak less. Tables 16.25 and 16.26 give estimates of VOC leak rates and dust generation from different types of equipment.

Minimize waste by changing the operating conditions: substitute continuous processing for batch processing to minimize cleanout cycles, and clean vessels with a dry ice spray instead of sandblasting. *Change the operating conditions*. Use hazardous materials under less hazardous conditions. Use hot water instead of steam and water instead of hot oil; use chemicals with higher flash temperatures. Use a vacuum to reduce the boiling temperature, reduce process temperatures and pressures, dissolve hazardous species in safe solvents, add diluents, and operate at conditions far from explosive limits and from reactor runaway conditions. Add inert gas (such as steam, nitrogen, or carbon dioxide) to combustible mixtures to reduce the concentration of oxygen to about 4% below the minimum. *Minimize the hazard from storage tanks* by providing double-walled tanks with water between the walls (provided that water does not react with the stored material). *Reduce the intensity of electric sparks;* ensure that the voltage used is so low that low-energy sparks do not ignite a flammable mixture. For mixtures of flammable vapors in air, these voltages are <0.01 to 1 mJ; for sensitive explosives, <0.001 mJ; for dust explosions, <0.1 mJ.

Recycle

Minimize the source through recycle.

16.7.2.3 Step 4. Minimize the Impact

If hazardous materials must be used and unsafe environments exist, *limit the potential for leakage*; use finned tube heat exchangers for vaporization on the shell side. *Develop special procedures during the startup phase,* when conditions go through the explosive limits. *Measure key variables to trigger safety measures*; for example, for reactors, include instrumentation to detect temperature runaways. For example, AIChE/CCPS (1995) recommends $d^2T/dt^2 > 0$ and $d\,(T_{reactor} - T_{coolant})/dt > 0$. Monitor the various streams for impurities. *Install explosion suppressors* in potentially explosive spaces for dusts, such as the exit ducts from grinders. *Dump cold liquid or inert solids* into systems on the verge of temperature runaway. *Add an inhibitor to neutralize* the catalyst for a potential temperature runaway (for example, add gaseous ammonia to neutralize the Lewis acid catalyst BF_3

complex). *Add inhibitor to short-stop* a polymerization reaction. (For example, add hydoquinone to stop vinyl polymerizations.) *Use fireproofing.*

16.7.2.4 Step 5: Isolate the Source

Sometimes the hazard and unsafe condition cannot be eliminated or minimized. One option is to let it exist in isolation. Solutions include barricades, separate pump rooms, and establishing a hot end of the plant vs. spark- and flame-free zones. The hazard can be enclosed using pneumatic conveying instead of belt conveying and by enclosing screens and grinders. Place the equipment under negative pressure, shield high-temperature surfaces, and seal sewers. Provide ventilation and use a vacuum, pressure, or sweep-through purging. Fires can be isolated via flame arresters.

For electrical safety, allow sparking to happen but in a safe environment. *For electrical sparks*, isolate/segregate, use flameproof enclosures, pressurize, and purge. *For static charge*, let the charge build up but supply a safe route to discharge by grounding or bonding the source to the ground.

Create alliances. Instead of a company producing a raw material and shipping it to a client, the company can form an alliance with the client and produce the material on the client's site.

16.7.2.5 Step 6: Isolate the Impact

If a fire, explosion, excessive pressure, or unsafe system occurs, we can isolate it from people and equipment by dumping the liquid and gaseous materials or by venting.

16.7.3 For Process Improvement

The six-step approach described above can be applied in the sequence given in Table 16.3. Use mass and thermal pinch technology, given in Section 16.8, to guide the direction.

16.7.4 For Troubleshooting

For troubleshooting, we use the safety, health, and pollution impacts as the major criteria to prioritize actions.

16.8 AIDS FOR DESIGN, PROCESS IMPROVEMENT, AND TROUBLESHOOTING

A broad range of software is available to help engineers. Table 16.27 lists some of the software that aids in design and process improvement. Software for troubleshooting is developed for specific types of process equipment. Most applications support *flowsheeting*, or the use of computer aids to predict the steady-state mass and energy balances, the size of the equipment, and the cost and engineering economics. In this section, the focus is on flowsheeting.

TABLE 16.27
Software Aids

Vendor	Process Synthesis and Analysis	Physical Properties	Steady-State and Dynamic Simulation, Optimization	Equipment Sizing and Rating, Costing
Aspen Technology www.aspentech.com	**Aspen Pinch™:** minimize energy usage **Aspen Split™:** conceptual design of azeotropic systems **Aspen Water™:** minimize water usage **Aspen PEP Process Library™:** comparison of processes development, route synthesis, and implementation **DISTIL**: synthesis of column sequences for multicomponent azeotropic systems **HX-NET:** conceptual design tool for heat exchanger networks; uses pinch technology **HYSYS.Concept:data** regression and thermodynamic database access for conceptual design of separation systems	**Aspen Properties™:** Databank, property and estimation methods **Aspen OLI™:** aqueous mixtures **DETHERM™:** compilation of pure physical properties	**Aspen Plus™:** steady-state simulation **Batchfrac™:** batch distillation **Ratefrac™:** distillation and absorber column distillation **Aspen Plus Optimizer™:** equation oriented optimization **Aspen Custom Modeler™:** new model builder **Aspen OnLine™:** online connection with knowledge capture **Aspen ADSIM™:** adsorption processes **Aspen Chromatography™:** chromatographic processes **Aspen FCC™:** fluidized catalytic cracker simulation **Batch Plus™:** batch process recipe oriented modeler	**Aspen Aerotran™ Aspen Hetran™ Aspen Teams™:** various heat exchanger design tools **CFX:** computational fluid dynamics tool for unit design **FLARENET:** design, rating, and debottlenecking of flare systems **HTFS:** thermal design and simulation of heat exchangers **PIPESYS:** pipeline flow modeling **STX/ACX:** rate and design shell-and-tube and air-cooled heat exchangers

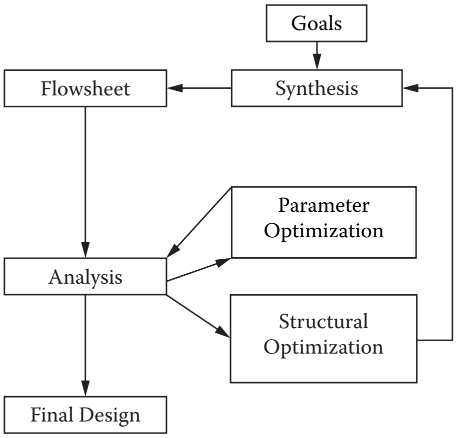

FIGURE 16.5 Synthesis, analysis, and optimization activities.

16.8.1 Steady-State Flowsheeting

Software flowsheeting aids are usually used for the preliminary engineering design (step 3 in Table 16.1) or perhaps in the conceptual design (step 2). The flowsheeting activity is divided into three basic steps:

Step 1. **Synthesis** or selecting the structure of the flowsheet: identification of the equipment, interconnecting and specifying the initial design values. In this step, a crude approximate flowsheet is created to consider recycles, purges, and possible separation schemes; make a simple, linear model to assess the effects of major parameters and structural variations; do necessary laboratory work; get more details for physical properties, thermodynamics, utilities, and process units; write unit models, if necessary; and fix the flowsheet layout.

Step 2. **Analysis** or solving the heat and material balances; sizing and costing the equipment; evaluating the economic worth of the project; assessing the safety and environmental impact; and analyzing the operability.

Step 3. **Optimization** of the structure and the parameters. For the structure, optimize the choice of equipment and the interconnection of units. For parameters, select values for the state variables (such as temperature, pressure, and level) within a given process configuration.

In an additional step 4, move from the steady-state condition to study the dynamics and controller effects and the operability.

The six key components in a process flowsheet simulator are the component database, the thermodynamic model solution package, the flowsheet graphic tool, the models of the unit operations, the data output generation, and the flowsheet solver strategy.

16.8.2 Formulating a Well-Posed Problem

To obtain a solution to a process model, first formulate a *well-posed problem* (Himmelblau, 1996). This requires that we (1) identify the stream variables entering and leaving a unit and the variables that describe the unit, (2) determine the number of independent equations for each unit, (3) calculate the degrees of freedom or number of decision variables for each unit, and (4) specify the values of variables equal to the number of degrees of freedom.

The degrees of freedom (DOFs) are the variables in a set of independent equations that must have their values assigned. DOF = no. of variables – no. of equations and constraints, or

$$N_d = N_v - N_c$$

For the DOF, important process *variables* include temperature, pressure, mass (mole) component flow rates, concentration and total flow rates, specific enthalpies, heat flow, work, and flow ratios (e.g., recycle, feed/product, reflux). The number of process variables to describe a stream containing N_{sp} species is given by $N_v = N_{sp} + 2$.

For the DOF, *equations and constraints* include the independent material balances for each species or a total flow balance and ($N_{sp} - 1$) species balances, the energy balance, the phase equilibrium relationships that link the compositions between phases, and the chemical equilibrium relationships. The unit and composition constraints may be explicit (e.g., a given stream fraction is condensing) or implicit (e.g., a species concentration is zero). Himmelblau (1996) provides the full derivation for the degrees of freedom for the following Examples 16.11–16.14.

Example 16.11

Determine the number of process variables, equations, and constraints and the overall DOF for an adiabatic stream splitter.

N_v:	Stream variables		$3(N_{sp} + 2)$
N_c:	Material balance		1
		Composition specification	$2(N_{sp} - 1)$
		Temperature specification	2
		Pressure specification	2

Overall DOF: $N_d = \{3(N_{sp} + 2)\} - \{2N_{sp} + 3\} = N_{sp} + 3$

Example 16.12

Determine the number of process variables, equations, and constraints and the overall DOF for a nonadiabatic mixer in which two streams are mixed to produce a single exit stream.

N_v:	Stream variables	$3(N_{sp} + 2)$
	Heat gain/loss (Q)	1
N_c:	Component balance	N_{sp}
	Energy balance1	

Overall DOF: $N_d = \{3(N_{sp} + 2) + 1\} - \{N_{sp} + 3\} = 2N_{sp} + 6$

Example 16.13

Determine the number of process variables, equations, and constraints and the overall DOF for a flash tank with three input liquid streams, a single vapor stream, and Q heat input. Assume that the component flows are known.

N_v:	Stream variables		$4(N_{sp} + 2)$
		Heat, Q	1
N_c:	Component balance		N_{sp}
		Energy balance	1
		Phase equilibrium	N_{sp}
		Temperature (exit)	1
		Pressure (exit)	1

Overall DOF: $N_d = \{4(N_{sp} + 2) + 1\} - \{2N_{sp} + 3\} = 2N_{sp} + 6$

Example 16.14

Determine the number of process variables, equations, and constraints and the overall DOF for a combination of a mixer and flash separator.

Mixer:
N_v: $3(N_{sp} + 2) + 1$
N_c: $N_{sp} + 1$
N_d: $2N_{sp} + 6$

Flash separator:
N_v: $3(N_{sp} + 2) + 1$
N_c: $2N_{sp} + 5$
N_d: $N_{sp} + 2$

Sum of DOF of individual units:
$N_d = 3N_{sp} + 8$

Less redundant variables and constraints:
Stream 3 = stream 4 $N_{sp} + 2$
Need one energy balance 1
Total DOF $N_d = \{3(N_{sp} + 8)\} - \{N_{sp} + 3\}$

16.8.3 Flowsheet Architectures

The two basic flowsheet software architectures are sequential modular and equation-based. In *sequential modular,* we write each unit model so that it calculates output(s), given feed(s), and unit parameters. This is the most commonly used flowsheeting architecture at present, and examples include Aspen+ plus Hysys (AspenTech), ChemCAD, and PROII (SimSci). In *equation-based* (or open-system) architectures, all equations are written describing material and energy balances as algebraic equations in the form $f(x) = 0$. This is the preferred architecture for new simulators and optimization, and examples include Speedup (AspenTech) and gPROMS (PSE plc). Each is discussed in turn.

16.8.3.1 Sequential Modular Architecture

Unit models are written to *calculate* output stream values, *given* input stream values and unit parameters. The recycle stream values are then calculated and checked against the estimated values for that iteration. If they agree within a tolerance, then the flowsheet has converged. This procedure is called *tearing* a recycle stream. The important questions for this approach are

1. How is a process flowsheet analyzed to determine whether there are recycles and which stream to tear (estimate)?
2. How do we handle many recycles, which may be nested?
3. How are calculated values for the recycle stream used for subsequent iterations?
4. What solution procedure should be used if not all the inputs to the process are known, but some outputs are specified?

16.8.3.1.1 Tearing

There are a number of approaches to develop better tearing strategies, but they require analysis of the number of components and number of recycles. Biegler et al. (1997) describe algorithms to minimize the number of tears and the number of recycle variables in the tears.

16.8.3.1.2 Convergence Block Schemes: Successive Substitution

Let X^k be the estimate for the tear stream variables at the *k*th iteration, Let $F(X^k)$ be the calculated result for that tear stream's values. The simplest iteration scheme is successive substitution, or fixed-point iteration:

$$X^{k+1} = F(X^x)$$

The next estimate on the tear stream is the newly calculated variable values. A more general, weighted form is

$$X^{k+1} = a\,F(X^k) + (1-a)X^k$$

that is useful if the iterations start to oscillate, e.g., $a = 0.5$.

Given the feed/process streams to a process unit, the sequential modular solution scheme is

1. Estimate the value of the recycle stream to that unit (tear).
2. Calculate all the units between the first unit and the recycle stream.
3. Check if new recycle values are approximately equal to guessed values:
   a. If not, go to step 1 and use new values as a next guess.
   b. If OK, then it is converged.

16.8.3.1.3 Wegstein Acceleration

Let X^k be the guess for the tear stream variables at the *k*th iteration. Let $F(X^k)$ be the calculated result for that tear stream's values. Treat each variable with a secant method. Do two or more successive substitution iterations to generate X^k, $F(X^k) = X^{k+1}$, $F(X^{k+1})$. Then accelerate:

$$X^{k+2} = X^{k+1} - \underline{\{(X^{k+1} - X^k)/(F(X^{k+1}) - F(X^k)\}}\, F(X^k)$$

The rate of change of the stream estimates (underlined term) is usually bounded between upper and lower bounds to prevent divergence (usually between –5 and 25).

16.8.3.1.4 Control Blocks for Design Situations where Some Outputs Are Specified

Information flow in a standard *simulation* problem calculates unit outputs (stream values) given input streams and unit parameters (simulation problem). *Design* requires specification of an output variable and then calculating an input value or equipment parameter (design problem).

Example 16.15

Compare simulation with design for the adiabatic flash shown in Figure 16.6.

	Simulation case:	**Design case:**
Given:	F, z_i, T, P	F, z_i, T, V
Calculate:	V, y_i, L, x_i	P, y_i, L, x_i

In Example 16.15, for the design case, assume that a vapor overflow V is to be calculated. The unit parameter, pressure (P) in this case, is to be adjusted to attain the vapor flow rate, V_{sp}. Key constraints include the dew and bubble pressures (to maintain a two-phase region in the flash) and

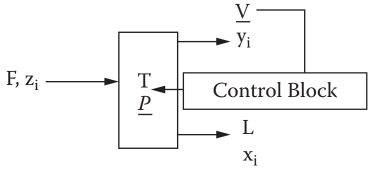

FIGURE 16.6 Symbols and configuration for the adiabatic flash in Example 16.15.

safety and operational constraints on the temperature and pressure in the vessel. A control block solves the equation:

$$Error = set\ point - value < tolerance$$

$$E = V_{sp} - V < error$$

The calculation procedure may proceed as follows:

For iteration k in the flash example,

1. If $k = 1, 2$, estimate P^k (make sure flash is in the two-phase region).
2. Calculate V^k.
3. Calculate $E^k = V_{sp} - V^k$.
4. If, $|E| <$ error, exit

else, $|E| >$ error, use secant method to calculate P^{k-1}:

$$P^{k+1} = P^k - \{(P^k - P^{k-1})/(E^k - E^{k-1})\}E^k$$

In many problems, there are recycle loops and design specifications. Recycle loops require convergence blocks. *Explicit* iterations occur to satisfy material, temperature, and pressure agreement in a given recycle stream. Design specifications require control blocks. *Implicit* iterations occur to satisfy a specification by adjusting an input stream variable or equipment parameter.

For a design problem, converge the entire flowsheet (close all the recycles) for every intermediate value of the adjust variable. This is very expensive computationally and is a major drawback to the sequential modular approach. Alternative and sometimes faster approaches include

- Partially converge the flowsheet, a less stringent recycle tolerance, for the intermediate adjusted variable values.
- For each iteration of the control block, converge only the units between the specified and adjusted variables; solve the entire flowsheet after the adjust variable is converged.

These alternatives are not guaranteed to converge, and partially converged flowsheets may provide poor estimates for the monitoring of the specified variable.

16.8.3.1.5 Partitioning and Precedence Ordering

Partitioning locates groups of units that must be solved together. *Precedence ordering* solves these groups of units within a process in the proper computational order. A partition is unique, but the precedence ordering is not. Partitions may exist where the order of the solution may have groups of units calculated in serial or parallel order. An effective algorithm developed by Sargent and Westerberg is

1. Trace from an arbitrary starting unit to the next unit, through a connecting stream, to form a "string" of units.
2. Continue, until
   a. A unit in the string reappears. Then all the units between the repeated unit occurrences, including the repeat unit, become a "group." The group is treated as a single unit in subsequent steps.
   b. A unit has no more outputs. Then the unit, or group, that has no output is placed at the top of a list of groups and is deleted from the problem.

The list will contain the groups in correct precedence order.

16.8.3.2 Equation-Based Architecture

Model equations are written in the open form, $F(x,u) = 0$, where x represents the stream variables and u the unit parameters. All the nonlinear equations are assembled and solved simultaneously. This creates a huge nonlinear equation set, typically between 10^3 and 10^5 equations. The solution methodology is complicated, because most equations include only a few variables in each equation. Typically, each equation has less than 5% (95% sparsity) of the total number of variables in the problem. The larger the problem, the higher the sparsity.

The advantage of the approach is that any parameter or stream variable can be specified as long as the problem has an equal number of equations and variables, and it is nonsingular with linearly independent equations. The two basic solution approaches for the equation-based flowsheeting systems are tearing and linearization. In *tearing*, we find the minimum number of variables that need to be guessed and iterate to find the rest of the variables. The equations are grouped to allow a few variables to be used to solve a group of equations. This requires preanalysis and does not generalize. In *linearization,* the set of nonlinear equations is solved by linearization and solution, such as Newton–Raphson.

The challenges with an equation-based strategy are the following:

1. It is difficult to use equations from existing sequential modular packages.
2. Equation management is complex.
3. Large computer storage is required.
4. There are numerical problems in obtaining derivatives and with singularity.
5. Starting values are needed.
6. The interface to thermodynamics packages must provide derivative information.
7. The ordering of equations affects the equation solution time.
8. We need input data verification to prevent singular problems (structural and numerical singularity).
9. Backup plans are needed if the solution fails to converge.

The advantages of equation-based strategies are that they remove the need for convergence and control blocks and allow for more flexible problem formulation. As such, they are the basis for all new simulators being currently developed.

16.8.4 Importance of Thermodynamics Packages

In using a flowsheet simulator, one of the most important decisions is the choice of thermodynamics package. The choice of thermodynamics options affects the accuracy of the material and energy balances. Appropriate choices depend on the compounds in the system, temperature, pressure, and the availability of parameters. Equations of state and activity models are used to calculate stream properties: number of phases, phase composition, PVT relationships, enthalpy, and entropy.

TABLE 16.28
Select the Model for the System

System	Margules	VanLaar	Wilson	NRTL	UNIQUAC
Multi	?	?	OK	OK	OK
Azeotropic	OK	OK	OK	OK	OK
Liquid-liquid-vapor	OK	OK	NO	OK	OK
Self-associating	NO	NO	OK	OK	OK
Polymers	NO	NO	NO	NO	OK

16.8.4.1 Vapor-Liquid Equilibrium

Liquid activity models must be used in vapor-liquid equilibria calculations, with the appropriate model tested against available data. Models often used include Margules, Van Laar, Wilson, nonrandom two-liquid (NRTL), and universal quasi-chemical (UNIQUAC). For mixtures, mixing rules are used to combine pure component parameters. Table 16.28 suggests regions of applicability for different models.

16.8.4.2 At High Pressure or near the Critical Region

At high pressure or near the critical region, the thermodynamic functions for the liquid phase cannot be assumed to be independent of pressure. Simple equations of state are not adequate for vapor-phase predictions. Chao–Seader method includes the calculation of liquid-phase fugacity coefficient by Pitzer's correlation. Chao–Seader uses the Redlich–Kwong equation of state with a temperature range of –20 to 250°C and pressure <10,000 kPa. The Grayson–Streed extension of the model of Chao–Seader is used for systems rich in hydrogen and methane at a temperature range of –20 to 450°C and pressure <20,000 kPa. It is advisable to check the simulator manual.

16.8.4.3 Equation of State, EOS

Commonly used EOS models include the ideal, virial, PengRobinson, Soave–Redlich Kwong, and Lee–Kesler. The reduced form of the EOS is particularly significant. Substances with the same reduced properties are in *corresponding states*. Van der Waal's EOS is a poor predictor of state properties, but the experimental data do correlate well with reduced conditions. Many of the cubic EOS models are based on the van der Waal equation.

EOS models are used to determine liquid and vapor densities, vapor pressures, fugacities, thermal property deviations from ideal, and enthalpies. EOS parameters can be adjusted to fit some data listed above, but usually one EOS set of parameters cannot fit all of the pure component data well. Flowsheet simulators allow the user to mix EOSs to get the best match between EOS parameters and desired state variables. In general, EOSs are very good predictors of the vapor-phase properties and of the liquid-phase density and composition. Cubic EOSs are relatively simpler to use. The Lee–Kesler model (based on the theory of corresponding states, and using reduced temperature and pressures) can cover a wider range of pressures and temperatures. It is recommended practice not to extrapolate the EOS results outside of conditions for which the parameters were fitted. Check the simulator manual for temperature pressure and composition restrictions. Generally, the higher the pressure (>10 bar), the poorer the prediction. If polar molecules are present (alcohols, acids), then EOS should not be used. Use an activity model for the liquid phase or a specially fitted EOS for those systems.

16.8.5 Tools for Flowsheet Development

Flowsheet development involves the selection of the equipment and the interconnects that integrate the equipment into a working system. Two approaches are used for the development of the flowsheet: mathematically based programming and the use of heuristics and evolutionary development.

16.8.5.1 Mathematically Based Programming

Mathematical programming approaches tend to use a superstructure approach with many alternative solutions embedded within a complex superstructure containing many alternate units and feed and recycle configurations. The mathematical program then solves the corresponding model to determine the flows and units for the optimal process configuration contained within the superstructure that meets the overall process design objectives. Engineering insights are used to develop the superstructure, identify candidate units, and weight the mathematical model toward a practical process configuration. Biegler et al. (1997) review modeling techniques.

16.8.5.2 Hierarchical Use of Heuristics for Evolutionary Development

The approach to conceptual design outlined in Table 16.2 is hierarchical and based on heuristics. In such evolutionary approaches, key insights set targets for attainable performance. Flowsheet changes act to improve performance. Software programs have been developed to assist in some of the tasks. For example, the task of energy integration (and optimization) can be assisted by the use of heat exchanger network analysis based on thermodynamics, called *pinch technology* or *methodology*. It is the most developed of the various process synthesis and integration methods. The method starts with the identification of streams as sources or sinks of heat (hot and cold streams). Streams have initial and final temperatures (supply and target temperatures) to be met. Typically, they are plotted as a function of temperature vs. heat load in the stream (Q), where Q = *mass flow rate* * *heat capacity* * ($T_{target} - T_{supply}$). The streams are dealt with as composite streams where, within a given temperature range, all the hot streams are treated as one composite hot curve, and all the cold streams are treated as a composite cold curve. The plot of the two composite curves is separated by the *minimum approach temperature (MAT)*, which is the closest temperature approach permitted in the heat exchanger design (the *pinch* point). As the MAT decreases, the required heat exchanger area increases, but the utilities decrease. An economic optimum exists as the optimal trade-off between capital and operating costs. The composite curves are plotted, and the overlaps denote the required utility loads. The overlap of the hot curve over that of the cold composite curve at the low temperature end is the required cold utility (where heat is rejected) target. The overlap of the cold composite curve to the hot composite curve at the high temperature is the required hot utility target. The key insight is that, at temperatures above the pinch temperature, the process is a net energy sink and that, below the pinch temperature, the process is a net energy source. This observation effectively partitions the process synthesis problems into simpler subproblems with a defined set of utilities that will be used in each part of the subproblem. Matching streams starting at the pinch temperature and moving outward to higher and lower temperatures, respectively, determine heat exchanger networks.

Most process simulators can provide plots of the composite curves and determine the pinch temperature, target hot and cold utility loads, and temperatures. Specialized tools are available to generate the heat exchanger network configuration; size; and cost of the heat exchangers, e.g., Aspen Pinch (Aspen Technology), SuperTarget (Linnhoff–March), Hextran (Simulation Sciences), and HX-NET (AEA Hyprotech). Similar techniques have been developed for water use minimization, hydrogen use in refineries, among other applications (Halale, 2001).

As suggested in Table 16.3, *pinch technology* can be used for process improvement as well as for flowsheeting.

16.9 PROCESS OPTIMIZATION

In Step 3, optimization of the structure and the parameters (Section 16.8.1), the two types of process optimizations are parameter and structural optimization. *Parameter optimization* is the process of determining the best value of a process unit parameter or stream quantity in terms of improving performance within a given set of constraints. Parameter optimization is usually a nonlinear continuous variable (over a range of variable values defined by upper and lower bounds). *Structural optimization* involves the determination of the best set of units and their interconnections such that the process configuration provides the best performance within a given set of constraints. Structural optimization requires discrete decisions. Pinch technology, described in Section 16.8.5, is a form of structural optimization.

16.9.1 Define the Problem

The first key steps are to determine the *objective function*, the *decision variables* (or design variables or degrees of freedom), and the *constraints*. The *objective function* is the performance measure to be used to determine the degree of improvement in the process. Examples include maximizing profit, minimizing cost, maximizing production, and minimizing a waste stream. *Decision variables* are those variables that can be changed, within a given process design, to improve the objective function. Examples of continuous decision variables include the pressure or temperature of a stream, and the number of stages in an absorber column would be a discrete decision variable. *Constraints* are of three types: variable bounds, equality constraints, and inequality constraints. Variable bounds are the upper and lower limits on a variable due to operational, physical, or economic considerations. Equality constraints are functions of process variables that define a relationship that must be enforced in a feasible solution, e.g., material balance on a unit. Equality constraints reduce the dimensionality of a problem, since each equation reduces the number of independent decision variables. Inequality constraints are usually one-sided feasible regions (less-than or greater-than relationships) defined by a function of process variables; e.g., distillation columns must be operated within flooding constraints.

16.9.2 Select the Optimization Solution Scheme

Combinations of these objectives, variables, and constraints are so common that the optimization solution schemes are tailored for the function properties. A key step in solving an optimization problem is to match the appropriate solution algorithm with the problem type as outlined in Table 16.29.

Optimization algorithms all require the definitions of the objective function and decision variables, and constraints if applicable. In addition, most solution algorithms require a reasonable initial set of values for the decision variables, preferably a feasible starting point. Optimization algorithms generally follow a pattern:

1. Provide a starting set of decision variables.
2. Determine a *search direction* for the decision variable to improve the objective function.

TABLE 16.29
Problem Types, Objective Functions, Constraints, and Decision Variables

Problem Type	Objective	Constraints	Variables
Single variable	Nonlinear	None	Continuous
Linear programming	Linear	Linear	Continuous
Quadratic programming	Quadratic	Linear	Continuous
Nonlinear programming	Nonlinear	Nonlinear	Continuous
Mixed integer linear programming	Linear	Linear	Continuous-binary (0, 1)

3. Determine a *step length* (change in the decision variables) that will be taken on any one step.
4. Set the criteria for *termination* of the algorithm at a feasible solution.

A preliminary *exploratory search* of the problem should be done by changing a few of the decision variables, within the constraint space (or *feasible region*), to ensure that the objective function is affected by changes in the decision variables. This is also known as preparing a *response surface* or *sensitivity analysis*. If the objective function is insensitive to changes in the decision variables, within the feasible region that is probed, then there is no optimization problem, because the problem will have a multitude of solutions with the same objective function value.

Solution algorithms, for continuous variable problems, generally increase in complexity with increasing nonlinearity of the constraints and increasing number of discrete variables (binary or integer variable values).

Edgar et al. (2001) survey optimization algorithms as applied to chemical engineering problems. A variety of simple algorithms for relatively small problems are available in Press et al. (1992).

16.9.2.1 Nonlinear Objective Function Problems

For *single*, nonlinear, continuous decision variable problems, common techniques are either nonderivative or derivative.

Nonderivative methods compare the value of the function with changes in the decision variable. Methods include polynomial approximation, Fibonnaci search, and golden section.

Derivative methods use the necessary condition for optimality where the derivative of the function with respect to the decision variables is zero at the optimum. Methods include Newton and quasi-Newton methods.

For *multivariable*, nonlinear, continuous decision variable problems, the choice of nonderivative or derivative methods (to determine the search direction) depends on the availability of derivatives of the objective function with respect to the decision variables.

Nonderivative methods include random search, grid search, simplex search, and conjugate directions (or Powell's method). The nonderivative methods use various patterns for generating new test points for decision variables, and then a comparison of the new objective function value against previous values. A subsequent test point is then generated, either based on the immediate comparison or using the previous history of test points.

Derivative methods and derivative approximation methods use steepest ascent/descent (or Cauchy's method), conjugate gradients, Newton's, or quasi-Newton methods.

Generally, for multivariable methods, a *line search algorithm* is used to determine the step length that the decision variables will be allowed to change along a search direction. If the steps are too small, then convergence is ensured, but it will take much iteration to reach the optimum. If the steps are too large, the procedure may become unstable.

16.9.2.2 Linear Programming

Linear programming is probably the most commonly used optimization method. Edgar et al. (2001) and Press et al. (1992) describe many available sophisticated algorithms.

16.9.2.3 Nonlinear Programming

Nonlinear programming problems are generally formulated as

Min. or max.	$f(x)$
Subject to	$h(x) = 0$
	$g(x) \leq 0$
	$1 \leq x \leq u$

where x is the set of decision variables bounded between 1 and u, $f(x)$ is the objective function, $h(x)$ is the set of equality constraints, and $g(x)$ is the set of inequality constraints. Nonderivative methods are generally slow and unreliable for problems with more than a few decision variables. Some variations on the simplex method have been made to incorporate constraints (Press et al., 1992). Most algorithms use derivative information, or approximations to the derivatives, for $f(x)$, $h(x)$, and $g(x)$. Example algorithms include successive linear programming, reduced gradient methods, and successive quadratic programming. Many programs are available to solve these classes of problems. Most optimization algorithms require continuity of the objectives and constraints within the exploratory region, which can be difficult for real process design problems. While some advances have been made in partitioning problems to seek the global optimum, this is still a relatively difficult area of optimization and not routinely used.

16.9.2.4 Discrete Decision Variables

Design problems in particular usually have discrete decisions. Few large-scale optimization algorithms are available that can handle nonlinear constraints with a mix of continuous and discrete variables.

16.9.3 Linking Optimization with the Flowsheeting Tool

The most important part of process optimization is linking the process flowsheeting tool to the optimization algorithm. With an *equation-based architecture*, the unit equations (material and energy balances, operating constraints, and specifications) are constraints in a general nonlinear programming formulation. The main problems are

- Problem size, as most process optimization problems have on the order of 10^4 to 10^6 constraints and at least 10 to 100 decision variables. Generally, this is done with sparse matrix algorithms or by partitioning the problem to take advantage of the equation structure due to the unit equations and recycles.
- Starting point for the decision variables, which generally requires a complete simulation of the process to be completed.
- Derivative information is required, which is especially problematic for thermodynamics packages and the avoidance of discontinuities in the search space.

With a *sequential modular architecture*, optimization is generally done on much smaller problems (usually less than 20 decision variables) using either of the following:

- Nonderivative search methods for multivariable problems, with simple bounds and testing of points to ensure that they are feasible.
- Derivative-based optimization methods, where the optimization algorithm is used to simultaneously converge the recycles and determine the decision variables that improve the objective function (Biegler et al., 1999; Edgar et al., 2001).

16.10 RULES OF THUMB FOR INTERPERSONAL SKILLS AND TEAMWORK

We need interpersonal skills and skill at teamwork.

16.10.1 Interpersonal Skills

The basis for effective teamwork in design, process improvement, and troubleshooting is good interpersonal skills that are developed through self-awareness and the application of five key principles.

16.10.1.1 Self-Awareness

Become aware of your own uniqueness and personal style and how you might differ from the style of others, through such validated inventories and readings as Kirton's KAI inventory, which illustrates how you wish to apply your creativity (Kirton, 1976); Schutz's FIRO-B inventory, which explores how you address the three different phases of group evolution of form, storm, and norm (Whetton and Cameron, 1984, p. 80); Jungian typology inventory, which suggests how you prefer to seek validation of your ideas, how collecting data contrasts with taking action, the relative weight placed on facts vs. feelings, and the relative importance of the big picture vs. details (Keirsey and Bates, 1984); self-awareness of the difference between men and women's approach to conversation (Tannen, 1990); and Johnson's approaches to resolving conflict (Johnson, 1986).

We move from self-awareness to self-acceptance, to acceptance of others with different styles, and to self-confidence.

16.10.1.2 Five Key Principles

We usually accept the best of people when we first meet and begin to work together. We trust; we expect them to behave honorably toward us. Our relationships can improve or deteriorate depending on how we handle the following five key ideas about effective interpersonal relationships:

Key 1. Honor the seven fundamental rights of individuals: R, to be Respected; I, Inform or to have an opinion and express it; G, have Goals and needs; H, have feelings and express them; T, trouble and make mistakes and be forgiven, S, select your response to others' expectations, and claim these rights and honor these in others.

Key 2. Avoid the four behaviors that destroy relationships: contempt, criticism, defensiveness, and withdrawal/stonewalling.

Key 3. Build trust. Trust glues relationships together. We build trust by *keeping* commitments to ourself and others; *clarifying* expectations that we have of ourself and of others; *showing* personal integrity, honesty, and loyalty to others, especially when they are not present; *apologizing* promptly and sincerely when we know we are wrong; *honoring* the fundamental *rights* listed above and avoiding the killers; *listening* and *understanding* another's perspective; *being truthful*; and *accepting others,* "warts and all." We destroy trust by the reverse of the builders of trust listed above and by selectively listening, reading, and using material out of context; not accepting experience of others as being valid; making changes that affect others without consultation; blind-siding by playing the broken record until we are eventually worn others out or subtly make changes in the context/issues/wording gradually so that they are unaware of what is happening until it is too late.

Key 4. The 12:1 rule applies to rebuild relationships. Twelve positive experiences are needed to overcome one negative experience.

Key 5. To improve and grow, we need feedback about performance. Give feedback to others to encourage and help them; it not for you to get your kicks by putting them down.

16.10.2 Effective Teams

A team is not just a collection of individuals. In a collection of individuals, each has a personal goal, trusts only himself, and rarely reveals personal skills. Decisions are usually not made, and conflict is ignored. In a team, all unanimously accept common goals, each is clear about his role, trust and involvement levels are high, personal unique skills are used effectively, decisions are made by unanimity, and the team has methods for handling conflict. Our meetings and teamwork improve when we strive for the characteristics of teams. Some target behaviors of teams follow:

- Have a purpose for each team and each meeting. Set and follow agendas to get the task done.
- No agenda, no meeting! If a meeting must be held without a circulated agenda, then spent the first five minutes creating the agenda.
- The team must have the correct membership and resources to achieve the goal.
- The team should be empowered and accountable to achieve the goal.
- Both *task* (getting the job done) and *morale* (feeling good about the group work and about how you have interacted with the other group members) are important.
- Have a chairperson whose role is to facilitate the team process: this person thinks through the tasks to be done, decides on the need for a team meeting, identifies the time and place for the meeting, sets and circulates an agenda, facilitates the meeting, and starts and stops the meeting on time.
- Being the chairperson and being a leader are different; different people may become leaders at different times.
- Group evolution tends to follow a pattern described by such descriptors as *"forming, storming, norming, and performing*."
- Establish norms. Agree on terminology and procedures for problem solving, for brainstorming, for decision making. Agree on the role of the chair in decision making (e.g., *vote or no vote);* roles, minutes, and records of decisions (e.g., *format, details, who prepares them, whether they are circulated, their use for subsequent meetings*); how to handle conflict and the level of intervention; combating "groupthink"; how to handle emergencies and criteria; and procedures for asking a member of the group to resign.
- Each has a clear idea of roles and of group norms.
- When groups are functioning effectively, about 70% of the time is spent on the task, 15% on morale-building activities, and 15% on task process activities.
- The products from groups or teams are improved when members have different "styles," as outlined in Section 16.10.1.1.

- The quality of decisions, product, and task is improved if group members offer different perspectives, disagree, and seem to introduce conflict into the process. The trick is to manage the apparent conflict well.
- Use the 20-min rule. After 20 min, either make a decision or identify the key information that is missing and arrange to obtain that information for the next meeting.
- Document decisions and record actions with "what," "who," and "when." *For example,* "Decide to compare two optional control strategies." Action: JBM by March 30.
- Systematically assess the quality of the teamwork and set goals for improvement. Table 16.30 is an example form for such an assessment.

16.11 RULES OF THUMB

Rules of thumb are suggested values that are reasonable to assume based on experience. Rules of thumb are based on the application of fundamentals. They do not replace fundamentals, but, rather, they enrich the correct use of fundamentals to solve problems. Rules of thumb

- Help us judge the reasonableness of answers
- Allow us to assess quickly which assumptions apply
- Are used to guide our better understanding of complex systems and situations
- Allow us to supply rapid order-of-magnitude estimates

These rules of thumb are organized by prime function, and within each function are listed the usual types of equipment. Some equipment is multifunctional. For example, a fluidized bed is primarily a device for mixing a gas-solid mixture. However, it is also used as a dryer, a heat exchanger, a reactor, and an agglomerator.

For each piece of equipment, the following are listed:

- *Area of application.* How to select the equipment, when you would use it, and the usual available size range (describing how big or small a single unit is usually built).
- *Guidelines.* How to size the equipment: rules of thumb for size estimation. In general, these usually work within a factor of ten but a factor of four is often preferable.

The following information is reproduced from the book, *Rules of Thumb for Process Design and Engineering Practice,* by D. R. Woods (Wiley-VCH, 2007).

TABLE 16.30
Rating Form for Teams

Assessment of your team & team meeting

Name: ________________
Date: __________________

Purpose of team: ____________________________________ unclear: ☐
Purpose of this meeting: ______________________________ unclear: ☐
Agenda for this meeting: detailed, clear, and circulated ahead of time ☐
bare minimum circulated ahead of time ☐
none ☐

Three minute team task to seek consensus about the rating of the Task and Morale:

• **Teamwork: Task** all members clear about and committed to goals; all assume roles willingly; all influence the decisions; know when to disband for individual activity; all provide their unique skills; share information openly; the team is open in seeking input; frank; reflection and building on each other's information; team believes it can do the impossible; all are seen as pulling their fair share of the load.

The degree to which these descriptors describe your team's performance (as substantiated by evidence: meetings, engineering journal, interim report, presentations).

None of these behaviors	Few of these behaviors but major omissions			Most features demonstrated		All of these behaviors
☐	☐	☐	☐	☐	☐	☐
1	2	3	4	5	6	7

• **Teamwork: Morale:** Trust high, written communication about any individual difficulties in meeting commitments; cohesive group; pride in membership; high *esprit de corps*; team welcomes conflict and uses methodology to resolve conflicts and disagreements; able to flexibly relieve tension; sense of pride; "we" attitude; mutual respect for the seven fundamental rights of all team members; absence of contempt, criticism, defensiveness, and withdrawal.

The degree to which these descriptors describe your team's performance (as substantiated by evidence: meetings, engineering journal, interim report, presentations).

None of these behaviors	Few of these behaviors but major omissions			Most features demonstrated		All of these behaviors
☐	☐	☐	☐	☐	☐	☐
1	2	3	4	5	6	7

Each, in turn, gives a 30-second summary of his/her perception of his/her contribution. This is presented *without discussion*.
Individual, 30-second reporting of his/her contribution to this meeting:

____

____

____

Four-minute team task to reach consensus about the five strengths and the two areas for growth.

Strength of your team	Areas to work on for growth
______________________	______________________
______________________	______________________
______________________	
______________________	

D. R. Woods (2001)

This form should be completed after each meeting and copies used as evidence of growth.

16.11.1 Overall Process

In this section, we consider rules of thumb for process control and the properties of fluids.

16.11.1.1 Process Control*

Area of Application

For all processes, provide the four levels of control with (1) the basic control system, (2) an alarm system, (3) a safety interlock system (SIS), and (4) a relief system. Related topics are discussed in Section 16.6 and the chapters on *safety* and *process control*.

Guidelines

Sensors. What are we to measure? Variables are measured by sensors to achieve the following objectives, in hierarchical sequence:

Safety, environmental protection, and equipment protection (see Section 16.7; this could include redundant temperature sensing and alarms on reactors and reboilers handling corrosive chemicals such as HF), smooth operation, product quality, profit, monitoring, diagnosis, and troubleshooting. Identify the objective and select a pertinent variable. Direct measurement of the variable is preferred. If direct measurement is impractical, select an inferential or calculated variable. *For example, temperature can infer conversion and composition*.

Variables must be measured that might quickly deviate from acceptable range, such as (1) non-self-regulating variables (e.g., *level*), (2) unstable variables (e.g., some temperatures in reactors), and (3) sensitive variables that vary quickly in response to small disturbances (e.g., pressure in a closed vessel).

How are we to measure? Select sensor to balance accuracy and reproducibility, to cover the range of normal and typical disturbed operations, and to provide minimum interference with the process operation and costs. *For example, prefer a low-pressure loss flow sensor when compression costs are high*. Use a second sensor for extremely large ranges due to startup, large disturbances, or different product specifications. The sensors should be consistent with the process environment. For example, for flow measurements, the instrument should be located downstream of sufficient straight pipe to stabilize the flow patterns reaching the instrument—at least ten diameters upstream and five diameters downstream of straight pipe. The sensors should be located to assist operators in performing their tasks and engineers in monitoring and diagnosing performance.

Sensors for control should compensate for known nonlinearities before the measurement is used for monitoring or control. Prefer sensors that do not need calibration.

Specifics

Temperature. Prefer resistance temperature detectors, RTD. Prefer narrow span transmitters instead of thermocouples.

Differential pressure. Prefer precision-filled diaphragm seals or remote heads for Δp, because signal depends in part on the density of the fluid in the sensing lines.

Flow. Prefer coriolis, vortex, or magnetic flow meters over orifice or venturi. Keep fluid velocity >0.3 m/s.

Composition

Level. Prefer tuning fork, radar, or nuclear, or consider radio frequency admittance if the composition changes.

Manipulated variables and final elements. The manipulated variable, usually flow rate, has a causal effect on a key controlled variable, can be manipulated by an automated final element, provides fast feedback dynamics, has the capacity to compensate for expected disturbances, and can be adjusted without unduly upsetting other parts of the plant. The final element, usually a valve,

* Based on communication from T. E. Marlin, McMaster University, 2001.

has a causal effect on the controlled variable. The number of *final elements* is greater than or equal to the number of measured variables to be controlled, and we must provide an independent means for controlling every variable.

Final elements must provide the desired capacity with the required precision of flow throttling over the desired range, usually 10% to 95% of maximum flow. The valve characteristic should provide a linear closed-loop gain, *except* choose linear or quick-opening characteristics for valves that are normally closed but must open quickly. Select the valve failure position for safety. The valve body should satisfy such requirements as required flow at 0% stem position, plugging, pressure drop, or flashing. The nonideal final element behavior, such as friction and deadband, should be small, as required by each application. Control valves should have manual bypass and block valves to allow temporary valve maintenance when short process interruptions are not acceptable. However, the bypass should never compromise safety interlock systems.

Specifics

Include the same length of upstream straight-run piping before control valves as for orifices. This is particularly important for rotary valves.

Globe valves. Permissible stroke range: 10% to 90%; sliding stem gives the highest sensitivity, and the actuator stem feedback position more closely represents the final element position (but not for fouling or solids).

Rotary ball valves. Permissible stroke range: 20% to 80%. Δp across the valve is small, but accounts for the pipe reducers needed for installation. Be sensitive to the need for upstream straight pipes.

Rotary butterfly valves. Permissible stroke range: 25% to 65%.

Signal transmission. Use sensor-matched transmitters. All measurements used for control should be transmitted using high-level 4–20 mA transmission.

Feedback controller. Match the type to the process requirements as follows:

Manual. When close regulation of the variable near its desired value is not required, and when knowledge is required that is not available in the control computer.

On/off. When the system responsed slowly to disturbances, and close regulation of the variable is not required.

Regulator. A self-contained P-only regulator offers low-cost and reliable control of noncritical variables that can be permitted to deviate from their setpoints for long periods.

PID. The proportional-integral-derivative algorithm is used for most single-loop applications.

PID control. Always determine the form of the PID algorithm being used. Select the PID modes: *P,* always; *I*, when the controlled variable should return to its set point; *D*, for processes that are undamped, unstable, or have a very large ratio of dead time/time constant.

Tuning. Typical values are $K_c = 0.8/K_p$, $T_I = 0.75\ (\theta + \tau)$, and $T_d = 0.0$. The proportional band ($100/K_c$) and the reset time ($1/T_1$) can be calculated from these. When fine tuning, observe the behavior of both the controlled and manipulated variables. Always use an implementation that includes antireset windup protection for use when the manipulated variable encounters a constraint. Use an implementation that includes initialization that starts automatic control bumplessly from the last manual condition. The digital execution period should be fast with respect to the feedback dynamics, with $\Delta t \leq 0.05\ (\theta + \tau)$ where possible.

Filtering. For control variables, when filtering is needed, use a first-order filter to reduce the effects of high-frequency noise. Do not excessively filter measurements unless absolutely necessary. The filter time constant, τ_f, should be much less than feedback dynamics.

For monitoring variables. Use filters to reduce the noise at frequencies higher than the effects being observed. Recall that "averaging" is a filter that is often performed by the DCS historian features.

Loop pairing. Where options exist, pair the most important variables with manipulated variables that have fast feedback dynamics and large capacity. Select pairings that give good integrity. For

example, select direct loop designs in which controllers will function when other controllers are not functioning. Usually avoid nested loops (a condition when some controllers will not function while other controllers are in manual or have their outputs saturated) that do not have individual causal relationships. Select loop pairings that require little adjustment to controller tuning when the controllers switch from manual to automatic. Tune the most important loops aggressively, and the less important loosely (when interaction is unfavorable).

DCS structure. All safety and basic regulatory controls should be highly reliable and executed in the lowest-level digital processes, with direct input and output wiring contact signals within the process. Should the LAN fail, the control system should provide means for personnel to operate the process, possibly through displays and adjustable parameters at the digital processor. The system should provide redundancy (with automatic switching) for key elements such as processors, power supplies, and LANs. The operator consoles should provide sufficient access to displays and adjustments for off-normal operations such as startup and disturbances.

Implementation hierarchy. Implement process control in a hierarchy based on frequency of decision making. The first level is protection (safety, environment, and equipment), and the second is smooth operation and stability (through control of flows, temperature, pressures, and levels and through alarms). The third level is product quality. The fourth level is profitability. The final level is monitoring and diagnosis.

16.11.1.2 Properties of Fluids

1. Vapor pressure doubles every 20°C.
2. Latent heat of vaporization of steam is five times that of most organics.
3. If two liquids are immiscible, the infinite dilution activity coefficient is >8.
4. Ten percent salt in water doubles the activity coefficient of a dissolved organic.
5. Infinite dilution is essentially <1000 ppm of dissolved organic.
6. Freezing temperature may be suppressed 1°C for every 1.5 mol% impurity present.
7. A ratio of impurity concentration between a solid/liquid phase greater than 0.2 is probably due to solid solution.
8. Dissolving 2% to 20% organic solute usually reduces the interfacial tension.

16.11.2 Transportation*

In this section, we consider gas moving equipment for pressure service and then for vacuum liquid moving equipment. Then, two-phase flow is considered in Section 16.11.2.4. Hydraulic conveying of solids is discussed in Section 16.11.2.5. Conveying solids is considered in Section 16.11.2.6, while Sections 16.11.2.7 and 16.11.2.8 address piping and steam.

16.11.2.1 Gas Moving: Pressure Service

Area of Application

Fans: 0.1 to 30 kPa; 1 to 10^5 dm^3/s.
Blowers: 10 to 300 kPa; 1 to 10^3 dm^3/s.
Rotary screw: 20 to 2500 kPa; 10 to 10^4 dm^3/s.
Centrifugal compressors: 20 to 30,000 kPa; 200 to 3×10^5 dm^3/s.

* For more details, see D. R. Woods. *Rules of Thumb in Engineering Practice.* Wiley-NCH, 2007.

Reciprocating piston compressors: 30 to 400,000 kPa; 5 to 10^4 dm^3/s. Usually economical for >6 MPa and <150 dm^3/s or any discharge pressure and flows <100 adm^3/s.
Axial compressors: 20 to 2,000 kPa; 4×10^3 to 10^6 dm^3/s.

Guidelines

Fans: Power: up to 7.5 $kW/m^3/s$.
Blowers: Power: up to 125 $kW/m^3/s$.
For compressors,

Adiabatic	pV^k = constant
Isothermal	pV = constant
Polytropic	pV^n = constant: for uncooled internally, $n > k$; for internally cooled, $1 < n < k$, with $n \approx k$. $k = c_p/c_v = 1.04$, increases to 1.67 as the molar mass decreases with air = 1.4 and such gases as ethylene, carbon dioxide, steam, sulfur dioxide, methane, and ammonia = 1.2 to 1.3.

Temperature rise between feed 1 and exit 2:

$$T_2/T_1 = (p_2/p_1)^{[(n-1)/n]}$$

$$(n-1)/n = (k-1)\eta/k_{\ p}$$

$$\eta_p = \text{polytropic efficiency}$$

For each stage, keep the exit temperature $(T_2 - 298) < 120 - 150$°C. For diatomic gases, k = 1.4, which limits the compression ratio (p_2/p_1) to 4; for triatomic gases, 6.

$\eta_p > \eta_{adiabatic}$. For uncooled compressors, polytropic, hydraulic, and temperature rise efficiencies are the same and range from 0.7 to 0.8 with the usual value of 0.72.

Rotary screw: Power: 100 to 750 $kW/m^3/s$.

Centrifugal compressors: These deliver actual volumetric flows (cubic decimeters per second, and performance should not be expressed as mass, moles, or standard volumetric flow). Assume compression ratios to be equal in all stages. The maximum number of stages that can be on one shaft or fit in the "frame" = eight minus one stage for each side nozzle. The compression ratio is 2.5 to 4. The pressure coefficient = 0.5 to 0.65; assume 0.55. The pressure differential increases with increase in suction gas density (increased molar mass or suction pressure, or decrease inlet temperature, decrease in k). Power: Up to 7.5 $kW/m^3/s$. Efficiency of large centrifugal compressors: 76 to 78%.

Centrifugal compressors operate between low volumetric flow rate "surge" conditions and high volumetric flow rate limited by the sonic velocity at the eye of the impeller. At "surge" conditions, the gas flow back through the compressor causes damage to the thrust bearings. The surge point is usually 0.33 to 0.5 of the normal operating capacity of the compressor. During startup, the machine goes through the surge region. The point of surge is a minimum for a single impeller. The range of stable operation decreases 5% with the addition of each impeller. High molar mass decreases the range of operation. Surge may be caused by a system disturbance (especially changes in the molar mass of the feed gas) and insufficient flow.

Surge is related to power used:

- When the molar mass of the inlet gas increases, the motor amps increase.
- If the molar mass increases by 20% and we control the suction drum pressure by recycling exit gas to the inlet (spill back control), the motor amps increase by 20%; if control is by throttle of the suction line, the motor amps increase by 10%. For every

10% decrease in the total number of moles compressed, the amp load on the motor drive decreases by 5%.

Reciprocating piston compressors. Compression ratios are 1.2 to 6; select to keep outlet temperature <150°C. Efficiencies for reciprocating compressors are 65% for compression ratio 1.5; 75% compression ratio 2, and 80% to 85% for compression ratios 3 to 6. Power: 70 to 1200 kW/m^3/s.

Axial compressors. Compression ratios of 1.2 to 1.5 per stage and 5 to 6.5 per machine. Efficiency: 70% except for liquid ring 50%. Power: 35 to 950 kW/m^3/s.

In general,

Velocity: pump gas 30 to 60 m/s
pump oxygen/chlorine: 20 m/s
pump steam 60 m/s

Pressure drop through pipes: 1 velocity head per 45 to 50 length/pipe diameter
Through shell and tube exchangers: 5 kPa/pass
Through wet sieve tray: 0.3 to 0.65 kPa/theoretical stage
Through packing tower: 0.2 to 0.75 kPa/m packing

moderate- to high-pressure distillation	0.3 to 0.6 kPa/m
vacuum distillation	0.08 to 0.16 kPa/m
absorbers	0.15 to 0.5 kPa/m

Through porous bed Δp (particle dia.)^3 depth: 2 to 50 kPa (mm^3/m)
Through cyclone: 0.5 to 1.6 kPa
Through venturi scrubber: 0.5 to 6 kPa

16.11.2.2 Gas Moving: Vacuum Service

Area of Application

Liquid-piston pump: down to 12 kPa absolute; 0.01 to 1,000 kg/h air
Rotary sliding vane: down to 4 kPa abs.; 0.01 to 300 kg/h
Wet reciprocating: down 3 kPa abs.; 0.01 to 100 kg/h
Dry reciprocating: down to 0.1 kPa abs.; 0.01 to 300 kg/h
Mechanical vacuum: down to 0.01 kPa abs.; 0.01 to 40 kg/h
Steam ejector:
1 stage: down to 5 to 6.7 kPa abs.; 0.01 to 100 kg/h air exhausted
2 stage: down to 0.5 to 1.4 kPa abs.; 0.01 to 100 kg/h
3 stage: down to 0.1 to 0.2 kPa abs.; 0.01 to 50 kg/h
4 stage: down to 0.01 to 0.25 kPa; 0.01 to 10 kg/h
5 stage: down to 0.001 to 0.0025 kPa abs.; 0.01 to 8 kg/h
6 stage: 0.0004 kPa abs.

The practical limit is 0.0004 kPa abs.

Guidelines

Air leakage into unit: 50 kg/h
Liquid-piston pump: 100 to 200 kW/m^3/s exhausted air
Rotary sliding vane: 130 to 250 kW/m^3/s air exhausted
Wet reciprocating: 2 to 50 kW/m^3/s air exhausted
Dry reciprocating: 2 to 50 kW/m^3/s air exhausted

Mechanical vacuum: 2 to 50 kW/m^3/s air exhausted
Steam ejector:
1 stage: 0.002 to 10 kg steam/kg air exhausted/kPa abs
2 stage: 100 kg steam/kg air exhausted/kPa abs
3 stage: 1 Mg steam/kg air exhausted/kPa abs
4 stage: 2 Mg steam/kg air exhausted/kPa abs
5 stage: 40 Mg steam/kg air exhausted/kPa abs
Steam ejector, general:
down to 10 kPa abs., 1 to 200 kg/h air; 1.3 kg steam/kg air exhausted/kPa abs.
down to 30 kPa abs., 1 to 20 kg/h air exhausted; 0.1 kg steam/kg air exhausted

The compression ratio of the first-stage ejector is set primarily by the intercondenser cooling water temperature.

Assume discharge pressure to atmosphere after the last stage = average barometric pressure + 7 kPa.

Assume motive steam = minimum steam pressure in header less 5 to 10%. Pressure drop on shell side of surface condenser usually <5% of absolute design operating pressure.

A related topic is covered in Section 16.11.3.13 for interstage direct contact G-L condensers, although current practice is to use surface shell-and-tube condensers.

16.11.2.3 Liquid

Area of Application

Centrifugal pumps: head = fluid viscosity <300 mPa·s
end suction, single stage: head = 0.2 to 100 m; 0.05 to 4000 L/s; 0.05 to 0.7 kW/L/s; efficiency 40 to 60%
end suction, multistage: head = 50 to 800 m; 10 to 400 L/s; 0.2 to 10 kW/L/s; efficiency 40 to 60%
Peripheral: 10 to 300 m; 0.1 to 2 L/s; 4 kW/L/s
Centrifugal axial: fluid viscosity <300 mPa·s: 0.3 to 10 m; >150 L/s; 0.1 kW/L/s
Reciprocating pumps: fluid viscosity <5,000 mPa·s, diaphragm or piston: 1 to 1,000 m; <50 L/s; 0.1 to 3 kW/L/s
Rotary screw: fluid viscosity, usually above 10 Pa·s; 0.2 to 300 m; <120 L/s

Guidelines

Optimum exit pipe size selection:
pump liquids at >1.5 m/s
hydrocarbons with low conductivity <0.3 m/s
Suction pipe of larger diameter to prevent cavitation
NPSH requirement [m] = $\{\text{rpm}/(5400 \text{ volumetric flow rate [L/s]})\}^{1.33}$
Centrifugal pumps operate on their operating head-capacity curve. Head-capacity curves are independent of the fluid, although the curve drops slightly at higher capacities for higher-viscosity fluids. For centrifugal pumps, the drive power required and pressure at the exit flange depend on the fluid density. Reciprocating pumps are constant-volume devices, producing essentially constant "pressure."
Pressure drop through pipes: 1 velocity head per 45 to 50 length/diameter; for water, 23 kPa/100 m pipe
Pressure allowance across a control valve for good operability: 20 to 50% of the dynamic head loss or 70 to 140 kPa

Pressure drop:
- shell and tube exchanger: 70 kPa
- plate exchanger: 50 kPa
- dialysis: 50 to 10 MPa
- RO: 0.1 to 4 MPa
- Filter press: 70 kPa
- Porous bed: 0.3 to 7 kPa/m depth of bed/L/m²·s usual: 5 to 10 bed volumes per h; 1 to 10 L/m²·s, usually limited to <80 kPa

Similitude for centrifugal devices: volumetric flow rate ratios = (diameter of impeller ratio) times (impeller rpm ratio); head ratios = (diameter ratio)^2 times (the impeller rpm ratio)^2; power ratio = (diameter ratio)^3 times (impeller speed ratio)^3.

16.11.2.4 Gas-Liquid (Two-Phase Flow)

Table 16.31 illustrates different flow regimes for vertical cocurrent upflow, vertical countercurrent, and horizontal flows. This also pertains to boilers (Section 16.11.3.3) and to evaporators (Section 16.11.4.1).

Two-phase flow over a packing is given in Section 16.11.6.15 for trickle bed reactors.

16.11.2.5 Pumping Slurries: Liquid-Solid Systems

Area of Application

Solid concentration: 25% to 65% w/w; solid particle size: 20 to 300 μm. For finer particle size, watch for non-Newtonian behavior. For higher concentrations, consider short pumping runs only; for small concentrations, beware of settling out. For larger particles, watch for settling out.

Guidelines

Pumping velocity: 1 to 4 m/s; 0.06 to 0.7 kW/Mg/h per km distance. Loading 0.3 to 1.7 kg solids/kg water. Economic trade-off between solids loading and pumping costs. Try to use the heterogeneous flow regime and consider adjusting pH to alter stability of dispersion.

TABLE 16.31
Superficial Velocities of Liquids and Gases, m/s

	Horizontal		Vertical Cocurrent Up		Vertical Cocurrent Down		Vertical Countercurrent Up	
	Liquid	Gas	Liquid	Gas	Liquid	Gas	Liquid	Gas
Dispersed: nearly all liquid entrained	Same as gas	>60	>1	<15				
Annular: liquid ring; central gas	<0.15	>6	<8	15–80	0.01–0.15	<0.5–10	0.01–0.2	<15
Stratified: liquid along bottom	<0.15	0.15–3						
Slug: periodic liquid slug	4.5 but < vapor	0.9–15	<1	1–15	0.15–0.8	<20		
Plug: alternating slugs of liquid & gas	<0.6	<1.2	<0.5	0.1–1.5				
Bubbles	1.5–4.5	0.15–0.6	<8	<0.1–1	>0.8	<8		
Choked/flooded			>10	>80	>1–100	>80	0.01–>0.2	0.1–>15
Part dry			<0.05	>20	<0.01	<80	<0.01	

16.11.2.6 Solids

Choice depends on particle characteristics (size, flowability, corrosiveness, abrasiveness, handling characteristics, safety-hazard [static electrification, fumes, flammability]), and vertical versus horizontal distance. A related topic is covered in Section 16.11.2.5, and bins for storage (Section 16.11.6.35).

Area of Application

Belt conveyors: <10° incline; 10 to 100 m horizontal distance; capacity 3 to 270 kg/s. OK for most diameters of particles but not for particles that cake or are light and fluffy.

Bucket/belt elevators: usually for >25 m vertical; 15 to 150 Mg/h; usually not for particles <150 μm dia. and not for particles that cake or are light and fluffy.

Screw conveyors: 2 to 75 m horizontal distance; 0.3 to 275 kg/s. Not for particles that cake or are light and fluffy. Can be used for inclines up to 20°.

Vibratory feeder: <20 m; 1 to 400 Mg/h; not for light and fluffy materials or particles <150 μm dia.

Apron feeder: <18° incline; 2 to 12 m horizontal; 10 to 150 Mg/h; not for particles that cake or are light and fluffy or are fine with <50 μm dia.

Pneumatic transportation: limited by solids loading that plugs pipe.

Dilute phase: pressure: continuous: particle dia. 60 μm to 0.3 cm; pressure drop <100 kPa. Distance <600 m. One-point collection and several-point delivery.

Dilute phase: vacuum: continuous: particle dia. 60 μm to 0.3 cm; Δp pressure drop <50 kPa. Distance <50 m. One-point delivery and several-point delivery.

Dense phase: pressure: batch: particle dia. 60 μm to 0.3 cm; pressure drop 550 to 700 kPa. High capacity (<10 kg/s) over long distances <2300 m. For materials that degrade easily or are highly abrasive.

Guidelines

Caution for all: dust explosions: dust explosion potential for particle dia. <200 μm. Minimum ignition temperature >300°C; minimum ignition energy 10 to 30 mJ.

Belt conveyors: keep speeds <1 m/s for fines; otherwise speeds in the range 2.7 to 4 m/s; burden thickness (cm) = 0.17 (volumetric capacity, dm^3/s)/{(belt speed, m/s)(belt width, m)}. Belt width 0.5 to 0.8 m.

Speed: 0.8 to 2 m/s.

Power: 0.02 to 0.4 kW/Mg/h per km horizontal distance.

Bucket conveyor: vertical: velocity <1.5 m/s; for material of density 0.4 Mg/m^3 capacity <16 kg/s; for 2 Mg/m^3 capacity <85 kg/s or <40 m^3/s. Power 0.15 to 0.35 kJ/kg or 0.013 to 0.023 kJ/kg/m of height.

Screw conveyors: 10 to 120 rpm and trough loading 15 to 95%, depending on the particle size, flowability, abrasiveness. Dia. 0.3 to 0.4 m. Power 10 to 20 kW/Mg/h per km horizontal distance.

Rotary, star valve feeder: used especially as solids feeders for dilute-phase pneumatic conveying to provide an air lock and to feed solids. Seal/wear depends on Δp and abrasiveness of powder. For pressure systems keep Δp <80 kPa; for vacuum systems Δp <40 kPa. Provide an air vent to take the air loss away from the gravity flow of the solids and to control the filling of the star.

Pneumatic conveying: dilute phase: pressure: continuous: nominal gas velocity 5 to 35 m/s with usual 11 to 25 m/s. Solids loading 3.5 to 15 kg solid/kg air with usual 6 to 15 kg solids/kg air or 1 to 7 m^3 solids/m^3 air. Power 7 to 11 kJ/kg. Problems: about 30% air leakage out of the system. Rotary/star valve problem/bridging: overcome with bin

agitation, astute bin design, and vent star valve to prevent the backflow of gas through the valve into the bin. Minimize bends.

Pneumatic conveying: dilute phase: vacuum: continuous: nominal gas velocity 20 to 35 m/s. Solids loading 2.8 to 11 kg solids/kg, gas with usual 3 to 4 kg solids/kg/air. Power 11 to 18 kJ/kg. Rate and distance sensitive.

Pneumatic conveying: dense phase: pressure: pressure, batch; cycle time 1 to 4 min; charge 10 s; convey 0.5 to 3 min; 20 to 50 batches/h, nominal gas velocity: horizontal 4.5 to 35 m/s with usual 6 to 10 m/s; vertical 1.5 to 27 with usual 3 m/s. Solids loading: horizontal 12 to 130 kg/kg; vertical 10 to 800 with usual 250 to 400 kg solids/kg air. Blow tank <15 m^3. Line dia. 3 to 10 cm. Power 3 to 5.5 kJ/kg. Watch for humid air and line plugging.

The longer the distance, the lower the solids loading or the more gas needed to convey.

Enclosed conveyor: 0.09 to 9 dm^3/s; conveyor size 7.5 to 25 cm; travel speed 0.02 to 0.3 m/s.

16.11.2.7 Ducts and Pipes

Guidelines

Pressure drops: see gas, Section 16.11.2.1; and liquid, Section 16.11.2.3.

Velocities, see gas, Section 16.11.2.1; and liquid, Section 16.11.2.3. Keep the velocity of compressible gases <0.6 sonic velocity.

Sonic velocity, m/s = 1.97 $[(c_p/c_v)$ pressure, kPa, × density, $kg/m^3]^{0.5}$.

Sewer pipes have maximum flow rate when liquid level is 93% of the diameter; flow rate when full = flow rate when liquid level is 80% of the diameter.

Schedule 40 = usual specification; schedule 80 is heavy duty.

16.11.2.8 Steam

Area of Application

Steam for power via turbine drives (Section 16.11.3.1) and via vacuum ejectors (Section 16.11.2.2). Thermal heating (Section 16.11.3.3), separations via evaporators (Section 16.11.4.1), distillation (Section 16.11.4.2), and dryers (Section 16.11.5.5).

Guidelines

For delivery, gas velocity 60 m/s. Typical steam gauge pressures: 100 to 200 kPa, 120 to 130°C. *Comment*: tends to be sluggish in response to changes in demand. 1 MPa, 185°C; 1.7 MPa, 210°C; 2.75 MPa, 230°C; 4.1 MPa, 255°C.

Steam leakage: 40 g/s at 0.7 kPa through a 6-mm dia. hole. Leak rate proportional to (hole diameter)^2 × pressure.

See also steam traps to separate condensate from steam (Section 16.11.5.1) and steam generation, furnaces (Section 16.11.3.2).

Steam flow through a control valve (called *wiredrawing*) occurs at constant enthalpy with a resulting increase in temperature or superheat.

16.11.3 Energy Exchange*

In this section, we consider drives and then a wide range of thermal energy exchangers: furnaces, heat exchangers, indirect fluidized beds, motionless mixers, direct contact liquid-liquid, kilns, fluidized beds, and multiple-hearth furnaces. Drying is considered in Section 16.11.3.10. Various direct-contact gas-liquid exchangers are considered in Sections 16.11.3.11 through 3.13. Thermal

* For details, see chapter on heat transfer. Reproduced from *Rules of Thumb for Process Design and Engineering Practice* with permission from Donald R. Woods, ©2001.

wheels are discussed in Section 16.11.3.14. Sections 16.11.3.15 through 16.11.18 discuss solidification of solids, heat loss to the atmosphere, refrigeration, and steam generation.

16.11.3.1 Drives

Area of Application

Gasoline/diesel engines: 200 to 800 rpm; >80 kW; efficiency: 28 to 38%.
Electric motors (synchronous): <500 rpm; 35 to 500 kW; use 480 V for motors up to 115 kW; 4160 V for >115 kW.
Electric motors (induction): >500 rpm; 10 to 15000 kW.
Steam turbine: single-stage, single-valve: 1000 rpm to 12,000 rpm; 50 to 1500 kW
Single-valve, multistage: 1500 to 2800 kW
Multivalve, multistage: 2800 to 30,000 kW
Gas combustion turbine: cogeneration

Guidelines

For less than 75 kW, select motor or turbine.

Gasoline-diesel engines usual application: 200 to 400 rpm; 500 to 1200 kW.

Electric motors: select synchronous for low speed; usual application for either synchronous or induction: 500 to 2100 rpm; 150 to 500 kW. Usually use total enclosed Fan cooled (TEFC) enclosure, efficiency: 84 to 95%.

Induction: available for large power requirements, relatively low efficiency, power factor is low if rpm <500 and at starting and fractional loads.

Synchronous: high efficiency at any speed, suitable for direct coupling for <1000 rpm. Power factor >1; constant speed without slip. Power consumption, kW = amps ($0.001\ \text{volt} \times \text{PF} \times 0.95 \times \sqrt{3}$).

Power, kW	Volts, V
0.1 to 1	110
1 to 75	220 to 440 3 phase
50 to 200	440 to 2,300
175 to 2000	2,300 to 4,160
>2000	11,000 to 13,200

Steam turbines: competitive above 75 kW; condensing: 2 kg/h steam/kW with 1.8 m^2 condenser surface area per kg/h steam. Multivalve, multistage efficiency: 42 to 78%.

16.11.3.2 Thermal Energy: Furnaces

Multiuse including heating, boiling, reactions. Related topics are distillation (Section 16.11.4.2) and reactors (Section 16.11.6.4).

Area of Application

250 to 1300°C; <30 MPa; thermal efficiency: 70 to 75%.

Guidelines

Heat flux in radiant section: 10 to 60 kW/m^2 based on outside tube area with fluid velocity inside tubes 0.1 to 3 m/s. Use 1.5 m/s. In the convection section: 12 kW/m^2.

Equate heat duties in the radiant and convection sections; 80% efficiency based on net heating values.

Size radiant section to absorb 50% of the radiant energy with 1.22 m^3 chamber per m^2 tube area.

Field fabricated for sizes above 5 MW total heat load.
Gas catalytic endothermic reaction inside tube, heat transfer coefficient $U = 0.045$ kW/m²·K.

16.11.3.3 Thermal Energy: Fluid Heat Exchangers, Condensers, and Boilers

Exothermic processes should supply all the heat requirements for the process.

Area of Application

Shell-and-tube: –200 to 600°C; <30 MPa; 0.15 to 4 THTU/pass and 5 to 150 kPa/THTU; fluid viscosities <100 mPa·s. Area: 2 to 2000 m².
Fixed tube sheet limited to low thermal expansion or if $\Delta T \leq 30$°C.
Usually need U-tube or floating head.
Spiral: –100 to 400°C; <1.8 MPa; use with sludges, slurries, high-viscosity materials (especially 4×10^4 to 4×10^5 mPa·s); >90% heat recovery. High heat transfer coefficients; low pressure drop. Ratio of flow rates being handled <3.5. Not when $\Delta T_1 >> \Delta T_2$. Area: 4 to 100 m².
Lamella: –200 to 500°C; <3 MPa. Ratio of flow rates 1 to 1.8. Area: 100 to 10,000 m².
Gasket/plate: –30 to 180°C; <2.5 MPa, depending on the gasket material; areas <2,000 m²; 0.2 to 3 THTU/pass and 15 to 200 kPa/THTU; fluid viscosities < 4×10^4 mPa·s. Holdup low, 1.5 L/m². Ratio of flow rates 0.7 to 1.3. Not when $\Delta T_1 >> \Delta T_2$. Area: 10 to 600 m².
Double-pipe: –200 to 600°C; <30 MPa; usually <20 m². Use for high pressure. Area: 0.3 to 200 m².
Air-cooled: OK when air can be used as coolant. Low maintenance, area: 20 to 2000 bare tube m². Finned area 16:1.
Cubic/monolithic: corrosive liquids, acids, bases, or used as catalyst/heat exchanger for reactors. Usually made of graphite or carbon that has high thermal conductivity, area: 1 to 20 m². Ceramic monoliths are used as solid catalyst for highly exothermic gas-catalyst mass transfer-controlled reactions.
Agitated falling film: usually to concentrate slurry; see evaporation, Section 16.11.4.1.
Agitated horizontal film (votator): usually to condition foodstuffs, crystallize, and react. Especially for viscous feed. OK for foaming, fouling, crystal formation, and suspended solids. Viscosities >2000 mPa·s. Relative to agitated film retention time of 1:1 and volume 1:1. Overall heat transfer coefficient 2 kW/m²·°C, decreasing with increasing viscosity; 3 to 12 kW/m². See also evaporation, Section 16.11.4.1.
Coil in tank: area: 1 to 30 m².
Jacketed: usually to exchange heat in a reactor or storage tank.
Cooling finger: added to tanks to increase the exchange area.

Guidelines

Media for heating and cooling:
Water: 18°C to maximum outlet 50°C with velocity >1.2 m/s
Air: 18°C to maximum outlet 50°C
Steam: 1.7 MPa: 203 to 220°C
43 MPa 260°C
For pressures 0.1 to 0.2 MPa:
–100°C, consider ethane
–50°C, consider propane, propylene
–30°C, consider ammonia
0°C, consider butane

175°C, consider Dowtherm J
200 to 400°C, consider molten salt
275°C, consider Dowtherm A
310°C, consider Dowtherm G

Shell-and-tube:
Use shell-and-tube exchangers for gas-gas and for low-viscosity liquid-liquid systems (<200 mPa·s).

Use floating head if the temperature difference between shell-and-tube fluids exceeds 30°C (to minimize impact of thermal expansion).
Surface compactness: for ordinary tubes: 70 to 500 m^2/m^3; for finned tubes 65 to 3300 m^2/m^3.

Number of Shell Passes Affected by Temperature Ratio $\frac{(t_{hot/in} - t_{hot/out}) + (t_{cold/out} - t_{cold/in})}{(t_{hot/in} - t_{cold/in})}$	**No. of Shell Passes**
0–0.8	1
0.8–1.1	1 or 2
1.1–1.3	2
1.3–1.4	2 or 3
1.4–1.5	3

Tube velocity >1 m/s; for crude preheat exchangers, tube velocity is 1 to 2 m/s; for overhead water condensers, tube velocity is 1 to 3.5 m/s. To minimize fouling, keep tubeside velocities 3 to 4.5 m/s, reduce the wall temperature, and use single-flow channels.

Nozzle velocity <2 m/s and Δp, kPa = 0.75 to 0.9 (nozzle velocity, m/s)^2.

Baffle cut <30%; baffle pitch: minimum should be the maximum of 5 cm or 1/5 of ID shell diameter. The maximum should be the smaller of 0.75 m or shell ID diameter.

For shell-and-tube heat exchange: numerous related topics including evaporation (Section 16.11.4.1), distillation (Section 16.11.4.2), crystallization (Section 16.11.4.6), freeze concentration (Section 16.11.4.3), melt crystallization (Section 16.11.4.4), and PFTR reactors (Section 16.11.6.5 and .6). Approach temperature 5 to 8°C; use 0.4 THTU/pass; design so that the total pressure drop on the liquid side is about 70 kPa. Allow four velocity heads pressure drop for each pass in a multipass system. Put inside the tubes the more corrosive, higher-pressure, dirtier, hotter, and more viscous fluids. Recommended liquid velocities 1 to 1.5 m/s with maximum velocity increasing as more exotic alloys are used. Use triangular pitch for all fixed tube sheets and for steam condensing on the shell side. Try U = 0.5 kW/m^2·°C for water/liquid; U = 0.3 kW/m^2·°C for hydrocarbon/hydrocarbon; U = 0.03 kW/m^2·°C for gas/liquid, and 0.03 kW/m^2·°C for gas/gas. Finned tubes: see air-cooled.

For shell-and-tube condensation: related topics include evaporation (Section 16.11.4.1) and distillation (Section 16.11.4.2). Prefer condensation outside horizontal tubes; use vertical tubes when condensing immiscible liquids to subcool the condensate. Assume pressure drop of 0.5 of the pressure drop calculated for the vapor at the inlet conditions. Baffle spacing is 0.2 to 1 times the shell diameter with the baffle window about 25%. Limit pressure drop for steam to 7 kPa on the shell side. U = 0.5 to 0.85 kW/m^2·°C.

For shell-and-tube boiling: approach temperature <25°C to ensure nucleate boiling. Related topics include evaporation (Section 16.11.4.1), distillation (Section 16.11.4.2), solution crystallization (Section 16.11.4.6), and reactors, PFTR nonadiabatic (Section 16.11.6.6).

Kettle: use for clean, relatively low-pressure, nucleate pool boiling; not for foams; 75 to 100% vaporized. U = 1.1 kW/m^2·°C.

Vertical/horizontal thermo syphon: use for clean, relatively low-pressure, nucleate pool boiling; 5 to 25% vaporized. Use 45 to 56 kW/m^2 heat flux for hydrocarbon and petrochemicals, 62 to 75 for aqueous, and 37 to 44 for vacuum. Rarely used for vacuum or very high-pressure service. U = 1 kW/m^2 K.

Forced circulation: use for vacuum or viscous/fouling fluids. Sensible heat only. Tube velocity 3 to 4.5 m/s.

For various configurations of evaporators, see evaporation, Section 16.11.4.1.

For steam usage, see steam traps, Section 16.11.5.1.

For shell-and-tube gas reactor with fixed catalyst inside tubes: related to reactor, Sections 16.11.6.6 and 16.11.6.7.

Endothermic reaction in catalytic fired tube: U = 0.045 kW/m^2·°C.

Exothermic reaction in catalytic multitube, nonadiabatic, with boiling water or molten heat transfer salt or liquid: 0.05 to 0.12 kW/m^2·°C.

Spiral: for large flows and alloys construction select spiral over shell-and-tube. Heat transfer coefficients about double that of shell and tube, liquid-liquid U = 2.8 to 4 kW/m^2·°C. Surface compactness: up to 185 m^2/m^3.

Lamella/plate (Raman): approach temperature 2°C; for liquid-liquid U = 1.7 to 2.5 kW/m^2·°C.

Surface compactness: 150 to 5900 m^2/m^3.

Gasket/plate: approach temperature 1°C; heat transfer coefficients about 3 to 5 times higher than shell-and-tube, for liquid-liquid U = 4 to 4.5 kW/m^2·°C. Surface compactness: 120 to 1000 m^2/m^3.

Double-pipe: for heat exchange: use for <20 m^2; attractive for the condensation of reacting gases because it provides least area per unit volume.

Air-cooled: two fins/cm of tube length; use finned tubes on gas side to give less weight, less pressure drop, but not for dirty gases on the fin side because of difficulty in cleaning. Use when the potential finned side coefficient is small (0.05 to 0.1 kW/m^2·°C) and when the ratio of tube side to gas side coefficient is 75 to 300, but not when it is 1 to 25. Use h_oA_o, not area only, for optimization (because heat transfer coefficient decreases as the fin area increases). Finned tubes with 15 to 20 m^2 total area/m^2 bare tube area, 0.4 to 0.6 kW/m^2·°C of bare tube; approach temperature >26°C; fan power is 5 to 13 kW/kW thermal energy transferred or 0.15 kW/m^2 of bare tube.

Cubic/monolithic: corrosive acids and bases: liquid-liquid U = 0.5 to 1.1 kW/m^2·°C. For gas-catalyst heat exchange, U = 3.5 to 7.5 kW/m^2·°C. Heat transfer areas up to 2200 m^2.

Agitated falling film: see evaporation, Section 16.11.4.1.

Agitated horizontal film (votator): thin liquids U = 2.2 to 4 kW/m^2·°C; viscous films U = 0.8 to 2.3 kW/m^2·°C; crystallization U = 0.15 to 3.7 kW/m^2·°C; sulfonation U = 0.8 to 2.2 kW/m^2·°C; polymerization U = 1 to 2.8 kW/m^2·°C. See also evaporation, Section 16.11.4.1.

Coil in tank: heating U = 0.6 to 2.5 kW/m^2·°C; cooling U = 0.2 to 1.2 kW/m^2·°C.

Jacketed: heating U = 0.2 to 1.7 kW/m^2·°C; cooling U = 0.1 to 0.6 kW/m^2·°C.

Cooling finger: cooling U = 0.5 to 1.2 kW/m^2·°C.

16.11.3.4 Thermal Energy: Fluidized Bed (Coils in Bed)

Related topics include direct heat transfer (Section 16.11.3.8), reactors (Section 16.11.6.27), mixing (Section 16.11.7.1), dryers (Section 16.11.5.5), and size enlargement (Section 16.11.9.5).

Area of Application

Use for highly exothermic reactions or for heating/cooling solids. Mixing provides uniform temperature in the bed and solids increase the heat transfer coefficients 5 to 25 times that of the gas alone.

Guidelines

Coils in fluidized bed: U = 0.2 to 0.4 kW/m²·°C; bed to wall U = 0.45 to 1.1 kW/m²·°C; solids to gas U = 0.017 to 0.055 kW/m²·°C; gas-solid thermal conductivity 0.17 to 42.5 kW/m·K.

16.11.3.5 Thermal Energy: Motionless Mixers

Related topics include reactors (Section 16.11.6.10), mixing (Section 16.11.7.3), size reduction, gas-liquid (Section 16.11.8.1), and liquid-liquid (Section 16.11.8.3).

Area of Application

Use for viscosity liquids <50 mPa·s and liquid reactions (Section 16.11.6.9).

Guidelines

Cooling melts U = 0.15 to 0.25 kW/m²·°C. Polymerization: 10 kW/m²·°C. Internal heat transfer coefficient h_{inside} = 3 × value for fluid flowing in empty pipe of same diameter and length.

16.11.3.6 Thermal Energy: Direct Contact Liquid-Liquid Immiscible Liquids

A related topic is size reduction (Section 16.11.8.3).

Area of Application

Exchange heat across a liquid-liquid interface. Droplet diameter and area per unit volume estimated from size reduction (Section 16.11.8.3).

Guidelines

Tray, sieve: U_v = 160 kW/m³ °C
Wetted wall: U_v = 20 kW/m³ °C
Baffles: U_v = 20 kW/m³ °C;
Spray tower: U_v = 2 to 100 kW/m³ °C
RTD: U_v = 260 kW/m³ °C
Pipeline: U_v = 200 to 1000 kW/m³ °C

16.11.3.7 Thermal Energy: Direct Contact Gas-Solid Kilns

A related topic is reactors (Section 16.11.6.17).

Area of Application

Temperature 520 to 1700°C; atmospheric pressure; particle diameter 7 μm to 20 mm; solid residence time 2000 to 35,000 s.

Used for drying (Section 16.11.5.5), incineration, and gas-solid reactions (Sections 16.11.6.17 through 16.11.20).

Guidelines

Rotary cascading kiln dryer: heat transfer coefficient U_m = 0.1 W/kg solids °C for coarse materials and 0.4 W/kg °C for fine materials.

Incineration: volumetric loading 5% solids; temperatures 820 to 1600°C; heat release from combustion 260 to 415 kW/m^3; gas velocity 4.5 to 6 m/s; solids residence time 1 to 2 h; gas residence time 2 to 4 s. L/D 3.4 to 4/1.

Reactor: volumetric solids loading 3 to 12%; heat usage: 25 to 60 kW/m^3 of kiln volume; solids capacity for cement 0.4 to 1.1 Mg/d·m^3 kiln volume; solids capacity pigments, dolomite 0.1 to 2 Mg/d·m^3 kiln volume.

16.11.3.8 Thermal Energy: Direct Contact Gas-Solid Fluidized Beds

Related topics are indirect heat transfer (Section 16.11.3.4), reactors (Section 16.11.6.24), mixing (Section 16.11.7.2), dryers (Section 16.11.5.5), and size enlargement (Section 16.11.9.5).

Area of Application

Particle diameter 40 to 100 μm.; surface area 20,000 to 100,000 m^2/m^3 bed. Used for drying (Section 16.11.), incineration, gas-solid, and gas catalyst reactions (Section 16.11.6.24).

Guidelines

Gas and particles leave the bed at the same temperature. Particle-gas heat transfer coefficient U = 0.01 to 0.06 kW/m^2·K.

Incineration: volumetric loading 5% solids; temperatures 650 to 980°C; heat release from combustion 200 to 340 kW/m^3; superficial gas velocity 60 to 75 g/s·m^2 of cross-sectional area for wet solids; 15 to 20 g/s·m^2 of cross-sectional area for dry solids combustion.

16.11.3.9 Thermal Energy: Direct Contact Gas-Solid Multiple-Hearth Furnaces

Related topics include dryers (Section 16.11.5.5) and reactors (Section 16.11.6.15).

Area of Application

Used for drying (Section 16.11.5.5), reactions (Section 16.11.6.15), and incineration.

Guidelines

Incineration: temperatures 790 to 980°C; heat release from combustion 150 to 250 kW/m^3.

Reactors: solids residence time 4 to 5 h.

16.11.3.10 Thermal Energy: Gas-Solid Drying of Solids

Topics in Sections 16.11.3.7 through 16.11.3.9 can be used to dry solids. Other dryers are described in Section 16.11.5.5.

Area of Application

See Section 16.11.5.5.

Guidelines

Solutions of salts: overall heat transfer coefficient: U = 0.12 to 0.35 kW/m^2·°C.

Slurries, powders, and granules: overall heat transfer coefficient: U = 0.03 to 0.23 kW/m^2·°C.

Drum dryer (conduction): overall heat transfer coefficient: U = 0.001 to 0.002 kW/m^2·°C.

Jacketed screw (conduction): overall heat transfer coefficient: U = 0.015 to 0.06 kW/m^2·°C.

Agitated pan (conduction): overall heat transfer coefficient: U = 0.01 to 0.05 kW/m^2·°C.

Tray/pan shelf (conduction; vacuum): overall heat transfer coefficient: U = 0.02 to 0.5 kW/m^2·°C.

Pneumatic or flash dryers: wall to gas/particle systems: U = 0.1 kW/m²·°C.
Spray dryer: volumetric heat transfer coefficients: U_v = 0.13 to 0.18 kW/m³·°C.
Rotary steam tube dryer: heat transfer coefficient: U = 0.03 to 0.09 kW/m²·°C.
Rotary cascading dryer: heat transfer coefficient: U_m = 0.1 W/kg solids °C for coarse materials and 0.4 W/kg·°C for fine materials.
Continuous freeze dryer: overall heat transfer coefficient: U = 0.001 to 0.01 kW/m²·°C, depending on the vacuum and residence time, with smaller values for lower total pressure and longer residence time.

16.11.3.11 Thermal Energy: Direct Contact Gas-Liquid Cooling Towers

Area of Application

Use of the latent heat of evaporation of 9% of hot water to cool the water by removing sensible heat from hot water; size range: 60 to 1500 L/s.

Guidelines

Volumetric heat transfer coefficients U_v = 0.5 to 15 kW/m³ °C; gas superficial velocity 1 m/s; liquid loading 1 L/s·m² cross-sectional area.

16.11.3.12 Thermal Energy: Direct Contact Gas-Liquid Quenchers

Area of Application

The quenching media can be any liquid. Gas flow rate 4 to 100 m³/s.

Guidelines

Tray: heat transfer coefficient, U = 7 to 20 kW/m²·°C. of tray area; volumetric heat transfer coefficient, U_v = 3 kW/m³ °C; superficial gas velocity =1 to 1.6 m/s; mass loading liquid/gas = 10 to 20/1.
Packing: volumetric heat transfer coefficient, U_v = 3 kW/m³·°C; superficial gas velocity = 1 m/s; mass loading liquid/gas = 1.5 to 3/1.
Spray tower: volumetric heat transfer coefficient, U_v = 1.8 to 5 kW/m³·°C; superficial gas velocity = 1 m/s; mass loading liquid to gas = 1 to 50/1.
Baffles: volumetric heat transfer coefficient, U_v = 0.5 kW/m³ °C; superficial gas velocity = 0.7 to 1 m/s; mass loading liquid to gas = 15 to 60/1.

16.11.3.13 Thermal Energy: Direct Contact Gas-Liquid Condensers

Area of Application

The condensing medium is water to condense steam or to cool gas. Use in steam ejector systems, although these are being replaced by indirect condensers. A related topic is vacuum service (Section 16.11.2.2). Body dia., 0.1 to 2.5 m; liquid flow rate, 3 to 700 L/s.

Guidelines

Liquid loading 43 to 85 L/s·m² cross-sectional area. Height/diameter = 5/1. Keep temperature increase in the cooling water limited to 8.3°C for operating pressures <6 kPa, limited to 17°C for operating pressures 6 to 25 kPa, limited to 25°C for operating pressures >25 kPa; and keep overall temperature <50°C to minimize erosion and corrosion.

Gas cooling: ΔT = 16 to 18°C.
Steam condensation: ΔT = 2.75°C; approach temperature at both ends of the condenser = 2.75°C.

Volumetric heat transfer coefficient U_v = 100 to 150 kW/m³ °C, but value is very sensitive to sensible heat load; usually about 30 kg water/kg steam condensed.

16.11.3.14 Thermal Energy: Gas-Gas Thermal Wheels, Pebble Regenerators, and Regenerators

Area of Application

Hot gas temperature: 180 to 950°C or cryogenic conditions; 80 to 180 kPa absolute. Usually used to recover "waste" heat. For pebble beds, temperatures up to 1700°C. Nominal gas flow rate to one side, 0.6 to 20 m^3/s.

Guidelines

For air to solids: U = 0.02 $kW/m^2{\cdot}°C$; for hydrogen to solids = 0.1 $kW/m^2{\cdot}°C$.

Pebble bed: heat transfer coefficient, U_v = 280 kW/m^3 K volume of pebbles; contact time, fractions of seconds. Surface compactness: up to 15,000 m^2/m^3.

Thermal wheel: contact time fraction of seconds; area 500 to 650 m^2/m^3 per wheel; gas face velocity 1 to 5 m/s, use 3.5 m/s; rpm 10 to 20. Surface compactness: up to 6600 m^2/m^3.

16.11.3.15 Thermal Energy: Solidify Liquids

A related topic, size enlargement, is discussed in Section 16.11.9.15.

Guidelines

Flaker: heat transfer coefficient, U = 0.35 $kW/m^2{\cdot}°C$.
Chilled belt: heat transfer coefficient, U = 0.35 $kW/m^2{\cdot}°C$.
Prilling tower: volumetric heat transfer coefficient, U_v = 0.005 $kW/m^3{\cdot}°C$.

16.11.3.16 Thermal Energy: Heat Loss to the Atmosphere

Area of Application

Depends on the type and thickness of insulation and the external weather conditions.

Guidelines

Heat transfer coefficient, uninsulated into still air, U = 0.005 to 0.01 $kW/m^2{\cdot}°C$; insulated into still air, U = 0.003 $kW/m^2{\cdot}°C$. Values increase as wind velocity increases: for 10 km/h, multiply U by 2; for 20 km/h, multiply U by 3.

Walls to wet earth, U = 0.0015 $kW/m^2{\cdot}°C$; walls to dry earth, U = 0.001 $kW/m^2{\cdot}°C$; floor to ground, U = 0.0007 $kW/m^2{\cdot}°C$.

16.11.3.17 Thermal Energy: Refrigeration

Area of Application

Mechanical vapor recompression for temperatures <20°C, ranging from 10 to –62°C. Refrigeration capacity 20 to 5000 kW.

Guidelines

About 0.2 kW compressor power/kW refrigeration.

16.11.3.18 Thermal Energy: Steam Generation

See thermal energy furnaces/boilers (Section 16.11.3.2). See Section 16.11.2.8 for steam distribution.

16.11.4 Homogeneous Separation*

Overall Guidelines

1. Keep it simple.
2. Exploit differences in properties between the key target species.
3. Consider mixing/blending of streams before considering separation.
4. Remove lightest component, most abundant, least expensive first; or remove the most difficult last.
5. Leave high specific recoveries until last.
6. Try to avoid adding an agent to achieve the separation.
7. Try to avoid extremes in operating conditions.
8. Consider shifting from homogeneous phase separation to heterogeneous phase separation.
9. Consider reaction to shift the species to another form.

16.11.4.1 Evaporation

This is related to crystallization (Section 16.11.4.6).

Area of Application

α_{vp} = 20 to 5000. Liquid feed concentration of target solute 2 to 50%; 1 to 40 kg/s feed rate. One product. Usually used when no solids, nonfoaming and doesn't thermally degrade, although special designs can accommodate these. Can be operated as multistage with up to 3 to 10 stages.

Guidelines

Dissolved solids elevate the boiling temperature between the solution and saturated vapor by 1.5 to 5.5°C.

Temperature-sensitive materials: use the Hickman decomposition hazard index, *HDHI*, which is expressed as the amount of time the material is kept under temperature (as measured by pressure, Pa) in units of Pa·s.

External short tube, vertical exchanger, natural circulation: OK for foaming but not for fouling, crystal formation, or suspended solids. Viscosities <20 mPa·s. Relative to agitated film retention time of 16:1 and volume 10:1. Overall heat transfer coefficient 1 to 1.5 $kW/m^2 \cdot °C$. HDHI = 10^8 to 10^9 Pa·s. Area 3 to 1000 m^2.

External short tube, vertical exchanger, forced circulation: OK for foaming, fouling, crystal formation, and some suspended solids. Viscosities <150 mPa·s. Relative to agitated film retention time of 42:1 and volume 13:1. Overall heat transfer coefficient 0.75 to 3 $kW/m^2 \cdot °C$, decreasing with increasing viscosity. Power 0.13 to 0.5 kW/m^2. HDHI = 10^7 to 10^8 Pa·s. Area 3 to 600 m^2.

External kettle reboiler, natural circulation: viscosities <200 mPa·s.

Internal calandria, vertical short tube: preferred for fouling and crystal forming systems. OK for foaming, fouling, crystal formation, and some suspended solids. Viscosities <1000 mPa·s. Relative to agitated film retention time of 168:1 and volume 3:1.

---

* Reproduced with permission from Donald R. Woods, *Rules of Thumb in Engineering Practice,* pages 87 to 135, 2007, copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, ISBN: 978-3-527-31220-7. See this book for more details, especially about Good Practice, Trouble shooting and Capital Costs.

Long tube, rising film: especially for clear and relatively dilute feed, OK for foaming, but not for fouling, crystal formation, or suspended solids. Viscosities 150 to 1000 mPa·s. ΔT > 14°C. Select ΔT to create annular or mist-annular flow. Overall heat transfer coefficient 2 to 5 kW/m^2 ·°C, decreasing with increasing viscosity. HDHI = 10^6 to 10^7 Pa·s. Area 3 to 300 m^2.

Long tube falling film: especially for heat-sensitive and moderately viscous feeds. Not for foaming, fouling, crystal formation. or suspended solids. Viscosities 150 to 1000 mPa·s. $\Delta T > 3$°C. Select ΔT to create annular or mist-annular flow. Outlet temperature 5 to 6.5°C < steam temperature. Overall heat transfer coefficient 2.5 to 5.6 kW/m^2·°C, decreasing with increasing viscosity. Residence time 15 to 30 s per stage. HDHI = 10^3 to 10^9 Pa·s. Consider multistaging with optimum. Area 3 to 1000 m^2. For condenser, use U = 1.1 to 1.25 kW/m^2·K.

Multistage rising or falling film evaporators: when the boiling temperature rise is large, use four to six multiple-effect stages with forward feed. When the boiling temperature rise is small, use eight to ten multiple effects. For multistaging, feed forward is the most common, but feed backward is used for highly viscous liquids. In feed backward, the more concentrated solution is heated with the highest temperature steam, and pumping is required between stages. The steam economy for n stages is $0.8n$ kg evaporated/kg of outside steam. Boost the interstage steam pressure with steam jet compressors (efficiency 20 to 30%) or with mechanical compressors (efficiency 70 to 75%).

Agitated falling film: especially for viscous feeds. OK for foaming, fouling, crystal formation, and suspended solids. Viscosities >1000 mPa·s. Relative to agitated film retention time of 1:1 and volume 1:1. Retention time about 1 to 30 s. Keep Δt high at 27 to 50°C to keep high heat transfer. Overall heat transfer coefficient 1 to 2 kW/m^2·°C, decreasing with increasing viscosity, although heat transfer coefficients as high as 150 kW/m^2·°C have been reported. Power 1.8 to 4 kW/m^2. HDHI = 10^4 to 10^6 Pa·s. A related topic is thin film reactors (see Sections 16.11.6.17 and 16.11.3.3).

Agitated horizontal film (votator): especially for viscous feed. OK for foaming, fouling, crystal formation, and suspended solids. Viscosities >2000 mPa·s. Relative to agitated film retention time of 1:1 and volume 1:1. Overall heat transfer coefficient 2 kW/m^2·°C, decreasing with increasing viscosity. Three to 12 kW/m^2.

Rising and falling film: especially for heat-sensitive. OK for foaming but not for fouling, crystal formation, or suspended solids. Viscosities <1500 mPa·s. Relative to agitated film retention time of 0.5:1 and volume 0.8:1.

16.11.4.2 Distillation

Area of Application

Liquid feed concentration 15 to 80% w/w; $\alpha_{vp} > 1.2$; with materials not temperature-sensitive, negligible solids, nonfoaming, 99%+ purity possible for both product streams. Maximum column diameter 12 m or feedrate = 300 kg/s; maximum height 35 m.

Guidelines

This is usually the first choice for homogeneous separation.

Configurations include ordinary, vacuum, molecular (small capacity and very high vacuum <3.5 kPa, usually for material with molar mass 250 to 1200) cryogenic (operating at temperatures <–100°C), steam stripping (steam provides direct heating or "inert" steam is added to provide very high "vacuum" when used with organics that are immiscible with water), extractive (solvent is added to the top of the column), azeotropic distillation (solvent is added to the feed to the column), HIGEE (unique spinning tray design), and reactive (reaction and distillation are combined, e.g., for selective catalytic hydrogenation of C4 to C6). The operation can be batch or continuous.

Prefer to remove the most valuable as distillate.
Prefer to remove components one by one as overhead.
Prefer separations that give equimolar splits.
Set the column pressure to try to use water as the coolant and steam as the energy source.
Overhead concentrations 95 to 99% mol.
Internals are trays, packing, or high-performance packing.
If trays are selected, then calculate the theoretical stages required.
Tray options: valve: usually cheaper than sieve, use for large-diameter columns at moderate to high pressures, moderate turndown ratio. Usually about 120 to 140 values per active m^2; sieve: use for large-diameter columns at moderate to high pressures, moderate turndown ratio; bubble cap: use for columns with small liquid flow rate, high turndown ratio, heat transfer needed internally.
Typical Δp/HETS = 0.4 kPa.
Downcomer: unaerated liquid velocity 0.5 m/s; head loss via underflow clearance <0.3 kPa. Allow 3 s liquid residence time and extend to 6 s for foaming systems. Weir overflow velocity = 5 to 20 L/s·m of outlet weir.
If packings are selected, then calculate the number of transfer units, NTU, required or number of theoretical stages (NTS).

C*onventional random dumped packings*: pall rings, Tellerettes, raschig rings, beryl or intalox saddles, lessing rings: use for columns <1 m dia., vacuum service, small pressure drop, high liquid flow rates, viscous liquids, minimum liquid holdup. Prefer Pall rings and Tellerettes; if ceramic, use saddles.

High-performance structured packing: Flexipac, gauze, Glitsch grid, Leva film: not for viscosities >2 mPa·s, pressures >200 kPa;

Δp/HETS 0.001 to 0.5 kPa; very small superficial gas velocity.

To estimate the NTS,

1. Estimate minimum reflux ratio from the Underwood equation, or as an approximation if the distillate is almost pure:

$$R_{\min} = \frac{1}{(a-1)(X_{LK,Feed})}$$

Select operating reflux ratio that is 1.2 to 1.5 times minimum. For vacuum distillation, the reflux ratio usually is >10:1, especially for packed columns.

2. Estimate the minimum number of theoretical stages using the Fenske equation, or as approximations:

Douglas': T = absolute temperature for overhead distillate, D, and for the bottoms, W:

$$N_m = \frac{T_D + T_W}{3(T_W - T_D)}$$

Latour's: x = mol fraction:

$$N_m = 0.11 \frac{T_D + T_W}{(T_W - T_D)} \log_{10}\left[\frac{x_D}{x_W}\frac{(1-x_W)}{(1-x_D)}\right]$$

The number of theoretical trays = twice the minimum number, N_m.

3. *For trays:* estimate the actual number of trays using the following tray efficiencies:
   Sieve, valve, or plate trays, tray efficiency 60%; pressure drop 0.7 to 1.4 kPa/tray or 0.3 to 0.65 kPa/theoretical stage (see Section 16.11.2.1)
   Sieve, valve, or plate trays with high viscosity feed, tray efficiency 25%
4. *For trays:* estimate the column height by the number of actual trays × 0.6 m tray spacing plus 1.2 m at the top and 1.8 m at the bottom.
5. *For trays:* estimate the column diameter with trays, assume acceptable superficial vapor velocity.

   0.3 m/s for high-pressure operation
   0.9 m/s for atmospheric operation
   2.5 m/s for vacuum <13 kPa
   or superficial density-weighted vapor flow rate, F factor, of 1.2 to 1.4 m/s $(kg/m^3)^{0.5}$ or boilup rate = 1.35kg/s m^2

   L/D <30; maximum height 55 m limited by windload
3. *For packing:* estimate the height of packing from the NTU × HTU (or NTS × HETS). For distillation, HTU ≈ HETS, because mass transfer resistance is in the gas phase, or k_L/k_G >> 1. For conventional dumped packing: column diameter/packing diameter >15; use 2.5-cm packing for gas flow rates about 250 dm^3/s; use 5-cm dia. packing for gas flow rates >1000 dm^3/s. In general, HETS 0.3 to 1.8 m; 2.5-cm Pall rings: HETS 0.4 to 0.8 m; 5-cm Pall rings, HETS 0.7 to 0.9 m.
   Split total height into self-supported sections:

Plastic packings: 3 to 4.5 m max. height to prevent weight from collapsing the packing
Metal packings: 6 to 7.5 m height max.

Use liquid distributors every five to ten tower diameters of height with at least one every 6 m. Distributors have 30 to 50 discharge nozzles/m^2 for diameters <1 m.
5. *For packing:* estimate the column diameter:
   For conventional dumped packing: acceptable superficial vapor velocity, expressed as a percentage of gas flooding velocity, is

   For intalox saddles, 80% of flooding; surface areas 50 to 700 m^2/m^3, with increasing values as the diameter decreases
   For raschig rings, 60% of flooding
   For Pall rings, 90% of flooding
   or 1.4 to 2.2 m/s or superficial gas density-weighted velocity, F factor, of 0.6 to 3.5 m/s $(kg/m^3)^{0.5}$

Superficial mass ratio weighted velocity for flooding = 0.35 m/s.
The liquid loading must be sufficient to wet the packing, which is 0.015 to 4 kg/s·m of wetted periphery of the packing (0.015 to 4 L/s·m) or superficial liquid loading of 3 to 35 $L/m^2 \cdot s$. Must be at least 0.5 $L/m^2 \cdot s$. If there is insufficient liquid, then increase the size of packing to reduce the area per unit volume.
Flooding at the density ratio-weighted superficial vapor velocity, k factor, of 0.1 m/s.
Δp for moderate to high pressure, 0.3 to 0.6 kPa/m packing height:
for vacuum 0.08 to 0.16 kPa/m and see Section 16.11.2.1.
HETP

Packing size, cm	HETP, m
2.5 cm	0.46 m (vacuum operation, 0.67 m)
3.8cm	0.67 m (vacuum operation, 0.82 m)
5 cm	0.91 m (vacuum operation, 1.06 m)

If structured packing is selected: design for 70 to 80% of flooding; for foaming, use 40% of flooding. Usual liquid flow rate of 0.007 to 5 L/s·m^2. Usual gas density-weighted superficial velocity, F factor, of 0.5 to 2.5 m/s (kg/m^3)$^{0.5}$. Δp/HETS = 0.01 to 0.05 kPa. If the Δp > 1.2 to 1.6 kPa/m, then the packing is flooded. HETS 0.12 to 0.45 m, with this increasing to 1.8 m for high liquid capacity Glitsch grid.

For *extractive distillation*, the solvent should have a boiling temperature 50 to 100°C higher than those of the products, with solubility parameters and molar volumes similar to those of one product but different from the other.

For molecular distillation, 0.2 to 0.5 g/s·m^2 with about 4.5 m^2/unit; 80 to 90% efficient.

For *steam distillation*:

For direct heating, 25 to 120 kg/m^3. For inert steam added, flow rate calculated.

For *HIGEE*:

Residence time 0.1 to 1 s; voidage 90 to 95%; 2 m dia. max., area per volume 2000 to 5000 m^2/m^3. 1000 rpm; film thickness 100 μm. Overall heat transfer coefficient U = 10 kW/m^2·K. See also reactive distillation, Section 16.11.6.32.

For *batch distillation*: size based on cycle time: fill, distill, discharge bottoms, clean.

for α_{vp} = 2, NTS = 10; reflux ratio 20:1
α_{vp} = 4, NTS = 6; reflux ratio 12:1
α_{vp} = 10, NTS = 3; reflux ratio 7.5:1

To convert TS to height of packing:

1 TS = 1 m of >5 cm dumped Pall rings or saddles
1 TS = 0.9 m of 4 cm dumped Pall rings or saddles
1 TS = 0.6 m of <2.5 cm dumped Pall rings or saddles
1 TS = 0.15 m of structured mesh packing in column of diameter <0.3 m
1 TS = 0.3 m of structured mesh packing in column of diameter >0.3 m

For *batch distillation*: As the more volatile species is removed, the separation becomes progressively more difficult. Too low a reflux gives can unattainable product, regardless of the number of trays. Gives high-purity recovery from a small concentration of a low-boiling species in a single operation. Keep the reflux holdup <10% to 15% of the initial batch charge.

16.11.4.3 Freeze Concentration

Area of Application

Liquid feed 1 to 30% w/w solute; operates below the freezing temperature of the *solvent*.

Guidelines

Don't exceed the K_{sp} of the solute. For juices, the solute concentration increases from about 10 to 50% when the freezing temperature is –10°C.

16.11.4.4 Melt Crystallization

Area of Application

Liquid concentration 60 to 90% w/w. Operates below the freezing temperature to solidify the target *solute*. Capacity usually <3 kg/s. Use for temperature-sensitive materials, when α_{vp} < 1.4, when azeotropes form, or for solid product. A freeze test shows >50% reduction in impurities.

Guidelines

Design based on heat transfer. Limited by eutectic formation. Multistaging possible but usually <10 stages.

Suspension crystallization: crystals and melt same temperature; design on degree of supersaturation; separation of crystals from melt depends on density difference in countercurrent operation. Scraped wall crystallizer (Section 16.11.4.6).

Progressive freezing: crystals colder than melt; design on temperature gradient; separation of crystals from melt by gravity draining. Static crystallization at crystal growth rates of 0.2 cm/h; falling film crystallization at crystal growth rates of 2 cm/h. Reflux ratio 1.3:1.

16.11.4.5 Zone Refining

Area of Application

Operates below the freezing temperature. Solid feed with input concentration of 20 to 70%, but usual is 95 to 99.9% w/w purity; can obtain 99.999999% purity. Temperatures 480 to 600°C. Impurity must lower the freezing temperature for method to be effective. Particulate impurities must not be encapsulated by the solidification front.

Guidelines

Design based on heat transfer with ΔT = 50 to 100°C from the freezing temperature and stop before the eutectic temperature. Ultrapurity of solids, low throughput at 10^{-7} to 10^{-6} kg/s. Multiple cycles might be needed to yield improved purity.

Design (velocity of freezing front)(liquid boundary layer thickness that depends on mixing)/(diffusivity of solute impurity in the liquid) = 1.

Typical velocities:
- Semiconductors and pharmaceuticals: 10 to 70 µm/s
- Organics: 0.5 to 10 µm/s

16.11.4.6 Solution Crystallization

Related topics include size enlargement (Section 16.11.9.13) and evaporation (Section 16.11.4.1).

Area of Application

Liquid feed 20 to 60% w/w; target solute becomes insoluble by producing supersaturation. Operates about the freezing temperature of the solute. Use for heat-sensitive materials, when α_{vp} < 1.4 or when a solid product is desired. Usual operation temperature 50 to 120°C. Very high-purity product with low energy usage. Never possible to obtain complete separation of the target species, because other species simultaneously crystallize with the target. Use for separation or to obtain a solid product.

Guidelines

Limited by K_{sp} and hydrate formation. Usually design with ΔT = 2 to 3°C from the solubility curve. Washing crystals is critical: too little, and product is contaminated; too much, and crystals redissolve and loss of yield occurs.

Solution concentration/saturation concentration = 1.02 to 1.05. Five options include: evaporate, use vacuum to both cool and evaporate, cool, use chemical reaction, or add an antisolvent.

If the solute solubility is relatively temperature-independent, add heat to remove the solvent or add an antisolvent to "drown out" crystals. For evaporation, 14 to 20 g vapor evaporated/s·m^2 exchanger area. For the exchangers, use 2.5-cm dia. tubes with fluid velocities 1.5 to 3 m/s to minimize plugging. Caution: if the vapor pressure rise >3.4 kPa/°C, then potential problems with control.

If the solute solubility is strongly temperature-dependent, use cooling (e.g., scraped surface: U = 0.15 to 0.3 kW/m^2·s °C) or might use vacuum cooling without external heat; that is, preheated feed followed by crystallizer.

If the solute solubility shows some temperature dependence, use vacuum cooling plus external heat.

If the reactants are highly soluble but the product is relatively insoluble, generate crystals by reaction.

If fouling is a problem, consider flash growth type Pachuca, draft tube MSMPR units, or classified product removal CPR type: Oslo, krystall type.

May be operated batch or continuous.

Seed the process because the nucleation sets the crystal habit and influences crystal size distribution (CSD). Importance of "contact nucleation" where crystals strike pump and mixer impellers. Crystal growth kinetics increase with temperature increase. Crystal growth rate = 0.1 to 0.8 mm/h with growth approximately the same in all directions

Batch: size based on cycle time: fill, crystallize, dump, clean. Use for production capacity of <0.15 kg/s and where target is relatively uniform and narrow CSD; although reproducibility may be difficult between batches. Batch gives narrower CSD than continuous.

Continuous CPR with classified fines and classified product removal gives increased crystal size and narrow CSD. Multistaging in series gives larger crystals and narrow CSD.

16.11.4.7 Precipitation

Area of Application

Liquid feed; operates at temperatures above the freezing temperature of the solute, usually in the range 18 to 35°C. Solute formed by reaction is insoluble, key parameter is K_{sp} of product. Provides a sharp first cut removal of solute.

Guidelines

Design based on mass transfer. Reactions are usually very rapid and design is based on mixing to distribute the reactant. For most precipitation reagents, allow 5-min residence time. If secondary reagents are needed to change the oxidation state of the target species before precipitation, then example residence times are

Arsenic: 30 min
Hexavalent chromium or iron: 20 min

Either pre- or post-pH change, allow about 0.180 kg acid or base/m^3 water.

16.11.4.8 Gas Absorption

See also heterogeneous gas-liquid separations, turbulent bed contactor (TCA, TVA) (Section 16.11.5.2), distillation (Section 16.11.4.2), reactors (Sections 16.11.6.11 through 16.11.6.17), and direct-contact heat exchange (Sections 16.11.3.11 through 16.11.13), with gas-liquid contacting characteristics described in Sections 16.11.8.1 and 16.11.8.2.

Area of Application

α = 2000 to 100,000, and gas feed concentration of target solute is 0.1 to 20%; 98% purity possible. Target species is soluble.

For high concentration and solubility plus particulates, use

Jets, venturis: very soluble gas only with target species Henry's law constant <10^3 kPa/mol fraction; feed gas concentration >1 vol%. Efficiencies 50% to 85%.

Turbulent bed contactor: both gas absorption and removal of heavy, sticky participates. Related to Section 16.11.5.2.

For high concentration and solubility, use

Spray column: target species Henry's law constant 10^3 to 10^4 kPa/mol fraction; feed gas concentration 0.3 to 4 vol%. Efficiencies 85 to 95%.

Spray chamber: target species Henry's law constant <10^4 kPa/mol fraction; feed gas concentration >1 vol%. Efficiencies 50 to 85%.

For low concentration, low range of solubility, and no particulates, use

Countercurrent packed column: target species Henry's law constant <10^7 kPa/mol fraction; feed gas concentration <1 vol%. Efficiencies 95+%. Vulnerable to plugging. OK for foaming and corrosive.

Countercurrent tray column: target species Henry's law constant <10^7 kPa/mol fraction; feed gas concentration <1 vol%. Efficiencies 95+%. Not for foaming, corrosive, or particulates.

For adsorption plus chemical reaction, consider cocurrent falling film multitube system. See also long tube falling film evaporator, Section 16.11.4.1.

Guidelines

To minimize the cost of recovering and recycling the solvent, contact the minimum amount of liquid with the maximum amount of gas. For packings, this means the liquid loadings about 3 L/m²·s with high gas flow rates of superficial density-weighted velocity *F*-factor of 3.5 m/s $(\text{kg/m}^3)^{0.5}$.

Selection of the solvent: select lowest molar mass liquid whose solubility parameters are similar to those of target species in the gas. Choose a solvent in which the target species are highly soluble. >700 mg/g solvent; Henry's law constant: <10^3 kPa/mol fraction; or $(HTU_G/HTU_L)(F_L/F_G)$(pressure, kPa/Henry's constant) >20: then gas phase controls mass transfer. This is most likely for many absorptions.

If target species have medium solubility: 100 to 700 mg/g solvent; Henry's law constant 10^3 and to 10^5 kPa/mol fraction: both liquid and gas phases control the mass transfer. These systems are usually processed in packed and tray columns.

If target species have low solubility: <50 mg/g solvent; 1/Henry's law constant: <8×10^{-5} mol fraction/kPa: liquid phase controls mass transfer.

Regeneration of the absorbent by distillation or pressure-reduction desorption.

Jets, venturis: economic NTU = 3.5; critical energy-consuming phase is the gas at about 20 kJ/m³ with liquid-to-gas ratio about 1.3 to 1.6 L/m³; design on gas phase controlling. Power usage 1 to 8 kW·s/m³. Δp gas = 1.2 to 6 kPa.

Peabody absorber/impingement baffle: economic NTU usually <5; liquid-to-gas ratio 0.2 to 0.7 L/m³; superficial gas velocity 1 to 1.6 m/s. Power usage 0.5 to 2 kW·s/m³. Δp gas = 1.5 to 3.7 kPa.

Spray column: economic NTU = 2.5; critical energy-consuming phase is the liquid; gas energy 8 kJ/m³; with liquid-to-gas ratio high; design on gas phase controlling, superficial gas velocity 1 m/s. Power usage 0.03 to 0.5 kW·s/m³. Δp gas = 0.6 to 1.2 kPa.

Spray chamber: economic NTU = 4; gas energy consumption 2.5 kJ/m³ with liquid-to-gas ratio about 1.5 L/m³; design on gas phase controlling, superficial gas velocity 0.9 to 1.2 m/s. Power usage 0.03 to 0.5 kW·s/m³. Δp gas = 0.5 kPa.

NTU needed:

$\text{NTU} + 2 = 6 \log_{10} (y_{in}/y_{out})$, or

Use the Kremser equation with a molar stripping factor or molar absorption factor of F_L/F_G m = 1.4. A molar stripping or adsorption factor = 5 is approximately the same as ∞.

Countercurrent packed column: Economic NTU usually <5; critical energy-consuming phase is the gas at about 3 kJ/m^3 with liquid-to-gas ratio about 0.7 to 1.5 L/m^3. Liquid loading on usual packings 3 to 35 L/m^2·s; (0.007 to 5 on structured packings) molar ratio liquid to gas 1.4 to 80; superficial gas velocity 1.4 to 2.2 m/s; design on mass transfer in both gas and liquid. Power usage 0.15 to 0.6 kW·s/m^3. Δp gas = 0.07 to 0.4 kPa/theoretical stage; HETS = 0.5 to 1 m. For low liquid loadings and high gas flow rates, $HTU_G/HTU_L \approx 2$; for high liquid loading and low gas flow rates, 0.2.

Assume 99% absorption; set molar flow rates F_L/F_G = 1.2 to 2 times the minimum. Use the Kremser equation for the design of dilute units with molar absorption factor F_L/F_G m = 1.2 to 2; use 1.4. NTU$_{OG}$ = 20 for 99% recovery.

Assume HTU$_{OG}$ = 0.6 m with maximum packing height 12 m. Superficial gas velocity 1 m/s and/or superficial density-weighted velocity F-factor of 0.6 to 3.5 m/s (kg/m^3)$^{0.5}$. Use 2.5-mm Pall rings or Tellerettes of metal or plastic.

Countercurrent tray column: economic NTU usually <5; liquid-to-gas ratio 1.5 to 18 L/m^3; superficial gas velocity 1 to 1.6 m/s and/or superficial density-weighted velocity F-factor of 1.2 to 1.8 m/s (kg/m^3)$^{0.5}$. Power usage 0.5 to 2 kW·s/m^3; Δp gas = 0.7 to 1.5/tray. HETS = 0.7 m. Tray efficiencies 10 to 20%.

Assume 99% absorption; use the Kremser equation for the design of dilute units with molar absorption factor for economic recovery of the solvent F_L/F_G m = 1.4 with general range 1.2 to 2. Tray spacing = 0.6 m with valve or sieve trays. See also Section 16.11.4.2 for such details as downcomer sizing.

For *multitube cocurrent falling film*: U = 0.6 kW/m^2·K.

16.11.4.9 Gas Desorption/Stripping

Area of Application

α = 2000 to 100,000 and liquid feed concentration of target solute is 0.1 to 5%; 98% purity possible.

Guidelines

Because the target solute usually has low solubility in the liquid, usually the desorption is liquid-phase controlled.

For packings the goal is high liquid loadings, about 30 L/m^2·s, and minimum gas flow rates. Superficial density-weighted velocity F-factor of 0.6 m/s (kg/m^3)$^{0.5}$.

Use Kremser equation for the design of dilute units with molar L/absorption factor for economic stripping of $F_G m/F_L$ = 1.2 to 2 with starting value of 1.4; m = Henry's constant/total pressure. For packing, HETS = 1.83 m.

Edible oil deodorizing: high vacuum. For <0.6 kg/s, irregular production, use batch. Requires processing time = 4 h/batch, low heat recovery. For >0.6 kg/s, continuous with processing time = 1 h. Keep liquid films thin to promote mass transfer of volatiles and use astute distribution of sparge steam.

16.11.4.10 Solvent Extraction, SX

A related topic is size reduction (Section 16.11.8.3).

Area of Application

General: feed concentration 0.03 to 95% w/w; for minerals, typically 0.01 to 2% w/w; separation factor α = partition coefficient ratio with values 2 to 500 and should be >5.

Spray and packed columns: gravity flow (spray, plate, packed column): superficial liquid velocity, 0.001 to 0.02 m/s; area per unit volume 7 to 75 m^2/m^3. Product of the density difference with the interfacial tension (Mg/m^3, mN/m) >1 and number of theoretical stages needed <3; interfacial tension <10 mN/m.

Gravity flow (raining bucket, RTL): product of the density difference with the interfacial tension (Mg/m^3, mN/m) >1 and number of theoretical stages needed <3; handles dirty liquids and ones that tend to emulsify.

Stirred tanks; mixer settler (including Lurgi): superficial liquid velocity, 0.00015 to 0.004 m/s; area per unit volume 400 to 10,000 m^2/m^3. Product of the density difference with the interfacial tension (Mg/m^3, mN/m) >4 and number of theoretical stages needed >3. Usually about one theoretical stage per unit. Rarely build more than 5 stages; can handle high phase ratios.

Stirred or pulsed columns: superficial velocity, 0.002 to 0.02 m/s; area per unit volume 75 to 3,000 m^2/m^3.

Reciprocating plate: product of the density difference with the interfacial tension (Mg/m^3, mN/m) between 1 and 4 and number of theoretical stages needed >2. Can handle dirty liquids.

Pulsed plate or packed: product of the density difference with the interfacial tension (Mg/m^3, mN/m) between 1 and 4 and number of theoretical stages needed >2. sensitive to contamination. Difficult to pulse large columns.

Rotating disk contactor, RDC, ARD contactor; Mixco, Scheibel, Treybal, Oldshue–Rushton, Kuehni: product of the density difference with the interfacial tension (Mg/m^3, mN/m) between 1 and 4 and number of theoretical stages needed >2. Low HETS; can handle dirty liquids, large throughputs. Needs flow ratios 1:1. Difficulty handling low interfacial tension systems that tend to emulsify.

Centrifugal extractor: product of the density difference with the interfacial tension (Mg/m^3, mN/m) <1 and number of theoretical stages needed <6. Cannot handle dirty systems or high phase ratios. For continuous differential type machines (density differences >0.05 kg/L; drop diameter >200 μm): six to eight stages per machine. For discrete, disc type machines (density differences >0.02 kg/L and handle drops <200 μm) 2 to 3 stages per machine.

Guidelines

Design flow rate about 50% to 90% of flooding with the superficial velocity selected varies directly with the density difference and interfacial tension. Solvent/feed = 0.5 to 1.5/1; with usual 1/1.

Gravity:

Spray: HETS increases exponentially with diameter; 10 to 20 m at 1 m dia.; superficial velocity about 5.5 L/s·m^2.

Packed: HETS increases exponentially with diameter; 2.5 m at l m dia.; prefer diameter <0.6 m; superficial velocity about 5.5 L/s·m^2, 2.5 cm Pall rings. Redistribute the dispersed phase every 1.5 to 2 m.

Sieve tray: HETS increases exponentially with diameter; 1 m at 1 m dia.; usually diameter >0.6 m; superficial velocity about 5.5 L/s·m^2. Efficiency inversely proportional to the interfacial tension: 40% at 5 mN/m.

RTL: HETS increases exponentially with diameter; 0.5 m at 1 m dia.; superficial velocity about 0.3 to 2 L/s·m^2.

Mixer settler: one theoretical stage per unit; input energy 1 kW/m^3; superficial velocity for the settler 0.5 to 7 L/s·m^2 with 1.4 L/s·m^2 being typical. Low values for small density differences. Height increases with increasing total feed flow rate with 1 m height for 10 L/s. Typical drop diameter is 150 μm; extraction efficiencies about 80%.

Lurgi contactor: HETS increases exponentially with diameter; 0.7 m at 1 m dia.; diameters <8 m; superficial velocity about 5.5 L/s·m^2.
Pulsed packed column: HETS increases exponentially with diameter; 0.7 m at 1 m dia.; max. diameter 2.5 m; superficial velocity about 5.5 L/s·m^2.
Pulsed sieve plate column: HETS increases exponentially with diameter; 0.4 m at 1 m dia.; max. diameter 3 m; superficial velocity about 5.5 L/s·m^2 sieve holes 3 to 8 mm; velocities through the holes <0.2 m/s to minimize the formation of small drops. Tray efficiencies about 20 to 30%.
Reciprocating plate: HETS increases exponentially with diameter; 0.35 m at l m dia.; max. diameter 1.5 m; superficial velocity about 11 L/s·m^2.
Rotating disk contactor, RDC, ARD contactor; Mixco, Scheibel, Treybal, Oldshue–Rushton, Kuehni: HETS is sensitive to rotor speed. HETS increases slightly with diameter; 0.5 m at 1 m dia.; superficial velocity about 5.5 L/s·m^2 with Kuehni 9.7 L/s·m^2. Mixco, Scheibel, Treybal, Oldshue–Rushton, diameter <2.5 m; RDC diameter <9 m.
Total flow through a column = 10 L/s·m^2 with a density difference of 0.2 Mg/m^3.
Centrifugal: two to six units per machine, depending on the machine.

16.11.4.11 Adsorption: Gas

Area of Application

Use when feed concentration of the more volatile species is small, 0.15 to 10%, and when $\alpha_{ads} > 2$; when the target species is difficult to condense.

Guidelines

Select adsorbent based on pore size related to the target species.

Alumina: surface area: 210 to 350 m^2/g; pore volume 0.21 cm^3/g, temperature <320°C; superficial gas velocity 125 to 500 dm^3/m^2·s; usually adsorb 800 kg/m^3 or 0.14 to 0.22 kg organics/kg dry solid; 0.15 kg water/kg dry solid. Lifetime: 150 cycles.
Silica: surface area: 750 to 830 m^2/g; pore volume 0.4 to 0.45 cm^3/g, temperature <230°C; superficial gas velocity 125 to 500 dm^3/m^2·s: usually adsorb 720 kg/m$^{3;}$; 0.3 to 0.6. kg organics/kg dry solid; 0.4 kg water/kg dry solid.
Four-Å molecular sieve: surface area: 640 to 80 m^2/g; pore volume 0.27 cm^3/g, temperature <300°C: superficial gas velocity 150 to 250 dm^3/m^2·s; usually adsorb 480 to 720 kg/m^3; 0.05 kg nitrogen/kg dry solid; 0.22 to 0.36 kg water/kg dry solid. Lifetime: 400 cycles.
Activated carbon: surface area: 1000 to 1500 m^2/g; pore volume 0.6 to 0.8 cm^3/g, temperature <540°C: superficial gas velocity 100 to 600 dm^3/m^2·s; capacity depends on organic; range 0.06 to 0.2 kg organics/kg dry solid adsorbent.
For fixed bed: batch: size on cycle time: load, swing out of service, regenerate, swing back into service. Loading time: 100 to 3000 bed volumes (BV)/h with time based on the ratio of the adsorption isotherm to the feed concentration of the target species (usual range 50 to 300 corresponding to load times of 0.2 to 2 h). Regenerate with steam (at 3 to 5 kg steam per kg organic removed), solvent, reduced pressure, combustion, or via vacuum/pressure shift. Use superficial gas velocity of 60 to 600 dm^3/dm^2·s or recommended value for the adsorbent to determine c*ross-sectional* area. Residence time 0.03 to 0.8 Bed volumes/second: (F/V) with depth >0.33 dia.

16.11.4.12 Adsorption: Liquid

A related topic is ion exchange (Section 16.11.4.13).

Area of Application

Prime option for dilute concentrations with a need for greater selectivity than solvent extraction can provide.

Guidelines

Select adsorbent:

Activated carbon: surface area: 1000 to 1500 m^2/g; pore volume 0.6 to 0.8 cm^3/g, temperature <540°C; loading very dependent on molar mass of target solute, solubility in the carrier liquid, and pH. Example loading 0.01 kg organic molar mass 100/kg dry solid. The value varies with the (molar mass)$^{3.5}$.
Acid-treated clay: surface area: 225 to 300 m^2/g.
Fuller's earth: surface area: 130 to 250 m^2/g.

Batch:

Fixed bed: batch: size on cycle time: load, backwash/clean, regenerate, swing on-stream. Load: typical flow rate 2 to 3.5 BV/h with the load time based on the ratio of the adsorption isotherm to the feed concentration of the target species (usual range varies with the application: 18 to 100 min, while for water treatment: 70 to 100 days). Backwash with velocity to fluidize the bed (see liquid fluidization, Section 16.11.7.5); velocity 0.8 BV/h. Time such that <5% feedrate used in backwash. Usually, carbon is removed and regenerated about four times per annum. Try to match the loading cycle to the regeneration cycle.
Use fixed bed if <20 L/s and carbon usage >180 kg/day. Superficial velocity 1 to 15 L/m^2·s; use 5 L/m^2·s to estimate cross-sectional area. Too low a superficial velocity (<3 L/m^2·s) gives poor feed distribution. Use 2 to 3.5 bed volumes/h to give the required residence time of 18 to 100 min. Bed depths in the range 3 to 10 m, but keep the pressure drop <75 kPa.
Height/diameter 1:1 to 4:1. Maximum size is based on carbon usage <9 Mg dry carbon per day.

Continuous:

Moving bed: use if >20 L/s. A related topic is transfer line reactor (Section 16.11.6.9).
Fluidized bed: use if slimes or fine particles in feed. Use superficial velocities of 8 to 14 L/m^2·s. Feed contacts bed for 30 min or 0.8 bed volumes/h. Related topics include reactors (Section 16.11.6.27), heat transfer (Section 16.11.3.8), drying (Section 16.11.5.5), size enlargement (Section 16.11.9.5), and mixing liquid-solid (Section 16.11.7.5).
Slurry approach: use if the carbon usage is <180 kg/day. Mix and suspend powdered adsorbent and then filter exit line. Often uses up to three stages of countercurrent contacting. Used for continuous bleaching of edible oils. Batch process is simple, flexible, and easy to change feedstocks. Continuous operation offers better protection against oxidation, provides shorter holdup, and has the potential of heat recovery. Bleach time 25 min. A related topic is transfer line reactor (Section 16.11.6.9).

Loading times and elution-regeneration times should be approximately equal.

16.11.4.13 Ion Exchange

Related topics include the use of ion exchange resins as catalysts in reactors (Section 16.11.6.32), liquid-solid fixed bed reactors (Sections 16.11.6.14 and 16.11.6.15), and adsorption-liquid (Section 16.11.4.12).

Area of Application

High-valence ionic species in liquid phase with $\alpha_{IX} = \Gamma^+(1 - c^+)/c^+(1 - \Gamma^+) = 1.01$ to 1.04 and feed concentration 0.02 to 2% w/w. Γ^+ = surface concentration of cations.

Guidelines

Select the ion exchange resin based on the pH of the environment and the valence of the target ion. For high efficiency, try to use weak electrolyte resin.

Weakly acidic cationic (WAC) exchange resin: carboxylic; pH >4; $T < 100°C$; hydrogen or sodium form, depending on regeneration preference; loading 3.5 equivalent/L of resin; good selectivity; greatest affinity for alkaline earth metals in the presence of alkalinity.

Strongly acidic cationic (SAC) exchange resins: sulfonic; full range of pH, $T < 120°C$; hydrogen or sodium forms; loading 1.9 equivalents/L resin; high capacity, high activity. Ionic sequence Ba > Pb > Sr > Ca > Ni > Mn > Be > Cd^{2+} > Cu > Co > Zn > Mg.

Weakly basic anionic (WBA) resin: aromatic polyamine: pH<7; temperature <50°C; chloride (more thermally robust) or OH form; loading 1.6 eq/L resin.

Strongly basic anionic (SBA) exchange resins: type I trimethyl amine: full range of pH; chloride (more thermally stable) or OH forms; loading 0.46 to 1 eq/L resin.

Ions being exchanged must have a higher valence than ions in bed from regeneration.

Batch:

Fixed bed: batch: size on cycle time: load, backwash/rinse, elute, standby. Try to match loading with off-line time. Load: loading feedrate 5 to 10 BV/h with loading time depends on the ratio of exchange capacity of the resin to the feed concentration of the target species. Usual ratio 10 to 100 corresponding with a loading time of 1.5 to 15 h. Backwash with a velocity to fluidize the bed for 1 to 10 BV (corresponding to about 1.5 h). Eluent feedrate 1 to 3 BV/h for typically 8 to 20 h. Standby is typically 20% of the backwash time. When the eluate is valuable, try to match the loading time with the backwash, eluate recovery, and standby.

Feed flow rate: superficial velocity 1 to 15 $L/m^2 \cdot s$; use 5 $L/m^2 \cdot s$. Superficial velocity <3 $L/m^2 \cdot s$ gives poor feed distribution; 5 to 10 bed volumes/hour; too deep a bed leads to excessive pressure drop; keep below 350 kPa. Add 2.5 m to height to allow for bed support and head room for backwashing. Typical bed depths 1 to 5 m; usual industrial bed cross section 5 m^2.

Use fixed bed if <20 L/s. Pressure, gravity, cocurrent, countercurrent, series, single bed, or mixed bed. Gravity is economical where the bed volume > 80 m^3.

Loading times and elution-regeneration times should be approximately equal.

For WAC and WBA systems, the backwash, regeneration, and rinse cycles are 30 to 60 min.

Continuous:

Moving bed: use if >20 L/s.

Fluidized bed: use if slimes or fine particles in feed, elution time >> IX time, eluant is expensive. Use 16 to 20 mesh resin with superficial velocities of 40 $L/m^2 \cdot s$. Try to operate at 50 to 200% bed expansion. Related topics include adsorption-liquid (Section 16.11.4.12).

16.11.4.14 Foam Fractionation

A related topic is size reduction, gas in liquid (Section 16.11.8.1).

Area of Application

Solute feed concentration usually 1 ppm to 0.1% with some applications up to 10% (10^{-3} to 10^{-9} mol).

Guidelines

Surface concentration 1 to 5 μmol/m^2 bubble area. Height to diameter 5:1 to 15:1. Usual liquid feed superficial velocity 0.1 to 1 L/s·m^2. Bubble diameter = 0.8 to 1 mm. Volumetric feedrate ratio of inlet gas to liquid flow rates: 4 to 7.5 dm^3 gas/L liquid. Volumetric ratio of gas in foam to overhead liquid in draining foam: 100 to 250:1. Liquid in the foam/liquid in the feed = 6 to 12% v/v; draining foam density 0.003 Mg/m^3. Superficial gas velocity for foam drainage section 3 to 250 dm^3/s·m^2. Scaleup based on constant superficial gas velocity.

16.11.4.15 Membranes: Gas

Area of Application

In general, there are two applications: remove organics (VOC) from air and separate permanent gases (such as nitrogen, hydrogen, carbon dioxide).

To remove organics from air, VOC: feed concentration is >0.1% v/v and the air flow rate is <480 dm^3/s. For lower concentrations, use adsorption (Section 16.11.4.11); for higher flow rates, use adsorption and condensation.

To separate permanent gases: feed concentration is 10 to 85% and the flow rates range from 0.05 to 65 Nm^3/s.

α = 1.4 to 4; gas feed concentration 5 to 75% w/w; 75 to 90% gas purity possible. Diameter of the target species: 0.1 to 1 nm.

Guidelines

Membrane type: asymmetric: homogeneous or microporous; composite of a homogeneous polymer film on a microporous substructure or symmetrical homogeneous or porous polymer film. Driving force for the rate of separation: hydrostatic pressure concentration.
Membrane: nonporous membrane elastomer or glassy.
Pressure: >0.7 MPa for separation of permanent gases.
Temperature: 0 to 60°C.

For VOC removal from air, use elastomeric membranes (rubbery membranes). The membrane has a 0.1 to 1 μm skin layer on a 100- to 300-μm substrate. These membranes tend to have lower selectivities and higher permeabilities, and are relatively impermeable to nitrogen. The permeability of organics tends to be 4 to 100 times higher than that of inert gases. For these membranes, the selectivity increases with increasing boiling temperature of the species. The permeability increases 10% per degree Celsius increase in temperature. Typical permeabilities for the organics are >200 Ndm^3·μm/s·m^2·MPa.

For the separation of permanent gases, use glassy membranes with higher selectivity and lower permeability.

Typical permeances are

for hydrogen methane separation: 0.22 to 3.75 Ndm^3/s·m^2 ·MPa.
for carbon dioxide-methane separation: 0.075 to 1.5 Ndm^3/s·m^2·MPa.
for air separation: 0.003 to 1.9 Ndm^3/s·m^2 ·MPa.

The temperature of the feed should be >20 to 40°C above the feed dew point.

16.11.4.16 Membranes: Dialysis

Area of Application

$\alpha = c_{21}\mathbf{D}_2/c_{11}\mathbf{D}_1$ = 6 to 25%; liquid feed concentration 2 to 25% w/w; 99% purity possible; c_2 = concentration of solute in the feed; $\mathbf{D}$ = diffusivity. Diameter of the target species: 0.5 to 5 nm.

Guidelines

Driving force for the rate of separation: concentration of target species.

Membrane: symmetric microporous with 0.1 to 10 mm pore diameter. Hydraulic permeability: 10^{-3} to 8 g/s·m²·MPa. Membrane-solute permeability 0.05 to 9 μm/s, depending on the solute and the membrane. Dialysis transfer coefficient: 1 to 10 μm/s.

16.11.4.17 Membranes: Electrodialysis

Area of Application

Diameter of the target species: 0.2 to 0.8 nm. Feed concentration <20% ionic. Feed range 0.005 to 5%.

Guidelines

Driving force for the rate of separation: electropotential

Membrane: ion exchange, homogeneous or microporous polymer with positively or negatively charged fixed ions

Hydraulic permeability: 10^{-3} to 8 g/s·m²·MPa

Pretreat feed until ferric < 0.3 mg/L

Mn < 0.1 mg/L

H_2S < 0.3 mg/L

Temperature: >10 and <43°C

Optimum feed concentration: 1000 to 5000 mg/L

Energy: about 5.5 to 9 MJ/m³ product

Pressure drop: horizontal stack 0.2 to 0.4 MPa; vertical stack 0.02 to 0.07 MPa

16.11.4.18 Membrane Configurations

Can be operated *dead-end* or *crossflow:* "batch" with 100% recycle of retentate; "continuous" with recycle ratios 15/1 to 30/1 and purge and "multistage," where the purge from one stage becomes the feed of the next.

Batch process: stop feed because the membrane performance has deteriorated or because the target concentrations or volumes of permeate or retentate have been achieved. Deteriorated membrane performance can be (1) because of a buildup of particulates or biological deposits (this can be corrected by backflushing with permeate or cleaning with detergents, acids, or bases) or (2) because the membrane needs to be replaced (the life of a membrane is one or two to ten years, depending on the operating conditions and the type of membrane). See Table 16.32.

Membranes:

Hydrophilic: cellulosic (temperature <30°C), polyacrylic, nylon 66, ceramic. Life: polymers: 1 year; ceramic: <10 years.

Hydrophobic: polysulfones, polyolefins, carbon. Life: polymers: 1 to 2 years; fluoropolymers <4 years.

Neither hydrophilic nor phobic: sintered.

16.11.4.19 Membranes: Pervaporation

Area of Application

$\alpha = (c_{i3}/c_{j3})/(c_{i1}/c_{j1})$, where i is the target permeate species, j is the reject; 3 = permeate, and 1 = feed, separates dissolved organics = 1.3 to 41. Particle diameter, 0.2 nm. Target concentration 5 to 20% w/w, but 0.1 to 10% w/w for economical. Temperature <120°C.

TABLE 16.32
Characteristics of Various Membrane Configurations

	Tubes: Fine Hollow Fibers to Tubules				Channel						
	RO Type	UF/Microfilter			Flat Sheet: Plate/Frame	Flat Sheet: Plate/Frame	Spiral Wound	Pleated Sheet	Tubular Monolithic Elements	Tubes	
Diameter or spacing, mm	0.01–0.03	0.02–0.1	0.5	1.1	0.2–0.4 0.5–1	1.2–2.5	0.75 or 1.1			2.5–6	12–25
Length, cm		< 100			45	45					1800

Holdup, L/m^2		0.33	0.120	0.3							
Flow conditions, Reynolds no.		Laminar, 500–3000				Turbulent	Laminar, 100–1300				Turbulent, Re > 10,000
Velocity, m/s		0.01–2.5	0.6–1	0.6–0.6	0.06–1.6		0.1–2				2–6
Feed rate/ surface area, L/s·m^2	0.002	0.002			0.25–0.5		0.25–0.5				1.–5
Shear stress/ length, l/cm·s		10–100			80–300		80–300				500–4000
Pressure drop along the membrane, kPa		30–130			70–1000		100–140				14–20
Area per unit volume, m^2/m^3	6000	600–1200	500–1100	320–505	400–1000		650–1000				25–70
Max size/unit, m^2		1	0.05–5		0.02–0.07		8–22				0.4

Guidelines

Driving force for the rate of separation: concentration gradient in the vapor pressure.
Membrane: asymmetric: homogeneous, or microporous (cellulose acetate, polyamide, polysulfone, polyacrylonitrile); composite of a homogeneous polymer film on microporous substructure (cellulose acetate, polyamide, polysulfone, polyimide, polyvinyl alcohol). Usual pore 0.1 to 0.2 μm.
0.1 μm PVA: water >> methanol > ethanol > other organics.
Silicone rubber: methanol > ethanol> aldehydes> ketones >> water; paraffins > olefins.
Cellulose esters: aromatics > paraffins; olefins > paraffins; dienes > olefins; *n*-paraffins > branch; low molar mass paraffins > high molar mass paraffins.
Capacity/unit: feed <1.5 kg/s.
Feed pressure: atmospheric.
Feed temperature: close to the normal boiling temperature; usually 50 to 100°C.
Permeate conditions: pressure 0.5 to 2 kPa absolute with condenser temperatures: –20 to +30°C.
For dehydration, use a difference in partial vapor pressure at least one order of magnitude; the permeate flux doubles for an increase in temperature of 10°C.
Permeate flux: depends on membrane but in the range 0.008 to 5 g/s·m^2.
Configuration: see Section 16.11.4.18.
Spiral wound, transverse hollow fiber.
Use *crossflow* with recycle ratio 15 to 30/1. Criterion: 10% of feed volume is permeate or purity of the permeate or retentate.
Membrane life: 2 to 4 years.
Cycle time: usually limited by life of membrane.

16.11.4.20 Membranes: Reverse Osmosis (RO)

Area of Application

α = 6 to 25; feed concentration 0.05 to 20% w/w; with suggested economic feed concentration <0.5%; 99% purity possible. Diameter of the target species: 0.2 to 0.8 nm. Must have a difference in osmotic pressure. The osmotic pressure coefficient in mass ratio units for different solutes = 20 to 80 MPa·kg/kg at 25°C. The higher the valence, the better the rejection.

Guidelines

Driving force for the rate of separation: hydrostatic pressure.
Membrane: asymmetric: homogeneous or microporous; active dense 20- to 50-μm layer of cellulose acetate with total thickness 100 μm; composite of a homogeneous polymer film on microporous substructure.
Pressure: 1.4 to 10 MPa (1.4 to 4.2 for brackish water; 5.6 to 10 for seawater). Inlet pressure > twice the inlet osmotic pressure.
Temperature: <45°C.
Capacity/unit: <7 L/s.
For cellulose acetate membranes: $1/\Theta^+ = Ap/B\rho$ = 1 to 500 with usual value 300 (dimensionless).
For aromatic polyamide membranes: $1/\Theta^+$ = 0.7 to 20.
A = permeate hydraulic permeability, g/s·m^2·MPa.
p = total operating pressure, MPa (1.4 to 10 MPa).
B = target solute transport coefficient, μm/s (10^{-6} to 10 μm/s).
ρ = mass density of the feed stream.

Hydraulic permeability, A: 0.0005 to 8 g/s·m^2·MPa (0.1 to 10 for cellulosic).

Permeate flux: 0.001 to 0.1 L/s·m^2; for cellulose acetate: 0.006 to 0.0075 L/s·m^2; for hollow fiber: 0.001 to 0.002 L/s·m^2; for thin film composite: 0.007 to 0.009 L/s·m^2. Permeate flux increases about 3% for every 1°C increase. Permeate flux decreases by 10 to 50%, depending on the concentration polarization. Permeate flux is reduced because of particulates and bacterial adhesion so that flux for tubular < spiral wound < hollow fiber.

Configuration: see Section 16.11.4.18.

Spiral wound, hollow fiber and tubular (used for low-volume, high-value commodities), pleated sheet, tubular monolithic elements, or plate and frame.

Use *crossflow* batch with 100% recycle; continuous with recycle ratio 15 to 30/1 or multistage (often three stages). Criteria to back wash and clean: operate until a given concentration or volume reduction is reached in the retentate or a given purity or volume is achieved in the permeate.

Membrane life: 2 to 4 years.

Cycle time: pretreat to prevent scaling or buildup or operate a short cycle, 2 to 12 h; cleaning with dilute nonionic detergent. Degree of pretreatment: hollow fiber > spiral > tubular.

16.11.4.21 Membranes: Nanofiltration

Area of Application

Molar mass cutoff = 200. Can handle fluid with significant osmotic pressure, sugars, dissociated acids, and divalent salts.

Guidelines

Driving force for the rate of separation: pressure

Membrane: asymmetric thin film, noncellulose membrane; membrane usually negatively charged to reject anions.

Pressure: (between UF and RO) = 0.3 to 1.4 MPa.

16.11.4.22 Membranes: Ultrafiltration (UF)

A related topic is filters (Sections 16.11.5.12 and 16.11.5.13).

Area of Application

$\alpha = \kappa_2 \boldsymbol{D}_2/\kappa_1 \mathbf{D}_1$ = 6 to 60; liquid feed concentration 0.04 to 20% w/w; 99.9% purity possible, κ = partition coefficient; **D** = diffusivity. Diameter of target species 0.8 to 200 nm; removes soluble macromolecules, colloids, salts, and sugars but cannot separate dissolved salts, species with molar mass <1000, or species exhibiting a significant osmotic pressure. Feed concentration <50% dissolved organics.

Guidelines

Driving force for the rate of separation: hydrostatic pressure.

Membrane: most UF membranes are polysulfone. Asymmetric microporous with thin skin 0.1 to 1 μm supported on a porous layer 50 to 250 μm. Pore size 0.001 to 0.2 μm. This is too porous for RO. Pore size prevents concentration polarization (limiting RO), but performance is limited by gel polarization with x_{gel} = 0.2 to 0.4. x_{gel} = 0.25 to 0.35 for macromolecules, 0.75 for colloids. Need to have membrane life >1 year.

Pressure: 0.1 to 0.7 MPa. Hydraulic permeability, A: 0.8 to 800 g/s·m^2·MPa. Feed concentration: 0.05 to 15% w/w.

Temperature: <90°C and pH 0.5 to 13 for polysulfone. Capacity/unit: 0.1 to 25 L/s.

Select diameter or channel spacing so that diameter of the target species is 0.1 of the diameter or channel spacing; except for spiral wound where, for 0.75-mm spacing, the particles must be <5 to 25 μm; or 0.006 to 0.034 diameter of spacing; for 1-mm spacing, particles should be <25 to 50 μm or 0.025 to 0.05 of the diameter or channel spacing.

Permeate flux: depends on the membrane and configuration: hollow fibers/polysulfone: 0.005 to 0.016 L/s·m^2; spiral wound/polysulfone: 0.08 to 0.14 L/s·m^2; tubes/polysulfone: 0.06 to 0.2 L/s·m^2.

Liquid permeability increases 25% for every 10°C increase in temperature.

Power depends on target species and configuration: water treatment 1.8 kJ/L permeate; food application: 32 kJ/L permeate; electropaint: 60 kJ/L permeate. Configuration: hollow fiber 6 kJ/L; plate and frame 9 kJ/L; spiral 3 to 6 kJ/L; tube 15 kJ/L; or hollow fibers: 100 to 280 W/m^2; plate and frame: 180 to 280 W/m^2; spiral wound 25 to 120 W/m^2.

Configuration: see Section 16.11.4.18.

Spiral wound, hollow fibers, plate and frame, and tubular (use for small flow, high value, and severe fouling applications).

For laminar flow operation of hollow fiber, plate and frame, and spiral wound, keep the operating pressure 0.1 to 0.2 MPa; for turbulent flow operation of plate and frame, spiral wound and tubes, operate at 0.5 to 0.7 MPa.

Use *dead-end* for low concentrations of particles >0.1 μm.

Use *crossflow* batch with 100% retentate recycle, continuous bleed with recycle ratio 15 to 30/1 and multistage: when a concentrated retentate is desired or when particle diameter <0.1 μm. Criterion to backwash/or clean: when 90% reduction in retentate volume is achieved; given quality or volume of permeate; the permeate flux <15% of initial flux; or when the viscosity of the retentate is 100 to 300 mPa·s. This corresponds to concentrations for pigments of 30 to 70%; for microorganisms of 1 to 10%.

Membrane life: 2 to 4 years.

Cycle time: clean by backwashing with permeate every 6, 24, 170, 360, 1000 h (depending on the criteria, the membrane, operating conditions, and the amount of pretreatment); example, 8 h on and 1 to 2 h off to clean; or short pulses every 150 to 300 s so that steady-state flux operation is never achieved.

Clean by steam, detergents, solvents, acids, or bases. Another option to lengthen cycle time is to add solids to the feed to mechanically wear away the gel layer. The choice affects membrane life. Steam cleaning gives 50 to 150 cycles before membrane replacement; nonsteam cleaning gives 200 to 500 cycles.

16.11.4.23 Membranes: Microfiltration

A related topic is filters (Section 16.11.5.13).

Area of Application

Particulate diameter 0.05 to 800 μm*;* feed solids concentration <75% w/w; <50% v/v. Remove solid or gelatinous particulates by pore size in the membrane. Pore size: 0.2 to 1 μm with the membrane cutoff sizes in the range 0.05 to 10 μm.

Guidelines

Driving force for the rate of separation: pressure.

Membrane: symmetric or asymmetric microporous. Ceramic, sintered metals, or polymers with pores 0.2 to 1 μm. Symmetric polymers have a porosity of 60 to 85%; asymmetric ceramic membranes, porosity 30 to 40%, are used for high pressure and higher temperature <200°C.

Hydraulic permeability, A: 70 to 10,000 g/s·m^2. MPa. Pressure: 0.3 to 0.5 MPa for ceramic. Capacity/unit: 0.001 to 1 L/s. Liquid permeate flux: 0.001 to 0.2 L/s·m^2 with the permeate flux through ceramic membranes 2 to 3 times higher than through symmetric polymeric or sintered metal membranes and 5 to 10 times higher than through asymmetric polymeric membranes because ceramic operates at higher pressure.

Configuration: see Section 16.11.4.18.

Use tubular for feed concentrations of 10 to 80% w/w; spiral wound or thin channels for low concentrations with particulates <100 μm. For more see UF, Section 16.11.4.22.

16.11.5 Heterogeneous Separations*

General Guidelines

1. Consider shifting from heterogeneous phase separation to homogeneous phase separation.
2. If possible, separate gas phase first, then the liquid, and then solid-solid.
3. Consider using dense media separation to preconcentrate before grinding to final liberation size.
4. Use feed assay and liberation size as criteria to guide selection of options.
5. Try froth flotation as the first option. Suggested heuristics are given by Woods (1994, pp. 5–71).

For solid-solid separation, see Section 16.11.5.17.

16.11.5.1 Gas-Liquid

Area of Application

Knockout pot: drop diameter >100 μm; feed concentration >1% liquid v/v.

Zigzag baffled chamber: >100 μm; >0.01% v/v, but keep superficial gas velocity <1 m/s to prevent reentrainment.

Wet cyclone: 10 to 400 μm; 4 to 60% liquid v/v.

Spray chamber: 10 to 100 μm; 0.1 to 8% v/v, with collection efficiency decreasing from 90% to 50% as mist diameter decreases.

Venturi: <100 μm; <0.1% liquid v/v, with collection efficiency decreasing from 95% as mist diameter decreases.

Mesh demister: 10 μm; 0.001 to 0.01% liquid v/v; see size enlargement, Section 16.11.9.1.

Crossflow packed tower: <10 μm; 0.001 to 0.1% liquid v/v.

Afterburner: <0.8 μm; <0.1% liquid v/v.

Steam traps: separate condensate from steam.

Guidelines

Knockout pot (drums and accumulators for high ratios of liquid/gas, as in distillation column overheads): use horizontal cylinder: size vapor space to provide the residence time for drops to settle out. Vapor volume between 20 and 50% with a minimum of 0.3 m. Design vapor-phase cross-sectional area to allow drops to settle in assigned length of the drum. Assume drops 0.1 to 200 μm. The Souders–Brown "separation" maximum superficial gas velocity is

$$v_{o\,max} = k((\rho_L - \rho_G/\rho_G))^{0.5}, \text{ where } k \text{ is usually } 0.13.\ k_{horiz} = 1.25\ k_{vertical}$$

and use superficial design value of 0.5 to 0.85% of v_{max}. (This separation superficial gas velocity is used to design/size many types of equipment: distillation columns, demisters.)

Design liquid volume usually 80% with sufficient volume for 300 s residence time to satisfy process control requirements. Typical length-to-diameter ratio of 3:1 to 5:1.

Knockout pot (for low ratios of liquid/gas, as in demisters): use vertical cylinder. Size the same as horizontal with height of the vapor space 1.5 times dia. with 15 cm minimum above the top of the inlet nozzle and use lower value for k in the above equation. For the liquid phase: maximum liquid level at least 18 cm below bottom of inlet nozzle; liquid residence time about 300 to 600 s.

Steam traps: ball float, open bucket, inverted bucket, liquid expansion, and thermodynamic. Float: continuous discharge, operating principle of buoyancy, OK for low loads but not high pressure. Inverted bucket: intermittent discharge, operating principle = weight of the bucket, robust, okay for high pressure and corrosive condensate, use check valve before trap. Balanced pressure, thermostatic: operating principle = vapor pressure of fluid inside bellows. Thermodynamic/kinetic energy: intermittent, operating principle is Bernoulli's principle/impulse, poor air handling, larger sizes more susceptible to back pressure. Usually for steam pressure <1.2 MPa, affected by ambient temperature.

Select inverted bucket traps based on condensate flow rate, pressure differential, and "safety factor."

The other units are sized using approaches used for gas-solid separations (Section 16.11.5.2).

16.11.5.2 Gas-Solid

Area of Application

"Fumes" are particles <1 μm. In general: use cyclones and settling basins for solids loading >20 g/m^3. Then, select bag filters unless fumes are also present, low temperatures (<100°C

for natural fibers; <300°C for synthetic glass), noncorrosive conditions and not close to the dew point. Select scrubbers if fumes are present. For high temperatures, consider electrostatic precipitators. Design can be "high efficiency" or "standard," with mass collection efficiency decreasing as size of target particle decreases.

Dry cyclone: dust diameter 10 to 1000 μm; feed concentration 5 to 75 g/m^3; temperature <400°C; gas phase Δp = 0.2 to 1.6 kPa; mass collection efficiency 50%; power usage 0.8 to 20 kW/m^3/s.

Settling basin: dust diameter >100 μm; feed concentration 2 to 75 g/m^3; temperature <400°C; gas phase Δp = 3 to 7 kPa; power usage 0.04 to 0.7 kW/m^3/s.

Bag filter: very efficient removal of small-diameter and small-particle loadings; dust diameter 0.5 to 70 μm; feed concentration 0.01 to 100 g/m^3; temperature <100°C for natural fibers and <300°C; gas phase Δp = 0.5 to 1 kPa: power usage 0.8 to 30 kW/m^3/s.

Wet cyclone: dust diameter 0.75 to 10 μm; feed concentration 5 to 75 g/m^3; temperature <100°C; gas phase Δp = 0.5 to 1 kPa, power usage 0.8 to 20 kW/m^3/s.

Crossflow scrubber: dust diameter >3 μm; feed concentration <10 g/m^3; temperature <100°C; gas phase Δp = 0.2 to 1.6 kPa.

Wet scrubbers: countercurrent wet packing: dust diameter 0.2 to 3 μm; feed concentration <0.1 g/m^3; temperature <100°C; gas phase Δp = 1.25 to 6 kPa.

Turbulent bed contactor (see also Section 16.11.4.8, absorber): temperature <100°C; OK for heavy, sticky particles; allows high gas and liquid flow rates with high mass transfer efficiencies for gas absorption; 1 to 2 μm; 2.5 to 20 kW·s/m^3.

Venturi scrubbers: dust diameter 0.02 to 3 μm; feed concentration 0.1 to 20 g/m^3; temperature <100°C; gas phase Δp = 1.25 to 6 kPa; mass collection efficiency 99%; power usage 3 to 40 kW/m^3/s.

Low-voltage electrostatic precipitator: dust diameter 1 to 100 μm and conducting particles; feed concentration <30 g/m^3; temperature <800°C; gas phase Δp = 0.02 to 0.1 kPa; power usage 0.04 to 0.7 kW/m^3/s. Mass collection efficiency 5%, increasing to 90% as the particle size increases from 0.01 to 5 μm.

High-voltage electrostatic precipitator: dust diameter 0.01 to 5 μm and conducting particles; feed concentration <25 g/m^3; with pressures <7 MPa and temperature <800 °C; gas phase Δp = 0.02 to 0.1 kPa; mass collection efficiency 99.5%; power usage 0.04 to 0.7 kW/m^3/s. Gas velocity 0.3 to 5 m/s across the face of the collecting surface. One high-voltage system/2500 m^2 collecting surface, 30 to 100 kV DC. High initial capital investment.

Afterburners: dust diameter <0.1 μm; combustible; feed concentration <0.1 g/m^3.

SO_2 scrubbers (double alkali, Catox, Tyco): power usage 30 to 40 kW/m^3/s.

Guidelines

Dry cyclone: size based on an inlet gas velocity based on the particle loading: for particle loadings of <7 g/m^3, use inlet gas velocity of 11 to 23 m/s to size inlet nozzle and then scale configuration from this dimension. For loadings of 10 g/m^3, use 20 m/s; loadings of 100 g/m^3, use 10 m/s; loadings of 1000 g/m^3, use 5 m/s; loadings of 10,00 g/m^3, use 1.8 m/s.

Gravity settler: 5 to 7 m/s at inlet baffle; but the gas superficial velocity should be <3 m/s to avoid reentrainment.

Bag filter: batch: load cycle and clean: intermittent shaking, reverse pulse, reverse blow ring or sonic cleaning. Load filter until the gas pressure drop across the filter is >1.5 kPa, then clean. Choice of fabric is critical: static charge on fabric, operating temperature, potential for fumes to absorb with moisture to deteriorate bag, and need to select dust removal option to keep the Δp across the bag of 0.5 to 1.5 kPa. Felted material gives higher gas flow rate per unit area than woven, costs 3 to 4 times more, and cannot be cleaned by

shaking. Gas-to-cloth ratio of 25 to 150 dm^3/s·m^2, but usually design on <75 dm^3/s·m^2. Usual range for woven fabric 7.5 to 50 dm^3/s·m^2; for felted fabric, use 7.5 to 100 dm^3/s·m^2; for microporous tubes, use 9 to 20 dm^3/s·m^2. Gas loading depends on density of particles, size, inlet dust concentration, type of fabric. Batchwise loading with dust removal by reverse jet or blowring is about 0.04 kW/m^2 of bag area. Bag length: diameter <33:1.

Wet scrubbers: limited to lower temperatures <100°C.

Wet cyclone: size on internal superficial gas velocity of 1 m/s; height to diameter of 3:1 and water usage of 0.4 L/m^3; water flow rate 1.3 to 2.5 L/m^2·s.

Crossflow scrubber: Δp = 0.3 kPa/m of width; 1 to 1.5 m width usual; water flow rate 2.7 L/m^2·s of horizontal cross-sectional packing; size on actual inlet gas flow rate to the packing face of 1 m^3/m^2·s.

Countercurrent wet packing: pressure drop 0.3 to 0.5 kPa/m of packing. Liquid loading about 0.4 L/m^3 gas or 0.6 to 1 L/s·m^2; superficial gas velocity 0.5 to 1 m/s; mass loading liquid/gas = 0.7 to 1.5.

Turbulent bed contactor: Liquid loadings 20 L/m^2·s; superficial gas velocity based on actual inlet gas flow rate 2 to 11 m^3/s·m^2 horizontal cross section; mass loading liquid/gas = 4 to 8. Related topics include fluidized bed, drying (Section 16.11.5.5); heat transfer (Section 16.11.3.8); reactors (Section 16.11.6.27); mixing (Section 16.11.7.1), and size enlargement (Section 16.11.9.5).

Venturi scrubbers: size on throat velocity of 15 to 150 m/s selected based on particle size to be removed with 40 m/s (and 25 kPa pressure drop) for 1 μm and 120 m/s (and 25 kPa) for 0.1 μm. Water usage is in the range 0.5 to 5 L/m^3 gas, with pressure drop increasing as throat velocity increases; mass loading liquid/gas = 1.3 to 1.6.

Wet impingement baffle (Peabody) scrubbers: height/diameter 1.3:1 to 4.6:1; liquid loading 1 to 2 L/m^2·s of horizontal cross-sectional area; mass loading liquid/gas = 0.2 to 0.7.

Electrostatic precipitator: Batch process: load electrodes, then clean: via wet spray or mechanical rapping. For particle conductivity between 10^{-8} and 0.01 reciprocal ohm·m. Prefer negatively charged configuration. May need to adjust conditions to get particle conductivity into acceptable range. For particles >10 μm, use 38-m^2 plate area per m^3/s gas flow; 1 μm, use 100-m^2 plate area per m^3/s gas flow; 0.4 μm, use 120-m^2 plate area per m^3/s gas flow.

16.11.5.3 Liquid-Liquid

Usual drop size 200 μm; interfacial tension 30 mN/m.

Area of Application

Decanter: drop diameter >100 μm:, feed concentration >2% v/v.

Hydrocyclone: drop diameter >20 μm; feed concentration 6 to 60% v/v. Interfacial tension must be >10 mN/m to prevent drop breakup.

Sedimentation centrifuge: disc type: drop diameter >20 and <200 μm; feed concentration 6 to 60% v/v; suited for low surface tension, density differences >0.02 Mg/m^3. Solids contamination <0.1% v/v. Use differential type for drop diameter >200 μm; feed concentration 6 to 60% v/v; suited for low surface tension, density differences >0.05 Mg/m^3. Solids contamination <0.1% v/v.

Electrodecanter: drop diameter 9 to 500 μm; feed concentration 0.8 to 8% v/v.

Fibrous bed coalescer: drop diameter 3 to 75 μm; feed concentration <3% v/v. See size enlargement, Section 16.11.9.2.

API separator: drop diameter >75 μm; feed concentration 0.015 to 3% v/v.

Dissolved air flotation: drop diameter >8 μm with feed concentration 0.005 to 0.015% v/v and drop diameter <8 μm; feed concentration 0.0075 to 0.1% v/v. See Section 16.11.5.15.

Coagulation/flocculation: drop diameter >8 μm with feed concentration 0.005 to 0.015% v/v and drop diameter <8 μm; feed concentration 0.0001 to 20% v/v. See size enlargement, Section 16.11.9.3.

Deep bed filtration: drop diameter >8 μm with feed concentration 0.0002 to 0.005% v/v, and drop diameter <8 μm; feed concentration 0.002 to 0.05% v/v. See filters, Section 16.11.5.13.

Solvent extraction: drop diameter 0.1 to 1 μm; feed concentration 0.001 to 10% v/v. See Section 16.11.4.10.

Guidelines

16.11.5.3.1 Decanter

Ill-behaved dispersions usually drift with time, are sensitive to incoming drop-diameter distribution and to upstream energy input. Examples include most systems with kerosene-based immiscible systems. First approximation: allow 20-min residence time or total overflow velocity of 0.35 L/s·m^2. *Feed concentration* <10% v/v, size as sedimentation-controlled provided surfactants and contamination negligible and mixture is not "ill-behaved." Use overflow total flow rate velocity of 0.5 to 3 L/s·m^2 based on horizontal cross-sectional area with a usual value of 1.4 L/s·m^2. This is for a horizontal cylinder with length-to-diameter ratios of 3.5. Allow both phases to have >20% of the diameter and no less than 0.2 m to ensure that the exit phases do not become cross contaminated. For process control, the minimum distance between the high and low levels of the interface should be 0.36 m or at least 2 min residence time.

Feed >10% v/v, or contamination present, or ill-behaved, size as coalescence controlled. For vertical decanters, allow a total residence time that depends on density difference and interfacial surface tension. For a typical 0.5-m height of coalescent band (or a decanter of 0.7-m height), use an overflow total flow rate velocity of 1.5 $(\Delta\rho/0.1)^{0.5}$ L/s·m^2, where the density difference is in units of Mg/m^3 to determine the horizontal cross-sectional area. For horizontal configurations, use half of the vertical overflow velocity. Can add parallel plates or high- and low-energy combination coalescer promoters (see size increase, liquid-liquid, Section 16.11.9.2).

16.11.5.3.2 Hydrocyclone

Design using the same principles as liquid-solid hydrocyclone, Section 16.11.5.8. For flooded underflow, the pressure drop is about two to seven times greater than for air core operation.

16.11.5.3.3 Sedimentation Centrifuge

Disc type: (Westfalia, Alfa–Laval, Robatel) continuous: centrifugal field about 10^4 g and 100 rps with residence times of 1 to 10 s. Power 3 to 10 kW·s/L of feed.

Differential type: (Podbielniak, Quadronic) continuous: centrifugal field about 500 g and 25 rps with about 10 to 75 s residence time. Power 1 kW·s/L.

16.11.5.4 Liquid-Solid: General Selection

Effect of Particle Diameter and Solid Concentration on the Choice

For particle diameter greater than 1000 μm and solid concentration >3%, use screens, Section 16.11.5.6. For particle diameter <2 cm and >5 μm and solid concentration 1 to 50%, consider settlers, filters, or centrifuges. For particle diameter <300 μm and solid feed concentration 0.01 to 20%, consider thickeners, Section 16.11.5.9. For particle diameter >20 μm and solid feed concentration greater than 50%, consider dryers, Section 16.11.5.5. For particle diameter 0.01 to 150 μm, consider deep bed filter, Section 16.11.5.13, or dissolved air flotation, Section 16.11.5.15. For particle diameter 0.6 to 40 μm and solids concentration <0.1%, consider homogeneous separation via ultrafiltration, Section 16.11.4.22. For particle diameters from 0.8 to 20 μm, consider using a filter aid to precoat on the filter medium. For example, use diatomous earth or perlite. A *fine* filter

aid is 8- to 20-μm diameter to give a precoat bed of permeability 0.05 to 0.5 μm^2; a *medium* filter aid is 30- to 60-μm diameter to give a precoat bed of permeability 1 to 2 μm^2; a *coarse* filter aid is 70- to 100-μm dia. to give a precoat bed of permeability 4 to 5 μm^2. For particle diameter less 1 μm, consider size increase via coagulation/flocculation, Section 16.11.9.3. An example coagulant is starch.

Effect of Recovery on the Choice

To recover liquid: in the order of preference of filters, Section 16.11.5.13, and filtering centrifuges, Section 16.11.5.12: deep bed, horizontal vacuum, pressure leaf, gravity flat table; cartridge, precoat drum, and plate and frame, or vertical basket filtering centrifuge. For high fluid viscosity, use plate and frame or horizontal filtering cone centrifuge.

To recover liquid: in order of preference of settlers, Section 16.11.5.7, thickeners, Section 16.11.5.9, and sedimentation centrifuges, Section 16.11.5.11: clarifier, settler, washing tray thickener, reactor-clarifier, hydrocyclone, batch tubular bowl centrifuge, batch automatic (horizontal or vertical bowl, disc with intermittent nozzle discharge); continuous disc bowl centrifuge with nozzle discharge.

To recover liquid and solids: in order of preference of filters: expellers and presses, Section 16.11.5.16.

To recover liquid and solids: in order of preference of settlers, Section 16.11.5.7, CCD, Section 16.11.5.10, and sedimentation centrifuges, Section 16.11.5.11: continuous countercurrent decanter circuit CCD, horizontal solid bowl centrifuge with scroll discharge.

To recover solids: in order of preference of filters: requiring good washing: pressure, vacuum, gravity table/pan, horizontal pressure or vacuum, horizontal belt, vacuum drum, cylindrical screen scroll discharge filtering centrifuge, and plate and frame. Requiring good washing and the crystals break easily: gravity, vacuum table/pan; vacuum, pressure, gravity drum, and plate and frame. If the cake is compressible, use low pressure, <200 kPa, or vacuum rotary drum. For dry solids: consider the following filtering centrifuges, Section 16.11.5.12: basket, basket automatic constant speed vertical, basket automatic variable speed horizontal; continuous conical with scroll conveyor, oscillating conical screen; cylindrical screen with pusher conveyor, or horizontal solid-screen scroll conveyor. To recover solids: in order of preference of thickeners, Section 16.11.5.9, and sedimentation centrifuges, Section 16.11.5.11: thickeners, deep thickener, rake thickener, and tray thickener or hydrocyclone, batch automatic solid bowl centrifuge, continuous conical bowl centrifuge, continuous contour bowl vertical or horizontal centrifuge.

16.11.5.5 Dryer

Use when the goal is solid recovery. Related topics are screens (Section 16.11.5.6), centrifugal filters (Section 16.11.5.12), and dewatering expellers (Section 16.11.5.16).

Area of Application

Particle diameter 20 μm to 1 cm; feed solid concentration >50% solids. Liquid contamination in exit solids 0 to 20% v/v liquid. Use batch for <40 g/s; use continuous for >280 g/s. Select initially on temperature sensitivity. Prefer "adiabatic" over conduction.

Indirect conduction options: (nonadiabatic) for temperature-sensitive solids (T < 40°C).

Batch:

Pan/tray/shelf, jacketed, atmosphere, or vacuum (conduction): batch, feed: thin or thick liquids, soft or stiff pastes, moist crumb, grains (>150 μm) and grits (<150 μm). Product: solid cake. *Pan, agitated,* atmosphere or vacuum (conduction): batch, feed: thin or thick liquids, soft or stiff pastes, moist crumb, grains (>150 μm), and grits (<150 μm). Product:

solid cake. *Rotary indirect* (steam or hot fluid) atmosphere or vacuum (conduction): batch feed: moist crumb, grains (>150 μm), and grits (<150 μm). Dries in <60 min. Product: crumb/powder. *Cone/double cone,* jacketed, atmosphere or vacuum (conduction): batch, feed: sticky, fine, moist crumb, grains (>150 μm), and grits (<150 μm). Product: crumb. *Freeze,* batch, atmosphere or usually vacuum (conduction): batch, feed: thin or thick liquids, soft or stiff pastes, moist crumb, grains (>150 μm), coherent sheets, discontinuous sheets. *Dielectric:* feed: thin or thick liquids, soft or stiff pastes, moist crumb, grains (>150 μm), and grits (<150 μm).

Continuous:

Drum dryer, atmosphere or vacuum (conduction): feed: thin or thick liquids, soft and stiff pastes, wet paper. Dries within 2 to 30 s. Product: flakes, dry sheet. Screw, jacketed, atmosphere or vacuum (conduction): feed: sticky, fine, moist crumb, grains (>150 μm), and grits (<150 μm). Product: crumb. *Conveyor,* jacketed, atmosphere or vacuum (conduction): feed: sticky, fine, moist crumb, grains (>150 μm), and grits (<150 μm). Product: crumb.

Indirect convection options: for moderately temperature sensitive, sensitive and very sensitive solids ($5 < T < 40$°C). Indirect heating means heat source temperature <200°C.

Batch:

Pan/tray/shelf, crossflow (indirect convection): batch, feed: soft paste, preform, hardpaste, granular, fragile particles, fibrous, discontinuous sheets, and shaped pieces. *Pan/tray/shelf, through flow* (indirect convection): batch feed: preform, granular, fibrous. *Open sand bed:* (natural convection): batch feed of wastewater sludge.

Continuous:

Spray (indirect convection) feed: thin liquids and slurries. Dries within 1 to 10 s. Product: 1- to 300-μm powder. *Flash/transported* (indirect convection) feed: preformed paste, granular, fibrous solids. Dries within 0.5 to 3 s. Product: powder. Particle diameter <2 mm. *Fluidized bed* (indirect convection): feed: soft paste, sludge, preformed paste, granular, fibrous solids. Product: powder. Particle size 0.05 to 15 mm. *Pan/tray/shelf* continuous (Turbo) (indirect convection). Feed: soft paste, preform, granular, fibrous. Product: solid cake. *Desolventizer:* feed: leached vegetable seeds contaminated with solvent (such as hexane). Product: solvent-free cake. *Tunnel/truck* continuous (indirect convection): feed: grains (>150 μm), discontinuous sheets and shaped pieces, soft paste, preform, granular, fibrous. Product: solid cake. *Belt, through flow,* continuous (indirect convection): grains (>150 μm), discontinuous sheets, and shaped pieces. *Rotary, continuous* (including steam tube) (indirect convection): feed: hard, granular, fibrous. Dries within <60 min, <50 kg/s/unit.

Direct convection options (adiabatic) for temperature-sensitive, moderately sensitive, and insensitive solids ($10 < T < 150$°C).

Options similar to *indirect convection,* but hotter gases are used.

Guidelines

Indirect conduction at reduced pressure: evaporative capacity 42 to 5 g water/s·m^2 as moisture goes from 0.5 to 0.015 kg/kg dry solids.

Convection with hot gas through the bed: evaporative capacity 1.2 to 0.25 g water/s·m^2 as moisture goes from 0.9 to 0.025 kg/kg dry solids.

Convection plus radiation: evaporative capacity 0.8 to 0.15 g water/s·m^2 as moisture goes from 0.9 to 0.025 kg/kg dry solids.

Indirect conduction options:

Batch: size on cycle time: load, dry, discharge, clean.

Pan/tray/shelf, jacketed, batch (conduction): evaporative capacity 0.13 to 0.27 g water/s·m^2 tray area for crystals, 0.07 to 0.14 g water/s·m^2 tray area for finely divided solids; loading 10 to 35 kg wet paste/m^2 tray area; pressure 7 to 27 kPa. *Pan, agitated, batch, atmosphere* (conduction): area 1.5 to 15 m^2; evaporative capacity 1 to 12 g water evaporated/s·m^2; power 4 kW/m^3. Heat transfer coefficient 10 to 50 W/m^2 °C; solids capacity 2.8 to 4.2 g dry solids/s·m^3. *Pan, agitated, batch, vacuum (conduction):* evaporative capacity 1.35 to 6.8 g/s·m^2; time 7.5 to 35 h. *Tray/pan/shelf* (conduction, vacuum): area 1 to 20 m^2; evaporative capacity 0.27 to 7.7 g/s·m^2; time 4 to 48 h. Heat transfer coefficient U = 0.002 to 0.5 kW/m^2·K. *Rotary indirect,* batch, vacuum (conduction): area 2 to 35 m^2; evaporative capacity 0.3 to 5 g water evaporated/s·m^2 with values increasing as initial feed moisture content increases; 0.7 to 5 g organic evaporated/s·m^2. Power 0.5 kW/m^2 area. *Cone/double cone,* jacketed, batch, vacuum (conduction): area 1 to 10 m^2; evaporative capacity 2.7 to 5.4 g water evaporated/s·m^2 of actual surface area. Power 0.5 kW/m^2 area. Freeze, batch, vacuum (conduction) drying temperature serum, –9 to –12°C; plasma, –20 to –25°C; penicillin –28 to –32°C; size vacuum pump to remove the water vapor; avoid air leaks. Pressure 10 to 200 Pa or 1/4 to 1/2 the vapor pressure at the temperature; 7 to 8 h drying cycle.

Continuous:

Drum dryer, atmosphere (conduction): area 2 to 50 m^2; evaporative capacity 7 to 11 g water/s·m^2; residence time: 6 to 15 s; solids capacity 5 to 50 kg/m^2; heat transfer coefficient 0.001 to 0.002 kW/m^2·°C; 1 to 10 rpm; 1 to 2.5 kW/m^2. 1 to 10 rpm; drive power 1 to 2.5 kW/m^2 drum surface area. Related topic is flakers, Section 16.11.9.15. *Fourdrinier machine* for paper: 37 cylinders, 1.5-m dia.; velocity of paper = 4 to 5 m/s; residence time 31 s; heat transfer coefficient U = 0.34 kW/m^2·°C. Water/solid = 0.4; 2.8 g water evaporated/s·m^2. *Screw, jacketed,* atmosphere (conduction): 2 to 30 rpm; area 4 to 60 m^2, volume 0.1 to 3 m^3, 0.03 to 0.5 kg water evaporated/s. Heat transfer coefficient 4 to 60 W/m^2 °C with 4 to 10 for hollow screw and 5 to 35 for hollow paddles; power 140 MJ/Mg. *Continuous band, vacuum*; (conduction): 2.2 kg steam/kg water evaporated; solid capacity 2 to 5 g dry solids/s·m^2 belt area; belt size <8 m^2. *Continuous band, atmospheric* (conduction): evaporative capacity 0.8 g water/s·m^2; dry solids output 2 g solid/s·m^2; area 56 m^2. *Freeze*, continuous tray: 50-mm thick bed; vacuum 13 Pa absolute: heat transfer coefficient, U = 0.01 to 0.02 kW/m^2·°C; relatively independent of stirring speed but dependent on residence time. Residence time 10 to 200 s. *Dielectric:* 315°C.

Indirect convection options: for moderately temperature sensitive, sensitive, and very sensitive solids ($5 < T < 40$°C).

Batch: size on cycle time: load, dry, discharge, clean.

Tray/shelf (indirect convection) crossflow: 0.05 to 0.2 g water evaporated/s·m^2 tray area; residence time 4 to 48 h; 1.5 to 5 m/s gas flow; steam 1.8 to 2 kg steam/kg water evaporated; power 8 to 15 kJ/kg; air temp. 50 to 110°C. solids capacity <6 g/s. *Open sand bed:* (natural convection) 1000 to 100,000 m^2 including piping, sand/gravel beds, and underground collection.

Continuous:

Spray (indirect convection): residence time 3 to 30 s; gas velocity 0.2 m/s; thermal efficiency 50%; adiabatic efficiency 100%; solid temperature = adiabatic saturation temperature; volumetric heat transfer coefficient 0.13 to 0.18 kW/m^3 K; 1.8 to 2.7 kg steam/kg water evaporated. Δp = 1.5 to 5 kPa. See size reduction sprays, Section 16.11.8.2; spray reactor, Section 16.11.6.12; heat exchange, Section 16.11.3.12; and size enlargement, Section 16.11.9.4. *Flash/transported* (indirect convection): 175 to 630°C, gas velocity 3 to 30 m/s or 2.5 to 3 times the terminal velocity of the particles; gas requirement 1 to 5 Nm^3/kg solid or 1 to 10 kg air/kg solid; exit air temperature 20°C greater than exit dry solid temperature; 4000 to 10,000 kJ/kg water evaporated. See transported slurry, transfer line reactors, Section 16.11.6.9. Heat transfer coefficient for gas drying: h = 0.2 kW/m^2·K. Fluidized bed (indirect convection): residence time 30 to 60 s for surface fluid vaporization; 15 to 30 min for internal diffusion; 3500 to 4500 kJ/kg water evaporated. *See fluidized* bed reactors, Section 16.11.6.27; heat transfer, Sections 16.11.3.4 and 16.11.3.8; size enlargement, Section 16.11.9.5; and mixing, Section 16.11.7.1. *Tray/gas flow through the bed:* 0.24 to 3.3 g water evaporated/s·m^2 tray area. Residence time 2 to 8.5 h; superficial air velocity 0.2 to 1 m/s; steam 2 to 6.8 kg steam/kg water evaporated. Fan power 1.6 to 2.5 kJ/g solids throughput, area 4 to 15 m^2; air temperature 9 to 100°C. Solids capacity <6 g/s. *Continuous tray, turbo* (indirect convection), 1 to 2 rpm; 10 to 50 trays/unit; residence time 0.25 to 2 h; diameter 1.25 to 11 m; height 1.5 to 18 m. Area 10 to 1000 m^2; evaporative capacity 0.05 to 15 g water evaporated/s·m^2. Gas velocity 0.6 to 2.4 m/s; fan power 8 to 15 kJ/kg solids handled; 0.08 to 15 kW/m^2, 0.1 kg steam/kg dry solid; capacity 0.003 to 2.3 kg/s. 5 to 8 kW/Mg dried solids; 5 to 7 kW/Mg water evaporated. Energy 50 to 100 kJ/m^2 drying area for dry solids; 70 to 200 kJ/m^2 drying area for wet solids. *Desolventizer:* combination of live and indirect steam; inlet solvent concentration about 30%; capacity 2 to 50 kg/s. Flakes 0.25- to 0.3-mm thick. *Tunnel/truck* (indirect convection) area 10 to 100 m^2; evaporative capacity 0.15 to 0.77 g water evaporated/s·m^2. *Rotary* (indirect convection) temperature 300°C; area 10 to 1000 m^2; evaporative capacity 9 g water evaporated/s·m^3 or 3.5 g water/s·m^2 of peripheral area; 5 to 10% solids, residence time 0.1 V/volumetric feed rate; gas velocity 1 to 1.5 m/s; peripheral velocity 0.1 to 0.5 m/s. Steam heated gas temp. 120 to 175°C; size on volumetric heat transfer coefficient. Power 0.15 to 0.25 kW/m^2 nominal circumferential area. L/D 5.5/1. *Rotary steam tube* (indirect convection): temperature 150 to 180°C; area 10 to 1000 m^2; evaporative capacity 0.77 g water/s·m^2; gas velocity 0.3 m/s; heat transfer coefficient U = 0.03 to 0.09 kW/m^2·°C. *Continuous metal band:* (heated by forced convection air, IR, direct steam, or direct hot water): heat transfer coefficient from impinging hot air: U = 0.06 to 0.09 kW/m^2·K. Air velocity 15 to 25 m/s. 5 to 50 kg water evaporated/m^2 drying surface.

Direct convection options: for temperature-sensitive, moderately sensitive, and insensitive solids [10 < T < 150°C]. *Hot gas temperature* 550 to 800°C

Continuous band: crossflow: <3-mm thick bed area: 20 to 100 m^2; evaporative capacity 2 to 13 g water evaporated/s·m^2; residence time 0.2 to 1.3 h; steam 1.7 to 1.9 kg/kg water evaporated; fan power 35 to 1300 kJ/kg; belt drive power 1 kW/m^2 belt. *Continuous band: gas flow through the bed:* 1 to 4 g water evaporated/s·m^2; steam 2 to 5 kg steam/kg water evaporated; 1.25 m/s gas velocity through the bed; area 5 to 25 m^2. *Rotary cascading dryer/kiln roto-louvre* area 10 to 1000 m^2; evaporative capacity 18 g water evaporated/s·m^3 or 7 g water/s·m^2 of peripheral area; 5 to 10% solids, residence time 0.1 V/volumetric feedrate; gas velocity 1 to 1.5 m/s or 1/2 terminal velocity of particles; peripheral velocity 0.1 to 0.5 m/s, 4 to 5 rpm; rpm times diameter = 3 to 12 rpm·m; L/D = 4 to 15/1; average temperature of evaporation throughout = 3°C above the inlet wet-bulb temperature. Countercurrent exit air temperature about 100°C; for cocurrent exit air, temperature = 10 to

20°C higher than the exit solid temperature; heat transfer coefficient 0.1 W/kg solids °C for coarse materials and 0.4 W/kg °C for fine. NTU = 0.5 for vegetables. NHTU (for air water) = 1.0 to 3.5 = $\ln(T_{hot\ gas\ in} - T_{wet\ bulb})/(T_{hot\ gas\ out} - T_{wet\ bulb})$. Drive power 0.075 to 0.16 kW/m^2 nominal circumferential area; area in the range 200 to 2500 m^2. Related topics are kilns (Section 16.11.3.7) and reactors (Section 16.11.6.20). *Open bed:* residence time: minutes; gas through bed 0.5 to 1 m/s.

16.11.5.6 Screens for "Dewatering"

See also Section 16.11.5.29, screens for solid-solid separation. Related topics are filters (Section 16.11.5.13), centrifugal filters (Section 16.11.5.12), and expellers (Section 16.11.5.16).

Area of Application

In general, particle diameter >1000 μm and solid concentration >3%. Special types include microscreens for >20 μm.

Batch:
Deep bed or granular: batch, for 0.01 to 50 μm (see filter, Section 16.11.5.13). *Fixed bar screen;* batch, grizzly (the filter cloth is made of rods and bars) removal of very coarse material of diameter >2 to 5 cm; low concentration of solids <15 mg/L; bars at 30 to 60° to the horizontal that can be cleaned manually or automatically. *Microscreen* (rotary drum or disk). Batch, removal of participles of diameter >20 μm; 20 mg/L solids feed concentration.

Continuous:
Fixed, inclined wedge wire screen (sieve bends, DSM): removal of particles >0.15 cm. Variable inclination from 65 to 45° to the horizontal; feed concentration 200 mg/L. For dewatering minerals, dewatering particles of diameter >40 μm. *Vibrating screens:* typical exit liquid concentration for <8-mm particle size, 20 to 45 vol% liquid; for >40-mm particle size, 2 to 10% v/v liquid. *Belt, gravity:* see Section 16.11.5.13.

Guidelines

Batch: consider cycle time: load, clean.

Bar screen: batch: fluid velocity through the screen 0.6 to 1.2 m/s; head loss 15 to max. 75 cm. Mechanical clean. *Rotating microscreen:* batch, fluid loading 3 to 6 $L/s{\cdot}m^2$ of submerged area; usually 66% area submerged; solids loading 0.05 to 0.1 $g/s{\cdot}m^2$; head loss 7 to 14 cm to max. of 45 cm. Clean by backwash at 2 to 5% volumetric throughput capacity.

Continuous:

Fixed, inclined wedge wire screen, sieve bend: fluid loading 6.7 to 20 $L/s{\cdot}m^2$; or 10 to 40 L/s·m of width; solids loading 1.4 to 4.2 $g/s{\cdot}m^2$; exit solids concentration 12 to 15% w/w solids. For dewatering minerals, fluid capacity of 0.0015 to 0.03 $L/s{\cdot}m^2$ with larger fluid capacity for larger size particles (1 to 2 mm) and smaller than the included angle of the bend. The bend in the screen is such that the oversized are continually sluiced off. *Vibrating screens:* see Section 16.11.5.29.

16.11.5.7 Settlers

Area of Application

Particle diameter <2 cm; solids concentration 0.2 to 50%.

Guidelines

Upward liquid overflow rate 0.25 to 0.6 L/s·m^2, with the value increasing as the feed concentration, particle diameter, and density increase.

For solids concentration 0.2 to 2, use 0.4 to 1 L/s·m^2; for 1 to 5, use 0.5 to 1.4 L/s·m^2. Usual depth is 4 to 5.2 m with drive for rake 0.5 to 10 kW.

16.11.5.8 Hydrocyclones

See also Section 16.11.5.21 for solid-solid separations.

Area of Application

Particle diameter 4 to 400 μm; feed solids concentration 4 to 30% solids v/v, but usual application is separating particles >50 μm and concentrations <10% v/v with pressure loss of 20 to 100 kPa. Regular hydrocyclones: particle "settling velocity" 2 μm/s to 5 mm/s and clarified liquid product of 0.1 to 70 L/s. Miniature hydrocyclones: particle "settling velocity" 0.05 μm/s to 0.04 mm/s and clarified liquid product of 0.02 to 30 L/s.

Guidelines

Determine diameter of hydrocyclone from D (cm) = 6 × 10^5 [Feed flow rate (L/s)/target diameter^2 (μm^2) Δp (kPa)] [ρ_L, density liquid (Mg/m^3) × liquid viscosity (mPa·s)/$\Delta\rho$, density difference, (Mg/m^3)].

Typical target diameter is 5 to 100 μm and is the diameter that 50% reports to the overflow and 50% reports to the underflow. Typically three times target diameter is the diameter below which all particles in distribution are removed. The standard hydrocyclone has an inlet diameter of 0.28 D; the overflow exit diameter = 0.34 D; the vortex finder length is 0.4 D; cylindrical body of height of 0.4 D, vertical length of cone = 5 D or cone angle about 10°. Underflow diameter adjustable to adjust the volume split between the overflow and underflow.

16.11.5.9 Thickener

Area of Application

Particle size 0.1 to 300 μm; try to avoid using a thickener for particle diameters >200 μm, especially if their density is >2 Mg/m^3. Feed solids concentration 0.01 to 20% v/v; exit liquid contamination in the solids exit 80 to 90% v/v liquid. Deep cone thickener: exit liquid contamination in the solids exit 30 to 40% v/v liquid.

Guidelines

Downward solid flux of 0.2 to 500 g/s·m^2 with low values of 0.2 to 2 for wastewater treatment, pickle liquor, and higher values of 40 to 70 for mineral processing. Higher flux rates by factors of 3 to 10 up to fluxes of 800 g/s·m^2 can be obtained with the addition of flocculants. Fluid residence times 2 to 4 h; solids residence times 4 to 24 h. Torque for rake (Nm) = K(thickener diameter, m)^2, where K = 15 to 30 for solid flux loadings of <2 g/s·m^2; = 70 to 130 for solid flux loadings of 2 to 7 g/s·m^2; = 150 to 300 for solid flux loadings of 7 to 23 g/s·m^2, and = >300 for solid flux loadings of >23 g/s·m^2. Operate the rake at 1 to 20% of design torque at the drive head. Rake tip speed 15 to 25 cm/s, but for appreciable amounts of particles of diameter >200 μm, increase tip speed to 25 to 40 cm/s. Pump the underflow at 1 to 2.4 m/s. See Section 16.11.2.5.

16.11.5.10 CCD: Countercurrent Decantation

Area of Application

When dilute liquid overflow is acceptable because high wash water ratios are used; for high-temperature operation when anticipate changes in feed materials and if the filtration rate is <140 g/s·m^2.

Guidelines

Wash ratio 2 to 2.2 water to 1 solid. Wash ratio and the number of stages are selected for expected recovery.

16.11.5.11 Sedimentation Centrifuges

Primarily to recover liquid, although it can be used to recover solids. Incomplete separation.

Area of Application

Liquid contamination in the exit solids: 10 to 15% v/v liquid.

Batch:

Tubular bowl: batch, very fine particles with settling velocities 5×10^{-8} to 5×10^{-7} m/s; particle diameter 0.1 to 500 μm, feed concentrations 0.1 to 20% v/v; <5% w/w. Clarify low concentrations. *Vertical solid basket:* batch, particle diameter >30 μm; feed solids concentration 3 to 5% w/w to prevent frequent cleaning. *Multichamber vertical solid basket, manual batch discharge:* particle settling velocity 2×10^{-6} to 7×10^{-5} m/s; particle diameter 1 to 50 μm*;* feed solids concentration <4 to 5% v/v. Very dry product and higher capacity. *High-speed disc vertical solids retaining:* batch, particle settling velocity 8×10^{-8} to 2×10^{-7} m/s; particle diameter <1 μm; feed concentration solids <1% w/w; <20% v/v.

Continuous:

High-speed disc, intermittent solids ejecting: particle diameter 1 to 500 μm; feed concentration solids 2 to 6% v/v and <5% w/w. *High-speed disc, continuous nozzle discharge:* particle diameter 0.1 to 500 μm; feed concentration solids 5 to 30% v/v; <10% w/w. Usually select when have a large amount of fines. *Horizontal scroll discharge:* (solid bowl decanter) 10^{-6} to 5×10^{-6} m/s; particle diameter 2 to 5,000 μm; feed solids concentration 0.5 to 50% v/v. Usually >10% v/v. Only option when feed concentration >40% v/v solids.

Guidelines

Scaled up based on liquid handling capacity.

Batch: size on cycle time: separate, remove solids, clean.

Tubular bowl: batch, up to 50,000 rpm; 3×10^3 to 6×10^4 g; L/D 4 to 8; liquid flow rates 0.03 L/s at high rpm, 0.1 to 10 L/s at lower rpm. Clarify low concentrations. Vertical solid basket: batch, 450 to 3500 rpm, 900 to 1100 g; L/D = 0.8; 1.6 to 2.8 L/s; 70- to 120-cm diameter bowl; 200 to 500 g/s·m²; area 0.5 to 3 m²; 3 to 17 kW. Multichamber vertical solid basket, batch discharge: 4500 to 8500 rpm; 3×10^3 to 3×10^4 g; 0.7 to 2.8 L/s; 30- to 60-cm dia. bowl. *High-speed disc vertical solid basket:* <12,000 rpm; 3×10^3 to 3×10^4 g; L/D = 1; <28 L/s; 15- to 100-cm bowl diameter; cone 35 to 50°. Solids retaining: 5 to 20 L/s;

Σ, m²	**Bowl dia., cm**
1000	10
10,000	20 to 30
100,000	60 to 90

Continuous:

Horizontal scroll discharge: 1600 to 6000 rpm; 1500 to 5000 g; L/D 1.5 to 3.5; 0.1 to 16 L/s;

Σ, m²	Bowl dia., cm
200	12 to 15 cm
1000	25 to 35
5000	50 to 70

16.11.5.12 Filtering Centrifuge

Table 16.34 summarizes the characteristics of different rates of filtration.

Area of Application

Liquid contamination in the exit solids: 4 to 13% v/v liquid.

Batch: vertical basket: batch, particle diameter >2 µm; feed solids concentration 2 to 50% w/w. Minimize damage to crystals. Low capacity: 0.003 to 5 kg/s. Product dryness 70% solids. Possible for sterilization between batches. *Vertical basket with bottom plough discharge:* batch, particle diameter 5 to 500 µm; feed solids concentration 9 to 90% w/w; capacity 0.1 to 1.25 kg/s. Product dryness 25 to 60% solids. Use with free draining, medium capacity, and where need multiple rinse. Horizontal basket, plough discharge: particle diameter 200 to 20,000 µm; feed solids concentration 10 to 70% w/w. Free slow draining, multiple rinses, low to medium capacity: 0.5 to 5.5 kg/s. Product dryness 87 to 96%. Keep feed consistent of high solids concentration.

Semicontinuous: horizontal basket, pusher discharge: particle diameter 50 to 5000 µm; feed solids concentration 15 to 70% w/w. Capacity 0.3 to 7 kg/s. Product dryness 85 to 98%. Free draining. Main advantage is to rinse the solids.

Continuous: horizontal combo solid-screen, scroll discharge: particle diameter >150 µm; feed solids concentration 10 to 75% w/w. Solvent-based reactions. *Vertical or horizontal cone:* slip discharge: continuous, particle diameter >200 µm; feed solids concentration 10 to 80% w/w, capacity 0.25 kg/s. Dewater crystals and free draining fibers. *Vertical cone, scroll discharge:* continuous, particle diameter 200 to 5,000 µm; feed solids concentration 5 to 60% w/w. Capacity 0.02 to 8 kg/s. *Horizontal cone oscillating/torsional vibration*

TABLE 16.34
Characteristics of Different Rates of Filtration

	Fast	Medium	Slow	Very Slow	Very, Very Slow
Intrinsic permeability, m⁴/N·s	$> 20 \times 10^{-10}$	$1–20 \times 10^{-10}$	$0.2–1 \times 10^{-10}$	$0.02–0.2 \times 10^{-10}$	$< 0.02 \times 10^{-10}$
for viscosity 1 mPa·s	> 50 µm	> 15 µm	> 4 µm	> 1.5 µm	< 1.5 µm
for viscosity 60 mPa·s	> 350 µm	> 100 µm	> 50 µm	> 17 µm	< 17 µm
Cake buildup rate, $g/s \cdot m^2$	> 700	70–700	7–70	0.02–7	<0.02
Possible option	Continuous pusher	Peeler centrifuge	Vertical basket centrifuge	Multichamber vertical solid bowl sedimentation centrifuge, **16.11.5.11**	Sedimentation centrifuge, **16.11.5.11**

discharge: particle diameter <6 mm; feed solids concentration 40 to 80% w/w. capacity 7 to 40 kg/s.

Guidelines

Batch: size on cycle times: accelerate to load speed, load and cake formation, accelerate to wash, wash, accelerate to full speed, spin dry, decelerate to unload speed, unload. Cake volume in the centrifuge is key. During load and cake formation, the particles migrate to the periphery to form a cake, the supernatant liquid moves through the bed to the cake surface, and then the liquid drains out of the interstices in the wet cake. The latter two times usually control. *Vertical basket:* batch with cycle: cake formation, wash, discharge, clean. Total cycle >10 min, e.g., 180 min. Cake buildup rate 200 to 1000 g/s·m^2; area per unit: 2.8 m^2; cake volume 0.009 to 0.5 m^3; cake thickness 25 to 150 mm with smaller thickness in smaller diameter centrifuges. 600 to 2100 rpm; 300 to 800 G. Basket diameter 0.3 to 1.5 m; L/D = 0.5 to 0.6/1. Power 3 to 6 kW/m^2 filter area. Temperature <175°C. *Vertical basket, bottom discharge:* batch with cycles: accelerate to load speed, load and cake formation, accelerate to wash, wash, accelerate to full speed, spin dry, decelerate to unload speed, unload: 3 to 120 s. Cycle time for free draining 2 to 6 min; slower draining materials cycle time 20 to 30 min with some >60 min, area per unit 0.4 to 4.5 m^2; cake volume 0.018 to 0.53 m^3; about 67% of feed volume; cake thickness 50 to 150 mm with smaller thickness in smaller diameter centrifuges. 900 to 1800 rpm. Basket diameter 1 to 1.2 m; L/D = 0.5. *Horizontal basket, plough discharge:* batch with cycles: load 7 to 25 s; wash 5 to 25 s, spin dry 12 to 30s, unload cake 3 to 12 s; total cycle time 20 s to 15 min but usually <3 min. Cake buildup rate 500 to 3000 g/s·m^2; area per unit 0.1 to 3.8 m^2; cake volume 0.03 to 0.17 m^3. Bowl dia. 0.3 to 1.2 m. 1000 to 2500 rpm; <1250 G. Power 25 to 40 kW/m^2 filter area.

Semibatch: particles move through the cycle continually. *Horizontal basket, pusher discharge:* 20 to 120 cycles/min: cake formation, wash, discharge. Cake buildup rate 1000 to 10,000 g/s·m^2; area per unit: 1.4 m^2; cake thickness <75 mm. Basket diameter 0.2 to 1.2 m; 300 to 600 G. Power 40 to 60 kW/m^2 filter area or 7 to 15 kJ/kg "salt" (about 3000 g/s·m^2). Keep feed solids concentration >40% w/w for optimum. Example data: adipic acid, urea 1.4 kg/s·m^2; crude sodium bicarbonate 1.45 kg/s·m^2; phosphate rock 2.2 kg/s·m^2; ammonium sulfate 2.36 kg/s·m^2; and sodium chloride 3.1 kg/s·m^2;

Continuous: horizontal combo solid-screen, scroll discharge: area per unit, 1.2 m^2; power 12 to 15 kW/m^2 filter area. *Vertical or horizontal cone:* slip discharge: cake buildup rate 3000 to 20,000 g/s·m^2; area per unit 4 m^2; cone angle 20 to 35° and greater than angle of repose of the solids. 2500 G. rinsing efficiency: fair. *Vertical cone, scroll discharge:* diameter 0.5 to 1 m. 2500 to 3800 rpm; 1800 to 2500 G. Product solids 24%. *Horizontal cone oscillating/torsional vibration discharge:* cone angle 13 to 18°; cycles >20 cycles/min. 300 to 500 rpm; <500 G. Diameter 0.5 to 1 m; L/D = 0.5 to 1/1. Product 92% solids. Limited liquid handling capacity. Power 0.2 kW/Mg solids.

16.11.5.13 Filter

Table 16.35 relates filtration rate to process operation.

For *incompressible* cakes, the filtration rate is directly proportional to the specific cake resistance and the pressure/vacuum, and inversely proportional to the viscosity and cake thickness. The filtration rate is inversely proportional to the ratio of solids to filtrate, while the rate of cake formation is directly related to this ratio. For *compressible* cakes, the filtration rate is relatively independent of pressure. The more flocculated the solids, the more compressible will be the filter cake.

TABLE 16.35
How Process Operation Relates to Filtration Rates

	Fast	Medium	Slow	Very Slow	Very Very Slow; Clarification
Cake formation rate, mm/s	>1	0.12–1	0.02–0.12	0.001–0.02	<0.001
Cake formation rate, g/s·m^2	700	70–>700	7–70	0.02–7	<0.02
Filtrate rate, L/s·m^2	>3	0.3–3	0.03–0.3	0.003–0.03 rarely filter for flux < 0.01	< 0.003
Typical cake resistance, m/kg	<8 × 10^8	8 × 10^8–10^{10}	10^{10}–5 × 10^{10}	5 × 10^{10}–3 × 10^{11}	>3 × 10^{11}
	Usual prefer continuous			Usually prefer batch	
Comments	Vacuum belt, screens, belts, top feed drum	Tilting pan, vacuum drums or disks	Continuous filters	Vacuum filter, rotary vacuum, pressure filters	Batch cartridge, precoat drums, deep bed

Area of Application

Prefer *batch* when cake formation rate is <0.01 mm/s (low concentrations of small diameter particles). OK for higher liquid viscosities and higher temperatures. Batch can be vacuum or pressure operation. Prefer vacuum operation for particle diameter >30 μm, if there is a small mass of fines (<50% with diameter <5 μm) and bed has permeability between 0.1 to 1000 μm^2. Prefer pressure filters for particle diameter 1 to 70 μm, if there is a large mass of fines (with >50% w/w with diameter <10 μm) and bed has permeability between 0.001 to 0.1 μm^2.

Prefer *continuous* for cake formation >0.01 mm/s (high concentrations of larger diameter particles); viscosity <50 mPa·s. Continuous is usually gravity or vacuum operation. For gravity operation particle diameter >1 mm and bed has permeability >1000 μm^2. For vacuum, usually particle diameter >30 μm, and bed has permeability between 0.1 to 1000 μm^2.

For *compressible* cakes, prefer mechanical compression via diaphragm plates or belt presses. Compressed volume = 0.6 to 0.75 volume before compression. Compression cycle 0.33 to 0.4 h for diaphragm plate and frame press. For *highly compressible*: latex, highly flocculated materials > silica, talc, attapulgite > kaolin >> barite, diatomaceous earth >> incompressible = polystyrene, carbonyl iron.

Batch: *leaf, pressure vertical:* particle diameter 1 to 120 μm; feed solid concentration 0.08 to 0.5% w/w. Recover liquid. *Leaf, vacuum:* particle diameter 1 to 500 μm; feed solid concentration 0.07 to 2% w/w; solids capacity <5.5 kg/s. *Leaf, horizontal pressure:* particle diameter 1 to 100 μm; feed solid concentration 0.003 to 0.05% w/w. Recover wet solid with good washing (rank 2). *Plate, horizontal vacuum:* recover liquid (rank 1). Recover wet solid with good washing (rank 2); liquid contamination in exit solids: 15 to 50% v/v liquid. Dry solids capacity <0.0027 kg/s. *Plate and frame:* particle diameter 1 to 100 μm; feed solid concentration 0.003 to 25% w/w. Recover liquid (rank 5); use for liquids with viscosity >50 mPa·s. Recover wet solid with good washing (rank 6); with good washing and fragile crystals (rank 3). Relatively incompressible solid bed. Liquid contamination in exit solids: 30 to 70% v/v liquid. Solid capacity <55 kg/s. *Diaphragm plate and frame:* compressible cake. *Deep bed:* particle diameter 0.01 to 50 μm; feed solid concentration 0.002 to 0.02% w/w. Recover liquid (rank 1); 50 to 90% removal efficiency. 10- to 300-mg/L feed solids concentration but usually <0.5 mg/L. Dry solids capacity <0.5 mg/s. *Cartridge:* particle diameter 0.8 to 50 μm; feed solid concentration 0.003 to 0.02% w/w. Recover liquid (rank 3). Dry solids capacity 0.0014 kg/s.

TABLE 16.36
Particle Diameter and Cake Permeability and Resistance

Particle Diameter, μm	Permeability (μm)^2	Intrinsic Permeability, m^4/N·s	Cake Resistance, m/kg
1	10^{-3}–0.1 depending on ∈	10^{-13}–10^{-10} depending on ∈ and liquid viscosity	10^{12}
10	0.1–10 depending on ∈	10^{-12}–10^{-8} depending on ∈ and liquid viscosity	10^{10}
100	10–1000 depending on ∈	10^{-10}–10^{-6} depending on ∈ and liquid viscosity	10^{8}
1 mm	1000–10^5 depending on ∈	2×10^{-8}–10^{-4} depending on ∈ and liquid viscosity	10^{6}
10 mm	10^5–10^7 depending on ∈		$<10^{6}$

Continuous: drum, gravity: particle diameter 40 to 5,000 μm; feed solid concentration 0.08 to 0.8% w/w. Recover wet solid with good washing and fragile crystals (rank 2). *Drum, pressure:* particle diameter 5 to 200 μm; feed solid concentration 0.75 to 5% w/w. Recover wet solid with good washing and fragile crystals (rank 2). *Drum, rotary vacuum:* particle diameter 1 to 700 μm; feed solid concentration 5 to 60% w/w. Recover wet solid with good washing (rank 4). Recover wet solid with good washing and relatively compressible cake (rank 1). Recover wet solid with good washing and fragile crystals (rank 2). Dry solids capacity <50 kg/s. *Drum, precoat rotary vacuum:* particle diameter 0.5 to 80 μm; feed solid concentration 0.02 to 0.1% w/w. Recover liquid (rank 4). *Disk, rotary vacuum:* particle diameter 15 to 500 μm; feed fraction solids 0.02 to 0.70. Free flowing. *Table/pan gravity:* recover liquid (rank 1). Recover wet solid with good washing (rank 1). Recover wet solid with good washing and fragile crystals (rank 1). Particle diameter 40 to 50 μm; feed fraction solids 0.02 to 0.20. Dry solids capacity 280 kg/s. *Table/pan vacuum:* particle diameter 40 to 50 μm; feed fraction solids 0.02 to 0.20. dry solids capacity: 280 kg/s. *Belt, gravity:* recover wet solid with good washing (rank 3). Liquid contamination in exit solids 20 to 30% v/v liquid. *Belt, vacuum:* particle diameter 20 to 70 μm; feed fraction solids 0.05 to 0.6. Dry solids capacity <30 kg/s. *Belt press:* dewater and handle flocculated solids. Rotary press: dewater and handle flocculated solids. Particle size 1 to 50 μm. Feed solids 0.1 to 25% w/w. Related to extruders, Section 16.11.7.7. *Ultrafiltration:* see Section 16.11.4.22. Particle diameter 0.4 to 200 nm; feed solids concentration <20% w/w. *Microfiltration:* see Section 16.11.4.23. Particle diameter 0.05 to 800 μm; feed solids concentration <75% w/w. *Dissolved air flotation, DAF:* see Section 16.11.5.15. Particle diameter 0.1 to 50 μm with typical target diameter 2 μm; feed solid concentration 0.002 to 0.08% w/w; >80% removal efficiency.

Guidelines

General porosity of cake over the usual range of pressure difference for filtration:

0.9: silica, polystyrene; 0.8 to 0.85: talc, zinc sulfide; 0.7: calcium carbonate; 0.6 titanium dioxide, ignition plug; 0.5 kaolin; 0.42 iron carbonyl.

Table 16.36 relates particle diameter to parameters important in filtration.

Batch:
Usually size unit on cycle and based on volume of cake removed. Select required cake volume in batch unit. Two thirds of the cake forms in 1/3 of filtration time: consolidation of the last 1/3 of the cake during the last 2/3 of the filtration time. Typically filtration cycle stops when the filtrate flux is <0.01 L/s·m^2. Cycle: filter, drain, 3 min, fill with wash, 2 min; wash to with volume = five times the cake void volume; air blow; unload, 6 min. *Leaf, pressure vertical:* cycle (for wet cake): filter 2 to 80 h; open, dump, close 0.4 to 4 h; cake volume/unit 0.1 to 2 m^3 corresponding to 5 to 90 m^2 filter area; leaves on 75 mm spacing. Δp 250 to 400 kPa. Cake buildup flux: 0.001 kg/s·m^2.

Precoat: 0.68 kg/m^2 filter. Solid flux for precoat 0.06 to 0.18 kg/s·m^2. Filtrate flux through precoat = 0.1 to 1.1 L/s·m^2. *Leaf, vacuum:* cycle: precoat; filter 0.6 h to 20 h; wash-clean. Cake formation rate 1.3 mm/s; solids flux 0.009 to 0.02 kg/s·m^2 filter area. Cake thickness <10 cm. Area per unit 1.2 to 180 m^2; Δp <80 kPa. Cake volume per unit: 0.1 to 4.5 m^3. Precoat: liquid filtrate flux for pharmaceuticals: 0.0003 to 0.0017 L/s·m^2. *Leaf, horizontal pressure:* cycle: precoat; filter 8 h; wash-clean. Availability per cycle for filtration 65 to 85%. Cake thickness <10 cm; solids flux 0.001 to 0.04 kg/s·m^2 of filter area; filtrate flux: 0.34 to 1 L/s·m^2. Area per unit <280 m^2; Δp 100 to 700 kPa. Cake volume per unit: 0.2 to 4.5 m^3. *Plate, horizontal vacuum:* cycle: precoat, filter, 70 h; wash-clean: 2 to 4 h. Solids flux: 0.003 kg/s·m^2 of filter area; area per unit <6 m^2; Δp <80 kPa. Cake volume per unit: 0.06 m^3. *Plate and frame:* cycle time: feed, wash, unload, clean; filtration: 10 min to 24 h, usually 2 to 8 h; wash 10 to 25 min. Cake formation rate <0.7 mm/s; solids flux 0.02 to 0.07 kg/s·m^2 of filter area; filtrate flux 0.004 to 0.8 L/s·m^2 of filter area. Area per unit <500 m^2; Δp 400 to 1600 kPa. Cake thickness 2.5 to 5 mm. Cake volume per unit: 0.012 to 2 m^3 corresponding to 1 to 160 m^2 filter area for 25-mm plates; 0.024 to 4 m^3 for 50-mm plates. *Diaphragm plate and frame:* cycle: fill, stop when about 80% of the plate has been filled: 0.2 to 0.5 h; squeeze, 0.25 to 0.4 h; discharge, 0.33 to 0.4 h. Postsqueeze volume/presqueeze volume = 0.63 to 0.75. Cake volume 0.003 to 7.8 m^3. Fill at 700 kPa; squeeze at 0.85 to 1.5 mPa. *Deep bed:* cycle: load 8 h; backwash 15 min; 93% availability. Cake formation rate 1×10^{-5} mm/s; solids flux 0.02 to 0.5 g/s·m^2 of filter area; filtrate flux 2.7 to 10 L/s·m^2 of filter area with fluid loading decreasing as solids feed concentration increasing. Area per unit <25 m^2; maximum depth 4.5 m. *Gravity upflow or downflow with single or multiple media;* pressure upflow or downflow. Use pressure units for small to medium fluid capacities where high terminal head loss is expected. Backwash at 6 L/s·m^2; see Section 16.11.7.5. *Cartridge:* cycle: days to months. Cake formation rate <0.000067 mm/s; area per unit 03. to 0.7 and 1.5 to 15 m^2.

Continuous: drum, gravity: cake formation rate >3 mm/s; solids flux 0.15 to 0.47 kg/s·m^2 of effective filter area. Actual filter area 0.7 to 15 m^2. *Drum, rotary vacuum:* cake formation rate 0.01 to 17 mm/s; solids flux 0.008 to 0.16 kg/s·m^2 of submerged filter area; filtrate flux 0.08 to 1 L/s·m^2 of submerged filter area. Total drum area per unit 0.59 m^2; Δp <80 kPa. rpm 0.4 to 1. Variety of options to remove cake: *belt:* submerged 35%. Air required 13 to 22 dm^3/s·m^2. Thickness of cake: >3 to 5 mm. *Roll*: submerged 35%. Air required 13 to 22 dm^3/s·m^2. Thickness of cake: >1 mm. *Standard scraper:* submerged 35%. Air required 13 to 22 dm^3/s·m^2. Thickness of cake: >6 mm. *Coil:* submerged 35%. Air required 13 to 22 dm^3/s·m^2. Thickness of cake: >3 to 5 mm. *String*: submerged 35%. Air required 13 to 22 dm^3/s·m^2. Thickness of cake: >6 mm. Wash ratio 1.5 water/solid. Agitate the feed pan to keep the feed solids in suspension but not interfere with cake formation, solid flux for fine diameter minerals 0.09 kg/s·m^2 of total drum area at pressure drop across the cake = 60 kPa; coarse diameter minerals 0.35 kg/s·m^2 of total area at pressure drop across the cake = 10 to 20 kPa. *Drum, precoat rotary vacuum:* submerged 35, 55, 85%. Usually 85%; air required 28 to 42 dm^3/s·m^2. Thickness of cake: <3 mm. Need low-viscosity liquid. Filtrate flux: 0.004 to 0.07 L/s·m^2. Procedure to form the precoat: use maximum drum speed, gradually increase the submergence from 5 to 85%. *Disk, rotary vacuum:* cake formation rate 0.01 to 1.6 mm/s; solids flux 0.01 to 0.55 kg/s·m^2 of submerged filter area. Total disk area per unit 0.4 to 300 m^2; Δp <80 kPa. Submergence 35%; cake thickness >13 mm. Air/vacuum: 8 to 25 dm^3/s·m^2. *Table/pan gravity:* cake formation rate 0.5 to 16 mm/s; solids flux 0.02 to 0.25 kg/s·m^2. Total table area per unit 8 to 200 m^2; Δp <80 kPa. Cake thickness >20 to 25 mm. Air vacuum needed: 10 to 40 dm^3/s·m^2. *Belt, gravity:* dilute sludges with 0.5 to 8% solids, typically dewater in 20 to 80 s. Length 2.4 m. (Often combined with downstream belt press.) *Belt, vacuum:* solids flux 0.08 to 2.2 kg/s·m^2; filtrate flux 0.038 to 1 L/s·m^2 area: for particles <0.3 mm, 0.08 to 2 L/s·m^2; for particles >0.3 mm, 2 to 12 L/s·m^2. Area per unit 1 to 120 m^2; Δp <80 kPa. Cake thickness 5 to 100 mm, usually 12 mm. Size on the filtrate flux. Vacuum air 25 dm^3/s·m^2. Velocity <0.75 m/s. Wash ratio 1.1 to 1.2 water/solids. Width <3 m; 22 h continuous operation plus 2 h routine maintenance; 1 L/s of sludge/m width. *Belt press:* belt width 0.5 to 2.6 m with areas from 6.9 to 35.7 m^2; belt

speed 0.04 to 0.15 m/s. For feed concentrations <5%, usually liquid dewatering controls: liquid load 2.5 to 3.5 L/s·m of belt width. For feed concentrations >5% solids throughput limiting: 0.15 to 0.275 kg/s·m of belt width. Δp <80 kPa. *Rotary press:* <3 rpm; dewatering area: 1.25 to 5 m^2. Solids flux 0.003 to 0.127 kg/s·m^2, depending on the feed solids concentration in range 0.1 to 6% solids. Product 20 to 75% solids. See also Section 16.11.7.7. *Ultrafiltration:* see Section 16.11.4.22. *Microfiltration:* see Section 16.11.4. *Dissolved air flotation (DAF):* see Section 16.11.5.15.

16.11.5.14 Leacher

Area of Application

Percolation leach: particle diameter >700 µm; liquid concentration 0.8 to 20%; relatively fragile solid (e.g., seeds). *Immersion leach:* particle diameter <700 µm; liquid concentration <20%; relatively robust solids (e.g., minerals). *Combo leach:* high feed concentration of solute, relatively robust solid. *Supercritical solvent:* usually CO_2 for small capacity of high value products, especially for temperature sensitive foods, cosmetics, and pharmaceuticals.

Guidelines

Percolation leach: high solute leach rate; solvent percolation through the bed >3 mm/s; 3 to 10 L/s·m^2; bed permeability >200 µm^2; low feed concentration of solute; 0.5 to 0.7 kg liquid solvent carryover from stage to stage/kg inert solid; solute diffusivities of essential oils 10^{-7} to 10^{-14} cm^2/s; of sugar in sugar beets 10^{-5} cm^2/s. Tend to use series of countercurrent contactors with time for diffusion and separation in each stage. *Rotating cells/baskets: capacity:* 30 kg/s flaked soybeans in 10-m diameter unit; prepressed cottonseed × 0.66; unpressed cottonseed × 0.33; sugar cane × 0.33; canola × 0.33. *Buckets:* 10 kg/s flaked soybeans with 40 buckets. *Belt:* 10 kg/s flaked soybeans with belt 20 m long; 2 to 5 kg solvent makeup/Mg oil seed feed. *Drag chain:* 10 kg/s flaked soybeans with belt 20 m long.

Immersion leach: low solute leach rate. Product of residence time × concentration of leachant for acid leach = constant for a given particles diameter. Tends to have a separate leacher followed by system to separate and wash solids. *Pachuca:* plus CCD, settler; particle diameter <70 µm; solids 30 to 60% w/w; agitator 0.07 to 0.2 kW/m^3; for CCD 1.5 to 2 kg liquid solvent carryover/kg inert solid. *Autoclaves:* plus CCD: particle diameter <70 µm; solids 30 to 60% w/w; 0.7 to 1.3 kW/m^3.

Combo leach: tend to use countercurrent contactors with time for diffusion and separation in each stage. *Sloped diffuser with rotating screw:* 10 kg/s sugar beets in 2 m diameter. *Tower with rotating screw:* 10 kg/s sugar beets in 0.3-m diameter unit. *Trough-scroll:* 10 kg/s sugar beets in three troughs. *Rotary diffuser:* 10 kg/s sugar beets in 5-m dia. unit.

Supercritical solvents: batch process operating at $T > 31°C$ and pressures >7.3 MPa. Solvency is intermediate between nonpolar and weakly polar solvents. Contact times 0.1 × usual leach times.

16.11.5.15 Liquid-Solid: Dissolved Air Flotation, DAF

Area of Application

Particle diameter 0.1 to 50 µm with typical target diameter 2 µm; feed solid concentration 0.002 to 0.08% w/w; >80% removal efficiency.

Guidelines

Bubble size 70 to 90 µm; air: solids 0.005 to 0.1 kg/kg; liquid loading 0.5 to 2 L/s·m^2. Liquid residence time 20 to 200 min with a minimum depth of 1.8 m. If feed concentration is <400 mg/L, use about 50% recycle.

16.11.5.16 Liquid-Solid: Expeller and Hydraulic Press

Area of Application

Particle diameter >1 cm; liquid concentration 10 to 60%.

Guidelines

Batch: hydraulic press: 30 to 60 MPa. Cycle: load, press, discharge.

Continuous: expeller: *expelling essential oils:* prepress capacity 0.02 to 5 kg/s; prepress capacity (which will be followed by leaching, Section 16.11.5.14) = 2 × full press capacity (where only expelling is used to remove the essential oils); prepressing 2.2 Mg/d cottonseed/rpm; relative capacities depend on seed being processed: cottonseed and soybean × 1; copra, wet corn germ, canola × 0.75 to 0.82; flax seed, safflower × 0.62; power 100 to 200 kJ/kg cottonseed prepress with the value increasing with feed capacity.

D*ewatering polymers:* capacity 1 to 1.5 kg/s; power 200 increasing to 450 kJ/kg as capacity increases. Related topics are dryer (Section 16.11.5.5), screens (Section 16.11.5.6), and centrifugal filters (Section 16.11.5.12).

16.11.5.17 Solid-Solid: General Selection

To separate solids having about the same density and particle size, use flotation, electrostatic and magnetic separators. Particle diameter must be >20 μm. To separate solids having about the same density but with a range of particle size, separate based on cut diameter and use air or liquid *classifiers* such as cyclones, hydrocyclones, or spiral classifiers. Particle size 25 to 2000 μm; feed solids concentration 5 to 40%. Cut diameter is the particle diameter that has equal chance to report to either the overflow or the underflow streams. To separate solids having about the same particle size but a different density, separate based on cut density and use *concentrators* such as jigs, tables, sluices, or dense media separators (DMS). Particle diameter must be >40 μm. Concentrate before flotation if the feed assay of mineral is <0.3%. To separate solids having different densities and particles sizes, use combinations, such as a screen, to provide narrow size range followed by concentrators. For minerals, the liberation size is 0.01 of the diameter of the mineral crystal.

16.11.5.18 Froth Flotation

Area of Application

For systems with a narrow range of both density differences and particle sizes. Density ratio 1 to 1.3; particle diameter usually 20 to 50 μm, although occasionally the diameter could be as large as 200 μm. Feed concentration of target solid >0.5%.

Guidelines

Condition the solids to alter the wettability of the mineral and the gangue. The fundamental surface wettability for sulfide ores is different from oxides, silicates, and salt-type minerals. pH is a critical variable. Typical conditioning chemical additions include collector about 0.01 to 0.1 kg/Mg solids; frother about 0.01 to 0.5 kg/Mg solids; activator about 1 to 4 kg/Mg solids; depressant about 0.02 to 2 kg/Mg solids. Allow 6-min contact for conditioning. Bubble size about 1000 μm. Flotation rate constant is 0.2 to 1 min^{-1}; sink rate constant is 0.005 min^{-1}. Flotation cells: *mechanical cell:* for fast float, sequential separation, and relatively coarse particle diameter; 1.6 to 2.4 kW/m^3 cell volume. *Pneumatic cell:* for relatively dilute feed concentrations and smaller particle diameters. Air blower 0.5 kW/m^3 cell volume. Typical solids throughput 0.4 to 0.8 $kg/s{\cdot}m^3$; feed concentration 10 to 40% w/w. Air escape velocity 0.02 m/s. Float times 6 to 20 min. Feed concentration to rougher or scavenger: 30% w/w; to cleaner: 10% w/w.

16.11.5.19 Electrostatic

Area of Application

For systems with dry particles, no slimes or organic coatings, a narrow range of both density differences and particle sizes, and a difference in conductivity. Particle diameter 40 to 3,000 μm: usually 80 to 1000 μm; feed concentration of target species 5 to 75%. Good conductors have relative permittivity >11; poor or nonconductors have relative permittivity <10; threshold voltage to make species conducting is 1 to 10 kV/cm.

Guidelines

Select voltage where one species conducts and the other does not. *Corona-active electrode rotary drum:* handles wide range of particle diameters from 75 to 1000 μm; high capacity, <0.75 kg/s·m of drum width; high efficiency 95%; separates good from poor conductors. Zero to 40 kV DC, 0.5 to 1 mA/electrode; insensitive to humidity and temperature; often can recycle the middlings with recycling 10 to 30% OK. *Active electrode rotary drum:* trouble handling fines; capacity <0.5 kg/s·m of drum width, moderate efficiency; separates good from poor conductors or two semiconductors. Zero to 30 kV DC, 0.04 mA/electrode. The voltage gradient must be sufficient to charge target particles, operates best in a controlled environment.

For roughers and scavengers, set the active polarity so that the valuable minerals become conductors. For cleaners and recleaners, set the active polarity so that the gangue and middlings become the conductors. Collect middlings if the valuable target is trapped in the gangue; if the density of the nonconducting is heavier than the conducting and if the feed has a wide range of particle diameters.

16.11.5.20 Magnetic

Area of Application

For systems with a narrow range of both density differences and particle sizes; particle diameter >50 μm; feed concentration of target species 0.4 to 40%. Magnetization = product of the mass magnetic susceptibility and the magnetic field, T m^3/kg. Ferromagnetic species: magnetization >10^{-4} T m^3 kg. Paramagnetic species: magnetization 10^{-8} < value < 10^{-5} T m^3/kg.

Batch: cycle: load, clean. *Plate:* batch: magnetization >10^{-4} T m^3/kg; particle diameter >6 mm; feed concentration of magnetic <0.01% w/w. Primarily to remove tramp ferrous metal. *Grate:* batch: magnetization >10^{-4} T m^3/kg; particle diameter <1.8 mm; feed concentration of magnetic <0.01% w/w. Primarily to remove tramp ferrous metal. *WHGMS (wire, Kolm–Marston):* batch: magnetization >2×10^{-9} T m^3/kg; particle diameter 1 to 30 μm; feed concentration of magnetic <0.05% w/w. Solids concentration in water 20%. *WHGMS (grooves, Jones):* batch: magnetization >2×10^{-9} T m^3/kg; particle diameter 200 to 1000 μm; feed concentration of magnetic <50% w/w; solids concentration in water <50%.

Continuous: pulley: magnetization >10^{-4} T m^3/kg; particle diameter >6 mm; feed concentration of magnetic <0.01% w/w. Primarily to remove tramp ferrous metal. *Belts/cross or inline:* magnetization >10^{-4} T m^3/kg; particle diameter >6 mm; feed concentration of magnetic 0.01 to 10% w/w. Primarily to remove tramp ferrous metal. *Belts/cross HGMS;* magnetization >10^{-4} T m^3/kg; particle diameter 150 to 1500 μm; feed concentration of magnetic 0.5 to 2% w/w. Primarily to remove tramp ferrous metal. *Wet belt:* magnetization >10^{-4} T m^3/kg; particle diameter 100 to 2500 μm; feed concentration of magnetic 0.3 to 2% w/w. *Dry drum/LGMS:* magnetization >2×10^{-5} T m^3/kg; particle diameter 0.1 to 100 mm; feed concentration of magnetic 1.5 to 75% w/w. *Dry drum high-speed/MGMS:* magnetization >2×10^{-5} T m^3/kg; particle diameter 100 μm to 30 mm; feed concentration of magnetic <10% w/w. *Dry rotor HGMS (induction):* magnetization >4×10^{-8} T m^3/kg; particle diameter 70 to 2000 μm; feed concentration of magnetic <0.05 w/w. *Wet drum/LGMS:* magnetization >10^{-4} T m^3/kg; particle diameter 70 μm to 6 mm; feed concentration of magnetic

>25% w/w. *WHGMS (carousel, BoxMag, Frantz):* magnetization >2 × 10^{-9} T m^3/kg; particle diameter 200 to 1000 μm; feed concentration of magnetic <50% w/w; solids concentration in water <50%.

Guidelines

Consider wet processing for particle diameter <6 mm to minimize dusting and electrostatics. For particle diameter >150 μm, prefer wet belt; <150 μm, prefer wet drum. Match magnetic gradient to the diameters of the particles. Match the machine to the liberation size (liberation size is 0.01 of the diameter of the mineral crystal). For wet machines, pump 4 Mg water/Mg solids, although 90% of the water can be recirculated.

Batch: plate: batch, remove tramp metal from solids moving in ducts or on conveying belt. Usually keep burden depth <20 cm; magnetic filed 0.3 T; gradient 0.04 T/cm. *Grate:* batch, magnetic field 0.05 T; gradient 0.02 to 0.5 T/cm. *WHGMS (wires, Kolm–Marsden):* batch; 100-μm wires; 10 to 80 kg/s per pole; 10 to 160 L/s·m^2 gap *cross-sectional* area; solids concentration in water 20 to 25% w/w; induced magnetic field 1 to 2 T; gradient 1000 T/cm; 35 to 42 kW/pole; 1 to 18 kJ/kg solids for magnet and 4.5 kJ/kg pumping; solids loading before unload 0.1 to 0.5 Mg/m^3 of matrix. *WHGMS (grooves):* batch, 0.03 to 0.04 kg/s; 8 to 12 kg/s per pole; solids in water <40% w/w; induced magnetic field 1 to 2 T; gradient 0.1 to 1000 T/cm, usually 10 to 200 T/cm; 16 kW/pole; 1.8 kJ/kg solids collected for magnet; feed <50%w/w solids in water.

Continuous: pulley: remove tramp metal from solids exiting from a conveyor belt. Usually keep burden depth <20 cm; magnetic field 0.1 to 0.3; gradient 0.04 T/cm. *Belts/cross or inline:* <1 kg/s·m width; gradient 0.1 to 1 T/cm; belt speed 1 to 2 m/s. *Belt with rotating disk:* 0.2 kg/s·m width; magnetic field 0.04 to 0.1 T; gradient 0.1 to 1000 T/cm. *Wet belt:* 3 kg/s·m width; magnetic field 0.3 T; gradient 0.1 to 1 T/cm. *Dry drum/LGMS:* 80 to 200 kg/s·m width of drum, 60 to 90 dm^3/s·m width for drum diameter <1.2 m; 25 to 35 rpm, peripheral speed 1 to 1.5 m/s; magnetic field 0.04 to 0.1 T; gradient 0.001 to 0.5 T/cm; drive power 2 to 5 kW/m width. *Dry drum high-speed/MGMS:* 0.5 to 20 kg/s·m width, 0.8 to 20 dm^3/s·m width with capacity decreasing as magnetization decreasing; 2.5 to 7 m/s with peripheral speed increasing as the number of poles increases from 6 to 44; 50 to 200 rpm; as particle diameter decreases, the number of poles and the rpm increase; for highest recovery, operate at lower rpm; for higher incoming concentration of mags and more efficient recovery of middlings, operate at higher speeds; magnetic field 0.04 to 0.1 T; gradient 0.001 to 0.5 T/cm; drive power 10 kW/m width. *Dry rotor HGMS (induction):* 0.8 to 1 kg/s·m width; induced magnetic field 1 to 2 T; gradient 0.001 to 1000 T/cm, usually 10 T/cm. *Wet drum/LGMS:* 1 to 5 kg/s·m width; 4 to 25 L/s·m width; water velocity 0.5 m/s; drum peripheral speed 2 m/s; 20 rpm; diameter 0.75 m; magnetic field 0.04 to 0.1 T; gradient 0.001 to 0.5 T/cm; constraint is the amount of magnetic material discharged from the drum; feed <25% w/w solids in water; drive power 1 to 2 kW/m width. *WHGMS (carousel, BoxMag, Frantz):* continuous 1 to 5 kg/s pole, 10 to 50 L/s·m^2 gap cross-sectional area; usual canister cross-sectional area 0.5 to 3 m^2; induced magnetic field 0.1 to 2 T; 1 to 6 MJ/Mg solids collected; feed solids concentration in water 30 to 50%.

16.11.5.21 Hydrocyclones

See Sections 16.11.5.3 and 16.11.5.8, separation of liquid-solid, for guidelines.

Area of Application

Cut diameter 5 to 1000 μm; capacities up to 50 kg/s per unit.

16.11.5.22 Air Classifiers

Area of Application

Separate solids with similar densities based on cut diameter. Conveying fluid is a gas such as air. Contrast with hydrocylcones and spiral classifiers, where the conveying fluid is a liquid such as

water. Particle cut diameter 30 to 1000 μm. Particle diameter >1.5 μm. Feed concentration of target solid 4 to 60% w/w.

Guidelines

Solids-to-gas ratio 2 to 8 w/w. Solids loading 2 to 4 kg/s·m^2. *Zigzag:* cut diameter 100 to 10,000 μm; capacity 0.01 to 0.08 kg/s. *Gas centrifugal separator:* cut diameter >20 μm; capacity <15 kg/s. *Gas cyclone:* cut diameter 10 to 50 μm; capacity <15 kg/s. *Gas gravitational inertial classifier (GIC):* cut diameter 50 to 200 μm; capacity <300 kg/s. *Gas Mikroplex spiral:* cut diameter 2 to 20 μm; capacity 0.01 to 1 kg/s. *Gas Nauta–Kosakawa:* cut diameter 3 to 300 μm; capacity 0.01 to 1 kg/s. *Gas classifiers for MSW:* cut diameter >100 μm with capacities up to 20 kg/s.

16.11.5.23 Rake Classifiers

Superceded by hydrocyclones (Sections 16.11.5.21 and 16.11.5.8).

16.11.5.24 Spiral Classifiers

Area of Application

Bird number (mass of solids with a ±0.1 density variation from the cut density) <15; particle cut diameter >50 μm but usually 1000 to 20,000 μm.

Guidelines

Two types: cut diameter >200 μm, use *high weir configuration;* cut diameter <200 μm, use *submerged spiral.* Size based on the target exit overflow concentration and "limiting" particle diameter. Diameter of the limiting particle should have a settling velocity double that of the cut diameter (cut diameter is about 70% of the limiting diameter). Separation efficiency is 50%; that is, use double the cross-section area obtained from the settling velocity of the "limiting" particle diameter. Capacity 2 to 250 kg/s. Underflow solids capacity is a function of the spiral diameter and solids density; independent of the separation. Angle of inclination 16°.

High weir: 1 m^2 pool area produces about 5 kg/s dry solids in the overflow with 400 μm limiting diameter or about 280 μm cut diameter and 30% concentration. *Submerged weir:* 1 m^2 pool area produces about 0.5 kg/s dry solids in the overflow with 150 μm limiting diameter or about 100 μm cut diameter and 16% concentration. For both configurations, increase the area by a factor of 10, increase the amount of overflow solids by 10 with the same cut and limiting diameters and overflow concentrations. Rotational speed increases with the cut diameter.

16.11.5.25 Jig Concentrators

Area of Application

Bird no. (mass of solids with a ±0.1 density variation from the cut density) <15; relative density ratio 2 to 2.5 and particle diameter 2 to 10 mm. Feed concentration 1.5 to 30% w/w.

Guidelines

Loading 1 to 8 kg/s·m^2 with loading increasing with increase in particle diameter. Power 1 kW/m^2 and water usage 13 L/s·m^2.

16.11.5.26 Table Concentrators

Area of Application

Bird number (mass of solids with a ±0.1 density variation from the cut density) <15; relative density ratio >2 to 2.5; usual particle diameter 70 to 2000 μm; only one valuable mineral. *Tilting frames:*

density ratio 2.5 and particle diameter >50 μm ranging to density ratio of 1.25 with particle diameter >5 mm. *Holman slimes table* for <70 μm.

Guidelines

Seven to 12 m^2 per unit; 6° incline; usual capacity 0.03 to 0.06 kg/s·m^2. The higher the Bird no., the lower the capacity. Power 0.15 kW/m^2; wash water 0.1 to 0.3 L/s·m^2.

16.11.5.27 Sluice Concentrators

Area of Application

Bird number (mass of solids with a ±0.1 density variation from the cut density) <15; relative density ratio >1.8; usual particle diameter 400 to 3000 μm; only one valuable mineral.

Guidelines

Humphreys and Reichert spiral: capacity/unit: 0.25 to 1.5 kg/s to handle particle diameters 75 μm to 2 mm.

16.11.5.28 Dense Media Concentrators (DMS)

Area of Application

This is for systems with a narrow range of particle sizes but with a range in densities. Bird number (mass of solids with a ±0.1 density variation from the cut density) 15 > Bi > 25; relative density ratio >1.25 to 1.5; usual particle diameter >10 mm.

Guidelines

Choose media with density between desired cuts. For media with density 1.2 to 2.2, use magnetite; for 2.9 to 3.4, use ferrosilicon. Use mixtures for intermediate densities; 2.5 to 15 kg/s·m^2 of pool area.

16.11.5.29 Screens

See also Section 16.11.5.6 for liquid-solid separation.

Screens can be used to wash or dewater (see Section 16.11.5.6); *scalp:* remove 5% of oversize and have >50% half size; *screen:* remove fines <425 μm; *size or separate:* choice depends on particle size: coarse >4.75 mm; intermediate size between 425 and 4750 μm, and fines between 45 and 425 μm. See filters, Section 16.11.5.13; centrifugal filters, Section 16.11.5.12; and expellers, Section 16.11.5.16.

Area of Application

Grizzly: particle diameter 15 to 30 cm and >30 cm; Use: primarily to scalp, screen fines. *Rod grizzly:* particle diameter 8 to 30 cm. Use: primarily to scalp. Rod deck screen: particle diameter 0.75 to 8 cm. Use: scalp, dewater, and separate. *Sieve bend:* particle diameter: 45 to 2000 μm. Use: dewater, separate intermediate and fines: 45 to 4750 μm. *Revolving screen, Trommel:* particle diameter 3 mm to 50 cm; feed solids concentration 5 to 25%. Use: separation. *Revolving screen, centrifugal:* particle diameter: 400 to 1200 μm, Use: dewater, separate intermediate diameters, and use high speed for fines. *Revolving screen, probability:* particle diameter <6 mm. Use: separate intermediate and fines 45 to 4750 μm. *High-speed vibrating horizontal screen* (600 to 3000 rpm with low amplitude <2.5 cm): 3 to 100 mm. Use for dense granular materials >0.3 Mg/m^3. Use to wash, dewater, scalp, screen fines, separate coarse. *High-speed vibrating inclined screen* (600 to 7000 rpm with low amplitude <2.5 cm): 200 to 100,000 μm. Use for dense granular >0.3 Mg/m^3. Use to wash, scalp, and separate wide range of particle diameters. *Low-speed oscillating screen* (25 to 500 rpm with 15 to 30 mm amplitude): 74 to 12,000 μm, especially for lower density solids, although some suppliers recommend this for only >12,000 μm. Use to separate. *Gyratory in the plane of the screen* (500 to 600 rpm; 5° inclination): fine separations particle diameter 50 to 4000 μm.

Guidelines

Screen: efficiency 85 to 95%; length/width of screen 2:1 to 1.5:1; rate of travel of solids along the screen face 0.3 to 0.5 m/s. The flux of solids passing through the screen is about: for coarse particle diameters, 2 to 5 kg/s·m^2; for intermediate particle diameters, 0.4 to 4 kg/s·m^2; for fine particle diameters, 0.08 to 0.4 kg/s·m^2, with fluxes decreasing as the density decreases.

Trommels: rotational speed should be slow enough that the particles free fall (about 45% of the transition rpm). L/D 2:1 to 5:1; residence time 30 to 60 s with flux rates of 0.03 to 0.1 kg/s·m^2.

16.11.6 Reactors and Vessels*

Reactors are considered in Sections 16.11.6.1 through 16.11.6.33; vessels are discussed in Sections 16.11.6.34 and 16.11.6.35. For most process equipment, equipment is sized based on the optimization criterion of cost. For reactors, the optimization criterion may be selectivity, yield, flexibility, ability to control, or cost. Section 16.11.6.1 lists the general rules of thumb. Section 16.11.6.2 gives examples of the reactor type based on the type of reaction. Sections 16.11.6.3 onward give rules of thumb organized by reactor type.

Symbols: adiabatic factor = adiabatic temperature change accompanying complete consumption of the reactant without regard to equilibrium considerations; *Bd*: = Bodenstein number; **D** = diffusivity; *D* = tube diameter; D_p = particle or catalyst diameter; *Eo* = Eotvos number; *GL* = gas-liquid; *GS* = gas-solid; *GLcS* = gas-liquid reaction with solid catalyst; *GrS* = gas reacting with a solid; *H* = height; *Ha* = Hatta number; heat generation potential = reaction activation energy/RT_{inlet}^2; *L* = length of tubes; *Nu* = Nusselt number; OD = outside diameter; *Pe* = Peclet number; *R* = ideal gas law constant. *RTD* = residence time distribution; *Re* = Reynolds number; *T* = temperature; and β = volume of liquid in the reactor/volume of mass transfer liquid "film" in the reactor.

16.11.6.1 General Rules of Thumb

1. The rate of reaction doubles for a temperature increase of 10°C.
2. Prefer continuous to semicontinuous to batch.
3. Prefer PFTR to CSTR.
4. Prefer minimum inventory in reactor by providing better mixing, increased temperature or pressure, or changing the catalyst.
5. Prefer internally heated/cooled to externally heated/cooled.
6. Consider light and ultrasound as optional forms of energy.
7. For gas reactions, usually use plug flow tubular reactors (PFTRs), static mixers, or fluidized beds.
8. For gas fixed-bed catalytic reactions, use $L/D_p > 100$ and $D_p/D < 0.10$ to ensure good gas distribution and negligible back mixing.
9. For liquid reactions, usually use continuous stirred tank reactors (CSTRs) (unless the pressure is very high), static mixers.
10. Prefer operating temperatures below the boiling temperature or dilute the liquid with a safe solvent.
11. For gas-liquid reactions, usually use CSTR or bubble column.
12. For reactions using solid catalysts: although many of the reactors described below are classed as "continuous," whenever a solid catalyst is used, the performance of the catalyst decays over time. The catalyst needs to be regenerated or replaced periodically. Time

* Reproduced with permission from Donald R. Woods, *Rules of Thumb in Engineering Practice,* pages 196, 225 to 278, 2007, copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, ISBN: 978-3-527-31220-7. See this book for more details, especially about Good Practice, Trouble shooting and Capital Costs.

for reaction between regeneration is usually years. If the catalyst decays rapidly, consider fluidized- or moving-bed operation. Regeneration options include combustion, alternate oxidation and reduction, high-temperature operation. *Catalyst life:* some illustrative life: iron, nickel, palladium promoted catalysts for the production of ammonia or sulfuric acid, the life years are 5 to 10, with the cause of decay being slow sintering. Copper on zinc and aluminum oxides catalysts for methanol synthesis, the life years are 2 to 4, with the cause of decay being slow sintering. Nickel on alumina catalysts for steam reforming, the life years are 2 to 4, with the cause of decay being sintering and carbon formation. Silver on alumina catalyst for ethylene production, life years are 1 to 4, with decay caused by sintering. Silver granule catalyst for the partial oxidation of methanol, the life years are 0.3 to 1, with decay caused by poisoning. Platinum catalyst for catalytic reforming, the life years are 0.01 to 0.5, with coking causing the decay. Zeolite catalyst for catalytic cracking, the life years are 10^{-5}, with decay caused by coking.

13. Prefer monolithic configuration for intensification with surface area/volume usually 1.5 to 4 times greater than traditional pellets. Excellent for mass transfer controlled reactions.
14. For gas reacting with solid: usually heat transfer controlled, because these are highly exothermic or endothermic reactions. Particle size and size distribution are critical. These reactions may follow different patterns:
    a. For multigranule reactions, the time for reaction is independent of particle diameter.
    b. For shrinking core without ash reactions, the time for reaction = particle diameter (for reaction controlled); = $\mathbf{D}^{1.5}$ (for fluid diffusion controlled with fluidized, fixed, or moving beds); = $\mathbf{D}^2$ (for fluid diffusion controlled with transported bed).
    c. For shrinking core plus ash, the time for reaction = D_p (for reaction controlled); = D_p (for fluid diffusion controlled); = D_p^2 (for fluid diffusion through the ash controlled).
15. For biological treatment of wastewater, $BOD_u \approx 1.43 \times BOD_5$; approximately 1.4 to 1.5 kg O_2/kg BOD_5. Microorganisms use the organic substrate, characterized by BOD_5 or COD, for growth and for endogenous respiration. Illustrative reaction rate terms include, for COD at 20°C: substrate concentration at which the specific growth rate is 0.5 maximum, K_s = 25 to 100 mg COD/L. Maximum specific utilization rate of the substrate, k = 6 to 8 kg COD/day·kg VSS. Biomass lost to endogenous respiration per unit time per unit biomass, K_d = 0.05 to 0.1 1/day. Yield of biomass produced per unit of substrate removed, Y_T = 0.35 to 0.45 mg VSS/mg COD.

16.11.6.2 Reaction Types and Typical Reactor Configurations

Below are listed typical reactions and the usual reactor configurations used. *Alkylation* C-C: LL series CSTR; *animation* by ammonolysis: GL trickle bed; *combustion (incineration): burning in presence of oxygen of liquids and solids:* fluidized bed backmix. *Cracking, steam:* PFTR; *esterification:* carboxylic acid plus alcohol (cat: acid catalyst, usually sulfuric acid): usually CSTR. *Fermentation:* batch. *Halogenation:* addition of halogen: multiphase usually CSTR. *Hydration:* trickle bed. *Hydroformylation:* addition of hydrogen and –CHO to the double bond of an olefin with subsequent reaction of CO + H2 in the presence of cobalt catalyst (OXO synthesis): usually CSTR. *Hydrogenation:* addition of hydrogen: for multiphase: usually semibatch STR or CSTR (series of CSTR). *Hydrolysis* (hydration): usually CSTR. *Nitration:* usually CSTR. *Oxidation:* GL trickle. *Polymerization:* batch, semibatch, CSTR, and multistage CSTR. *Sulfonation* of aromatic by oleum, batch.

16.11.6.3 PFTR: Empty Tube

Bodenstein number = ∞. Peclet number > 100. Usually controlled by reaction kinetics, heat transfer, or both.

Area of Application

Phases: gas, liquid, gas-liquid, liquid-liquid. Use if the order of the reaction is positive and >95% conversion is the target, and for consecutive reactions with an intermediate as the target product. *Gas* (or gas with homogeneous catalyst): residence time: 0.4 to 2000 s; heat of reaction: endothermic; reaction rate, fast; capacity: 0.001 to 200 L/s; good selectivity for: consecutive reactions and irreversible first order; volume of reactor 1 to 10,000 L; OK for high pressures. For temperatures <500°C. *Liquid* (or liquid with homogeneous catalyst): residence time: 0.4 to 2000 s; heat of reaction: endothermic; reaction rate, fast or slow; capacity: 0.001 to 200 L/s; good selectivity for consecutive reactions; volume of reactor 1 to 10,000 L; OK for high pressures. *Gas-liquid:* residence time: short; heat of reaction: primarily for endothermic reactions. Beware of highly exothermic reactions because of inability to control temperature; good selectivity for consecutive reactions in which the product formed can react further. See transfer line, Section 16.11.6.9, or bubble reactors, Section 16.11.6.11. *Liquid-liquid:* see transfer line, Section 16.11.6.9, or bubble reactors, Section 16.11.6.11.

Guidelines

Gas: residence time 0.5 to 1.3 s; gas velocity 3 to 10 m/s; Re > 10^4, L/D > 100. To eliminate backmixing, Pe > 100. *Liquid:* residence time 1 to 6 s; liquid velocity 1 to 2 m/s; Re > 10^4, L/D > 100. PFTR is smaller and less expensive than CSTR. PFTR is more efficient/volume than CSTR if the reaction order is positive with simple kinetics. For fast reactions, use small-diameter empty tube in turbulent flow. For slow reactions, use large-diameter empty tubes in laminar flow. If reaction is complex and a spread in RTD is harmful, consider adding motionless mixer (Section 16.11.6.10). *Examples: hydrolysis of corn starch to dextrose; polymerization of styrene; hydrolysis of chlorobenzene to phenol; esterification of lactic acid. Gas-liquid:* see transfer line, Section 16.11.6.9, or bubble reactors, Section 16.11.6.11. *Liquid-liquid:* see transfer line, Section 16.11.6.9, or bubble reactors, Section 16.11.6.11.

16.11.6.4 PFTR: Fire Tube

For temperatures >500°C, put tubes in furnace. Same area of application, guidelines, and good practice as empty tube, Section 16.11.6.3. Radiant heat flux in furnaces 30 to 80 kW/m^2. Reformers:

Gas oil: heat flux: 40 to 50 kW/m^2; fluid velocity inside tubes 1.5 to 2.5 m/s
Light oil: heat flux: 25 to 40 kW/m^2; fluid velocity inside tubes 1.4 to 2.3 m/s
Heavy oil: heat flux: 25 to 35 k.W/m^2; fluid velocity inside tubes 1.7 to 2.1 m/s

Cracking: ethylene as product from

Ethane: heat flux: 23 to 28 kW/m^2 at exit conditions with double values at inlet
Propane: heat flux: 14 to 17 kW/m^2 at exit conditions with double values at inlet
Butane or naphtha: heat flux: 11 to 15 kW/m^2 at exit conditions; at inlet the values are twice as large.

See thermal energy: furnaces, Section 16.11.3.2.

16.11.6.5 PFTR: Fixed-Bed Catalyst in Tube or Vessel: Adiabatic

Area of Application

Phases: gas, liquid, gas-liquid. Use if the order of the reaction is positive and >95% conversion is the target, and for consecutive reactions with an intermediate as the target product. *Gas or Liquid with fixed bed of solid catalyst:* residence time: 0.4 to 2000 s; heat of reaction: endothermic;

reaction rate, fast; capacity: 0.001 to 200 L/s; good selectivity and activity for: consecutive reactions and for irreversible first-order reactions; volume of reactor 1 to 10,000 L; OK for high pressures. High conversion efficiency, simple, flexible, gives high ratio of catalyst to reactants. *Gas-liquid downflow over fixed catalyst:* see trickle reactors, Section 16.11.6.15, or bubble reactors, Section 16.11.6.11.

Guidelines

Catalyst diameter 1 to 5 mm. *Gas with fixed catalyst bed:* residence time <1 s; favored if the life of the catalyst is >3 months; select fluidized (Section 16.11.6.27) or slurry reactors (Section 16.11.6.9) if the catalyst deactivates rapidly. Catalyst must have an axial crush strength >50 to 80 kg/cm^2. To ensure good gas distribution and negligible backmixing, $Pe > 2$; length/catalyst particle diameter $L/D_p > 100$ and $D_p/D < 0.10$. Usually, bed volume porosity 0.42, which decreases to 0.38 as the bed ages. PFTR lesser volume than slurry or fluidized-bed reactors. If the main reactant undergoes 90% conversion within a reactor length of bed height/catalyst particle diameter = 100, then the reaction is not mass transfer–controlled. Select a bed height such that the height of the bed/mass flow velocity ($kg/s \cdot m^2$) is >0.5 $m^3 \cdot s/kg$ fluid. Δp is <1 to 10% of total pressure; if too high, then use larger catalyst or change catalyst. For adiabatic operation with exothermic reactions, limit the height of the bed to keep temperature increase <50°C. Tube diameter <50 mm to minimize extremes in radial temperature gradient. For fast reactions, catalyst pore diffusion mass transfer may control if the catalyst diameter is >1.5 mm. Temperature gradients within the catalyst and in the external bulk phase:

1. Within a catalyst pellet the internal temperature gradient is rarely >1 to 2°C between the surface and the center. Assume temperature at the center of the catalyst = surface temperature.
2. The external temperature gradient is usually high, with the catalyst surface temperature possibly being 10 to 30°C hotter than the temperature in the gas phase.

Concentration gradients within the catalyst and in the bulk phase:

3. Within the catalyst pellet, the internal concentration gradient is often very high (with 0 concentration at the center).
4. External concentration gradient is usually small except for very fast reactions.

A related topic is gas adsorption (Section 16.11.4.11).

Liquids with fixed catalyst bed: to minimize backmixing, $Pe > 1$; use $H/D_p > 200$ and $D_p/D < 0.10$. Temperature gradient within the catalyst and in the external bulk phase:

1. Within the catalyst, the internal temperature gradient is low. Assume the temperature at the center of the catalyst = surface temperature.
2. The external temperature gradient from the catalyst surface temperature to the bulk is low.

Concentration gradient within the catalyst and in the external bulk liquid phase:

3. Internal concentration gradient depends on the reaction.
4. External concentration gradient may be high because of slow mass transfer or fast reaction.

For IX resin, height/vesel = 0.5. If the main reactant undergoes 90% conversion with the bed height/catalyst particle diameter = 10,000, then the reaction is not mass transfer–controlled. Since this height/diameter ratio is usually achieved, check if mass transfer controls.
A related topic liquid is adsorption (Section 16.11.4.12).

Gas-liquid downflow over fixed catalyst: see trickle reactors, Section 16.11.6.15.

16.11.6.6 PFTR: Multitube Fixed-Bed Catalyst: Nonadiabatic

Area of Application

Phase: gas, liquid. Use if the order of the reaction is positive and >95% conversion is the target, and for consecutive reactions with an intermediate as the target product. Exchange heat generated if the product of the adiabatic factor × heat generation potential >10.

Guidelines

Shell-and-tube exchanger with reactants and catalyst inside the tubes, 250 to 400 m^2/m^3. Tube diameter <50 mm. *Gas* with fixed bed of catalyst: use high mass gas velocity to improve heat transfer kg/s·m^2 > 1.35. To ensure good gas distribution and negligible backmixing, $Pe > 2$; height/catalyst particle diameter $H/D_p > 100$ and $D_p/D < 0.10$. Gas velocity 3 to 10 m/s; residence time 0.6 to 2 s. Heat transfer coefficient $U = 0.05$ kW/m^2·K. For fast reactions, catalyst pore diffusion mass transfer may control if catalyst diameter is >1.5 mm. *Liquids* with fixed bed of catalyst: to minimize backmixing, $Pe > 1$; use $L/D_p > 200$ and $D_p/D < 0.10$. Liquid velocity 1 to 2 m/s; residence time 2 to 6 s. Heat transfer coefficient $U = 0.5$ kW/m^2·K.

16.11.6.7 PFTR: Multibed Adiabatic with Interbed Quench

Area of Application

Phase: gas. For fast reactions that are strongly exothermic or endothermic. Use if the order of the reaction is positive and >95% conversion is the target, and for consecutive reactions with an intermediate as the target product.

Guidelines

Limit the height of the bed to keep temperature increase <50°C to minimize effects of radial temperature gradients. Bed can be shallow and wide. Quench can include injection of cold reactants, internal or external heat exchangers.

16.11.6.8 PFTR: Fixed Bed with Radial Flow

For fast reactions, strongly exothermic or endothermic reactions. Phases: gas with solid catalyst. Use to minimize pressure drop limitations.

16.11.6.9 PFTR: Transported or Slurry, Transfer Line

A related option is fluidized reactor (Section 16.11.6.27).

Area of Application

Phases: gas-solid, gas-solid reactant, gas-liquid, liquid-solid, gas-liquid-solid. *Gas plus catalytic solid:* gas residence time in milliseconds. Reaction rates very fast and very rapid deactivation of catalyst. Solid particle diameter 0.007 to 1.5 mm. *Gas plus solid reactant:* solid residence time, 0.8 to 300 s: gas residence time, <1 s; solid particle diameter 0.007 to 1.5 mm. *Gas-liquid:* see size reduction, Section 16.11.8.1. *Gas liquid plus solid catalyst:* for fast hydrogenation reactions. Compared with trickle bed, Section 16.11.6.15, or PFTR fixed bed with upflow, Section 16.11.6.5. (1) Catalyst particles are small, so less chance of diffusional resistance to mass transfer. (2) Better control of temperature (because of better heat transfer efficiency and high heat capacity of slurries), attractive for exothermic reactions. (3) No need to shut down for catalyst replacement or reactivation. (4) Partial wetting and need to maintain a coating film of liquid (as needed in the trickle bed) are not issues. (5) The space time yield is usually better in slurry reactors (under comparable conditions).

Guidelines

Gas plus catalytic solid and *Gas plus solid reactant:* see pneumatic conveying, Section 16.11.2.6. *Gas-liquid:* see size reduction, Section 16.11.8.1, and two-phase flow, Section 16.11.2.4. Surface area 50 to 400 m^2/m^3; power 1 to 80 kW/m^3 total volume. *Gas-liquid plus solid catalyst:* usually operate in the churn-slug and piston-slug flow regimes with gas velocities >0.05 m/s for water-like liquids. Flow regimes are given in Table 16.31, Section 16.11.2.4. Gas holdup is proportional to the (superficial gas velocity)^n, where n = 0.7 to 1.2 in the bubbling regime and n = 0.4 to 0.7 in the churn turbulent regime. Gas holdup is independent of diameter but very sensitive to trace contaminants and foaming. Jet loop recycle reactor k_L about 0.04. to 0.05 cm/s; k_La = 7 1/s; power 2 kW/m^3; air lift k_La = 0.27 1/s.

16.11.6.10 PFTR: Motionless Mixer in Tube (Static Mixer)

Area of Application

Phases: gas with mixer as catalyst, gas-liquid, liquid, liquid-liquid. Fast competing parallel or consecutive reactions that are highly exothermic. For gas-liquid: fast reactions in the liquid phase.

Guidelines

See heat transfer, Section 16.11.3.5, and mixing, Section 16.11.7.3. For *gas reactions:* example oxidation of ammonia to nitric acid, production of maleic anhydride, xylene, styrene, vinyl chloride monomer, ethylene dichloride. *L/D* for mass transfer mixers 6:1 to 20:1. Gas velocity for turbulent flow. For gas-liquid reactions: cocurrent mass transfer in bubble flow: gas superficial velocity 0.6 to 2 m/s; liquid superficial velocity 0.3 to 3 m/s; spray flow: gas superficial velocity 3 to 25 m/s; see size reduction, Section 16.11.8.1. For *liquid-liquid reactions:* dispersed phase drops diameter 100 to 2000 μm, with diameter decreasing as the velocity increases, the surface tension decreases, and the hydraulic radius of the mixing element decreases; surface area 100 to 20,000 m^2/m^3, depending on the drop diameter and the concentration of dispersed phase. Turbulent flow. Example reactions as a PFTR; polymerizations of polystyrene, nylon, urethane; sulfonation reactions and caustic washing; see size reduction, Section 16.11.8.3.

16.11.6.11 PFTR: Bubble Reactor

Area of Application

Phases: gas-liquid, gas-liquid catalytic solid, and liquid-liquid. Use if the order of the reaction is positive and >95% conversion is the target, and for consecutive reactions with an intermediate as the target product. *Gas-liquid:* For large liquid holdup, slow reactions that are kinetically controlled reactions that require long residence times, and low-viscosity liquids. Preferred if large gas volumes needed or if liquid vol. is >40 m^3; OK for high pressure. Cocurrent: surface area 50 to 400 m^2/m^3; downflow: surface area 20 to 1000 m^2/m^3; see size reduction, Section 16.11.8.1. *Gas-liquid catalytic solid:* surface area 50 to 350 m^2/m^3. *Liquid-liquid:* surface area 7 to 75 m^2/m^3. Rotating disk contactor (RDC) can handle dirty fluids and large throughputs. Need flow ratios 1:1; difficulty in handling systems with low interfacial tensions that tend to emulsify. Related topics are solvent, extraction, Section 16.11.4.10, and size reduction, Section 16.11.8.3.

Guidelines

Gas-liquid: can operate countercurrently or cocurrently. Holdup: volumetric liquid holdup per total reactor volume: >0.7 and usually 0.95. Gas holdup = 0.05 to 0.4, increasing with increase in gas velocity. Superficial gas velocity 1 to 30 cm/s, although it has been as high as 50 cm/s. Mass transfer coefficients: typical liquid mass transfer coefficient = k_La = 0.005 to 0.01 1/s; k_L = 0.6 to 0.7 10^{-4} m/s. For gas phase k_Ga = 1 to 3 1/s. Surface area gas-liquid per volume of reactor: 20 to 1000 m^2/m^3 volume reactor depending on flow conditions. Surface area gas-liquid per volume

of liquid phase: 120 to 700 m^2/m^3 liquid phase. Volumetric ratio liquid to mass transfer liquid film, $\beta > 100$. Fast reaction systems, consider mass transfer: film diffusion. Power: cocurrent: 0.03 to 2 kW/m^3; countercurrent: 0.04 to 1 kW/m^3. See size reduction, Section 16.11.8.1. *Gas-liquid catalytic solid:* catalyst diameter, <0.1 mm. Operate semibatch. Holdup: volume fraction liquid 0.8 to 0.9; volume fraction catalyst 0.01; volume fraction gas 0.1 to 0.2. Gas holdup slightly less than for GL systems. Backmixing: solids backmixing $Pe = 2$ to 5 for superficial gas velocities of 2 to 7 cm/s; Liquid-phase backmixing about the same as gas-liquid systems; gas-phase backmixing, about the same as gas-liquid systems. Surface area: surface area solid 500 m^2/m^3; surface area gas-liquid 100 to 400 m^2/m^3; power 0.1 to 2 kW/m^3 sufficient to keep catalyst in suspension. Heat transfer solid wall to mixture >1 $kW/m^2{\cdot}K$; presence of solids increases the heat transfer coefficient. Catalyst activity: variable but often able to avoid diffusion limitations because of small-diameter catalyst. Catalyst selectivity: OK. Catalyst stability: change catalyst between batches, heat exchange OK. Consider complications because of catalyst deposition and erosion. *Liquid-liquid:* superficial dispersed drop velocity 0.001 to 0.02 m/s with usual values 5.5 $L/s{\cdot}m^2$. Smallest reactor volume. *For example, for esterification: reactor volume divided by the daily production, $m^3{\cdot}day/kg$.*

PFTR	0.7
3 CSTR in series	0.85
Batch STR	1.04
CSTR	1.22

RDC: sum of the superficial velocities for both phases is 1 to 2.5 cm/s; dia. <9 m for SX but usually <2.5 m for reactions. A related topic is SX (Section 16.11.4.10).

16.11.6.12 PFTR: Spray Reactor and Jet Nozzle Reactor

Area of Application

Phases: gas-liquid, liquid-liquid. *Gas-liquid:* residence time, very short. Reaction rates, very fast; need rapid absorption. Very high gas capacity. Used for neutralization reactions with one of the reactants in the gas phase. For surface area see size reduction, Section 16.11.8.2. *Gravity spray:* surface area 30 to 70 m^2/m^3; target species Henry's law constant 10^3 to 10^4 kPa/mol fraction; feed gas concentration 0.3 to 4 vol%. *Venturi jet nozzle:* surface area: 200 to 2500 m^2/m^3; very soluble gas only with target species Henry's law constant $<10^3$ kPa/mol fraction; feed gas concentration >1 vol%. *Liquid-liquid:* surface area: 7 to 75 m^2/m^3. Related topics are solvent extraction (Section 16.11.4.10) and size reduction (Section 16.11.8.3).

Guidelines

Gravity spray towers: superficial velocity about 5.5 $L/s{\cdot}m^2$; mass transfer coefficients liquid phase: $1.5 \times 10^{-4} < k_L < 3 \times 10^{-4}$ m/s: for the gas phase $0.4 < k_G < 1$ $mol/m^2{\cdot}atmos{\cdot}s$, or in other units, $0.01 < k_G RT < 0.25$ m/s; critical energy-consuming phase is the liquid; gas energy 8 kJ/m^3; with liquid-to-gas ratio high; design on gas-phase controlling. Superficial gas velocity 1 m/s. Power usage 0.03 to 0.5 $kW{\cdot}s/m^3$. Δp gas = 0.6 to 1.2 kPa. Related topics are gas-solid separation (Section 16.11.5.2) and size reduction (Section 16.11.8.2). *Gas-liquid venturi:* Δp gas = 5 kPa, velocity in the throat 30 to 100 m/s and usually 100 m/s; mass transfer coefficient for liquid phase $k_L = 7 \times 10^{-4}$ m/s; for gas phase, $k_G = 10^{-2}$ to 3×10^{-2} m/s; gas-liquid surface area 150 to 300 m^2/m^3. For fluids with surface tension 40 to 70 mN/m and viscosity of liquid = 1 mPa·s; critical energy-consuming phase is the gas at about 20 kJ/m^3 with liquid-to-gas ratio about 1.3 to 1.6 L/m^3; design on gas-phase controlling. Power usage 0.04 to 8 $kW{\cdot}s/m^3$. Δp gas = 1.2 to 6 kPa. Related topics are gas-solid separation (Section 16.11.5.2) and size reduction (Section 16.11.8.2). *Liquid-liquid:* superficial velocity = 50% flooding.

16.11.6.13 PFTR: Trays

Related topics are gas absorption (Section 16.11.4.8), distillation (Section 16.11.4.2), and reactive distillation (Section 16.11.6.32).

Area of Application

Phases: gas-liquid, liquid-liquid. *Gas liquid:* residence time, short. Use for very fast reactions; all reaction is in the liquid film and is mass transfer–controlled. Gas-liquid surface area, max. observed 800 m^2/m^3 with the usual range 200 to 500 m^2/m^3 or slightly higher than a bubble column. Target species Henry's law constant <10^7 kPa/mol fraction; feed gas concentration <1 vol%. Not for foaming, corrosive, or particulates. *Liquid-liquid:* can operate as gravity flow or with fluid pulsed operation. For pulsed operation: surface area 75 to 3000 m^2/m^3. Related topics are solvent extraction (Section 16.11.4.10).

Guidelines

Gas-liquid: liquid holdup = 0.15; typical liquid mass transfer coefficient = $k_L a$ = 0.01 to 0.05 1/s; k_L = 1.5×10^{-4} to 4.5×10^{-4} m/s; for gas phase k_G = 0.02 to 0.2 m/s sieve tray; power 0.03 to 2 kW/m^3. *Liquid-liquid:* sieve tray holes 3 to 8 mm with a smaller diameter as the surface tension increases; spacing between the holes three to four times the diameter of the holes to prevent coalescence soon after the drops are formed. For pulsed operation: superficial velocities 2×10^{-3} to 0.02 m/s.

16.11.6.14 PFTR: Packing

Related topics are gas absorption (Section 16.11.4.8), distillation (Section 16.11.4.2), and reactive distillation (Section 16.11.6.32). Porosity 0.6 to 0.95, depending on the packing. (Contrast with trickle bed with solid catalyst "packing," Section 16.11.6.15.)

Area of Application

Phases: gas-liquid, liquid-liquid, gas-liquid bio solids. *Gas-liquid:* use for very fast reactions; all reaction is in the liquid film and is mass transfer–controlled. Gas resistance important with very soluble gases. Surface area gas-liquid per volume of reactor: 50 to 250 m^2/m^3 volume reactor; surface area gas-liquid per volume of liquid phase: 1000 to 1600 m^2/m^3 liquid phase. Cocurrent over packed: surface area 400 to 3000 m^2/m^3. Target species Henry's law constant <10^7 kPa/mol fraction: feed gas concentration <1 vol%. Vulnerable to plugging. OK for foaming and corrosive. *Liquid-liquid:* surface area 7 to 75 m^2/m^3. Sensitive to contamination. Related topics are solvent extraction (Section 16.11.4.10) and size reduction (Section 16.11.8.3). *Gas-liquid bio solids:* gravity and rotating: *gravity:* trickling filter reactor (carbon removal): surface area 45 to 115 m^2/m^3. Standard-rate loading: 1.3 to 4.2 kg $BOD_5/s{\cdot}m^3$. High-rate loading: 4.2 to 21 kg $BOD_5/s{\cdot}m^3$; (carbon oxidation/nitrification combo): plastic media: loading <4 kg $BOD_5/s{\cdot}m^3$; (nitrification): biofilter: (carbon removal) organic loading: 20 to 50 kg $BOD_5/s{\cdot}m^3$. *Rotating:* rotating biological contactor (RBC): (carbon oxidation): loading 0.250 g BOD_5/L; capacity 20 to 5000 L/s; (nitrification): loading 10 to 20 mg NH_3 – N/L.

Guidelines

Gas-liquid: liquid holdup per total reactor volume: volume fraction liquid 0.05 to 0.15; superficial velocities: select for loading on packings that are 0.5 to 0.7 times flooding conditions; backmix: for short column heights = 0.2 to 0.3 m, significant backmixing can occur with Peclet for the liquid = 0.4 to 2; Peclet for the gas = 4 to 20. For short columns, double design height to account for backmixing. Typical liquid mass transfer coefficient = $k_L a$ =0.005 to 0.02 1/s; volumetric ratio liquid to mass transfer liquid film. β = 10 to 100. *Packing:* plastic packings have effective surface area = 1/2 corresponding value for ceramic if fluids are polar. OK for nonpolar; metal stainless steel less wetted than ceramic but better than plastic. Preferred packings include unglazed ceramic, Intalox 2 to 3.8 cm, but >5 cm, the interfacial area is too small, and <2 cm, the capacity is reduced

because of flooding. Other recommended packings include Pall rings, mini-rings, Sulzer, Multinit, and tellerettes. *Liquid-liquid:* Superficial velocity of continuous phase = 30 to 50% of flooding. Backmixing less than in spray column or tray columns. The walls and packing must be preferentially wetted by the continuous phase. Packing size = 0.5 to 1 cm. Superficial velocities 0.001 to 0.02 m/s. Prefer diameter <0.6 m; superficial velocity about 5.5 L/s·m^2; 2.5 cm Pall rings. Redistribute the dispersed phase every 1.5 to 2 m. *Gas-liquid bio solid:* gravity: trickling filter reactor: gas holdup 0.46 to 0.94; (carbon oxidation): *standard rate:* liquid superficial velocity 0.01 to 0.04 L/s·m^2, depth 1.8 to 3 m; recycle ratio 0; *high rate:* liquid superficial velocity 0.1 to 0.4 L/s·m^2, depth 0.9 to 2.4 m; recycle ratio 1/1 to 4/1; (carbon oxidation/nitrification combo): liquid superficial velocity = 0.095 to 0.18 L/s·m^2. Six-meter depth, recirculation ratio 1:1; (nitrification): liquid superficial velocity = 0.3 to 1.3 L/s·m^2. Biofilter reactor: media depth 1.5 to 6.5 m, usually 4 m; liquid recycle ratio 0.4; liquid loading: 2.3 L/s·m^2.

Rotating: RBC: (carbon oxidation) liquid residence time <1 h; 3 to 3.6 m dia.; 40% submerged; 1 to 2 rpm; bio layer 2 to 4 mm thick. Liquid loading 0.0005 to 0.004 L/s·m^2; temperature >13°C; Module 10,000 m^2; power = 3.5 kW; (nitrification): liquid loading 0.0004 to 0.0025 L/s·m^2. Temperature >13°C.

16.11.6.15 PFTR: Trickle Bed

Gas and liquid flow cocurrently down through a packed bed of catalyst. Porosity 0.38 to 0.42. (Contrast with packing described in Section 16.11.6.14.)

Area of Application

Phases: gas-liquid catalytic solid. Gas-liquid catalytic solid: use for very fast reactions; all reaction is in the liquid film and is mass transfer–controlled.

Guidelines

Gas-liquid with solid catalyst: catalyst particle diameter 1 to 5 mm. Operate close to the boundary between two-phase (trickle) and pulse flow. Superficial liquid velocity $0.005 < v_{Lo} < 9$ mm/s (although some operate in the range 0.8 to 25 L/s·m^2 or mm/s). The velocity should be reduced if liquid tends to foam. Superficial gas velocity is >0.010 m/s. Holdup volume fraction liquid 0.05 to 0.25. Static liquid holdup is constant for low Eotvos number, $Eo < 4$ (Eo = density liquid × gravitational constant × particle diameter squared/liquid-gas surface tension). Liquid holdup increases with Eo for $Eo > 4$. Dynamic liquid holdup increases with liquid flow rate but is independent of gas flow rate. The liquid axial backmixing is negligible if the height/particle diameter is >150. Holdup volume fraction catalyst 0.6 to 0.7. Holdup volume fraction gas 0.2 to 0.35. Surface area solid 1000 to 2000 m^2/m^3. Surface area gas-liquid 100 to 3500 m^2/m^3. Power input 1 to 100 kW/m^3. Catalyst activity: variable but often reduced because of mass transfer limitation. Plug flow is favorable. Catalyst selectivity: often reduced because of mass transfer limitation; plug flow is favorable. Catalyst stability: should have stability because of difficulty in replacing. Heat exchange: challenging, so usually work adiabatically.

16.11.6.16 PFTR: Monolithic

Related topics are motionless mixer in tube (Section 16.11.6.10) and trickle bed (Section 16.11.6.15).

Area of Application

Phases: gas with solid catalyst; liquid with solid catalyst; gas-liquid with solid catalyst.

Guidelines

Prefer because of intensification with 1.4 to 4 times the surface/volume. Possible to install in pipelines. Use when mass transfer affects selectivity or reactivity. Perhaps not for highly exothermic

reactions because of limited radial heat transfer unless crossflow is used. See Section 16.11.3.3, cubic/monolithic.

16.11.6.17 PFTR: Thin Film

Related topics are evaporation (Section 16.11.4.1) for gravity and agitated falling films, absorbers (Section 16.11.4.8), and shell-and-tube heat exchangers (Section 16.11.3.3).

Area of Application

Phases: gas-liquid, liquid-liquid. *Gas-liquid:* residence time 3 to 600 s; reaction rate: mass transfer controlled, fast adsorption and highly exothermic reactions; highly endothermic reactions producing a volatile compound whose desorption is desirable to shift the equilibrium or prevent side reactions; volume 1 to 80 L; capacity 0.02 to 5 kg/s. Gravity falling film or agitated falling film for viscous fluids. *For gravity film:* liquid residence time: 5 to 100 s; surface area gas-liquid per volume of reactor: 3 to 100 m^2/m^3 volume reactor; surface area gas-liquid per volume of liquid phase: 300 to 600 m^2/m^3 liquid phase; film surface area per unit 0.1 to 100 m^2/unit; viscosity <1500 mPa·s. *For agitated film:* liquid residence time: 5 to 600 s; film surface area gas-liquid per total reactor 0.1 to 25 m^2/unit reactor; viscosity: <2,000,000 mPa·s. *Liquid-liquid:* surface area 5 to 120 m^2/m^3. Related topics are solvent extraction (Section 16.11.4.10) and size reduction (Section 16.11.8.3).

Guidelines

Gas-liquid: gravity falling film: holdup: liquid holdup per total reactor volume: volume fraction liquid 0.01 to 0.15; liquid holdup per total reactor volume: 0.0002 to 0.5 m^3; liquid loading: 0.06 to 1.1 L/s·m of length. Volumetric ratio liquid to mass transfer liquid film, β = 10 to 200; energy for a falling film = energy as packed tower. *Gas-liquid: agitated thin film:* holdup: liquid holdup per total reactor volume: 0.0002 to 0.2 m^3; liquid loading: 0.06 to 1.25 L/s·m of length; backmixing: liquid plug flow or as a series of at least five backmix stages; energy needed = 1 kW/m^2 film surface. *Liquid-liquid:* gravity wetted wall; superficial velocities 2×10^{-5} to 8×10^{-4} m/s.

16.11.6.18 PFTR: Multiple Hearth

Phases: gas plus reactant solid. A related topic is energy exchange (Section 16.11.3.9).

Area of Application

Solid residence time 5,000 to 30,000 s; solid particle diameter 0.2 to 20 mm.

Guidelines

Solids loading 1.25 to 2 g/s·m^2 of single hearth or 2 to 20 g/s·m^2 of total hearth. Hearth area is 42 to 62% of nominal read based on overall OD. For fast reactions, bulk phase film diffusion may control, and pore diffusion may control if the solid diameter is >1.5 mm.

16.11.6.19 PFTR: Traveling Grate

Phases: gas plus reactant solid.

Area of Application

Solid residence time 2,500 to 20,000 s; gas residence time <1 s; solid particle diameter 8 to 30 mm. Product diameter 80 to 150 mm; capacity 15 to 300 kg/s; product crush strength >10^4 kPa.

Guidelines

Sintering: capacity 0.015 to 0.04 kg/s·m^2. For fast reactions, bulk phase film diffusion may control, and pore diffusion may control if the solid diameter is >1.5 mm. *Incineration:* temperature 1000°C; solid residence 1200 to 2700 s. See heat transfer, Section 16.11.3.7.

16.11.6.20 PFTR: Rotary Kiln

Phases: gas plus reactant solid. Related topics are incineration (Section 16.11.3.7) and drying (Section 16.11.5.5).

Area of Application

Solid residence time 2,500 to 20,000 s; gas residence time <1 s; solid particle diameter 7 μm to 20 mm. Sinter product: product diameter 80 to 150 mm; capacity 15 to 300 kg/s; product crush strength $>10^4$ kPa.

Guidelines

See heat transfer (Section 16.11.3.7) and related topic (drying, Section 16.11.5.5). Sintering: 0.012 kg/s·m^3 volume. For fast reactions, bulk phase film diffusion may control, and pore diffusion may control if the solid diameter is >1.5 mm. Incineration: see heat transfer, Section 16.11.3.7.

16.11.6.21 PFTR: Shaft Furnace

Phases: Gas plus reacting solid.

Area of Application

Solid residence time 20,000 to 200,000 s; gas residence time <1 s; solid particle diameter 8 to 300 mm.

Guidelines

For fast reactions, bulk phase film diffusion may control, and pore diffusion may control if the solid diameter is >1.5 mm.

16.11.6.22 PFTR: Melting Cyclone Burner

Phases: Gas plus reacting solid.

Area of Application

Solid residence time 0.004 to 2 s; gas residence time <1 s; solid particle diameter, 0.002 to 0.4 mm.

Guidelines

For fast reactions, bulk phase film diffusion may control.

16.11.6.23 PFTR Via Multistage CSTR

$Bd = 2n$, where n = number of CSTRs in series. About 100 CSTR in series to provide negligible backmixing.

Area of Application

Phases: liquid, gas-liquid bio solids. *Liquid:* use for residence time >4 h; for systems where PFTR conditions are desired. Heat of reaction: highly exothermic reaction rate, slow. Capacity 0.2 to 100 kg/s. *Gas-liquid bio solids:* variety of reactor configurations to remove soluble BOD_5 from wastewater: aerated lagoon. *Pure-oxygen backmix-activated sludge,* CSTR in series: 85 to 95% removal, compact unit for use where space is limited.

Guidelines

Gas-liquid bio solids: aerated lagoon: three CSTRs in series: residence time: 1 day for each CSTR, removal 80 to 95%; GL bubble reactor: retention time less than a facultative lagoon, biomass suspended, plus subsequent settling = no recycle activated sludge reactor. Oxygen requirements control if residence time is <1 d; mixing controls if residence time is >1 d; length/width <1.5; depth 2.4 to 5.4 m; SS concentration = 1 to 5 g/L; power 0.011 to 0.023 kW/m^3; 80 to 95% removal; food/microorganism ratio = 22 mg BOD_5/s·kg MLSS; depth 2.4 to 5.4 m; 0.01 to 0.25 kW/m^3; SS

1 to 5 g/L. *Pure-oxygen backmix-activated sludge,* CSTR in series with recycle: mean cell residence time = 8 to 20 days; food/microorganism ratio = 3 to 12 mg BOD_5/s·kg MLVSS; volumetric loading = 1.6 to 4 kg BOD_5/m^3; MLSS = 6 to 8 g/L; residence time =1 to 3 h; recycle ratio = 0.25 to 0.5.

16.11.6.24 STR: Batch (Backmix)

Bd = 0; *Pe* < 1. A related topic is mixing (Section 16.11.7.3).

Area of Application

Batch, semibatch, and continuous stirred tank reactors: residence time 600 to 15,000 s (10 min to 4 h); heat of reaction: primarily exothermic; reaction rate slow to moderate. High-pressure autoclaves <100 L. *Unique to batch STR:* phases: L, LL, LcS, L bioS. Low capacity, <3 L/s, but usually <0.3 L/s; use if the concentrations of all reactants are high and need good selectivity for consecutive reactions. For low and variable production rates, use a variety of similar products or several products sequentially; low fixed capital cost, but usually the product cost is high because of the cycles. Details of other applications and guidelines are given in Section 16.11.6.26, CSTR. Liquid plus biosolid: anaerobic digesters: (first stage): STR batch: batch microbiological treatment of municipal sludge: high rate.

Guidelines

Batch operation: size on operating cycle: load, temperature and pressure adjustment, react, return to usual conditions, discharge and, perhaps, clean. Loading and discharge times are proportional to the volume of the reactor (0.75 to 1 h each); reactant heating and product cooling depend on the reaction temperature (about 1 to 3 h each); cleaning (for polymer reactors 0.5 to 1 h). Liquid plus bio solid: *Anaerobic digesters:* (first stage): residence time 10 to 15 d; 2 to 10 × washout retention time; operating temperature 18 to 38°C, usually 35; organic VS loadings =18 to 25 mg/s·m^3 digester volume; pH 7 to 7.1; volatile acid concentration 0.2 to 0.8 g/L; alkalinity concentration 2 to 3.5 g/L; Circular, diameter 6 to 35 m; depth 6 to 14 m; power 0.006 to 0.03 kW/m^3.

16.11.6.25 STR: Semibatch

Bd = 0; *Pe* < 1. A related topic is mixing (Section 16.11.7.3).

Area of Application

Batch, semibatch, and continuous stirred tank reactors: residence time 600 to 15,000 s (10 min to 4 h); heat of reaction: primarily exothermic; reaction rate slow to moderate. High-pressure autoclaves <100 L. *Unique to semibatch:* phases: liquid, gas-liquid, liquid-liquid, gas-liquid catalytic solid. Use where a batch operation is appropriate (Section 16.11.6.24), but one reactant (e.g., gas) needs to be added continuously or if the initial reaction rate is very high. Selectivity is best for parallel reactions. For more details, see CSTR, Section 16.11.6.26.

Guidelines

Batch operation: size on operating cycle: load, temperature and pressure adjustment, react, return to usual conditions, discharge and, perhaps, clean. Loading and discharge times are proportional to the volume of the reactor (0.75 to 1 h each); reactant heating and product cooling depend on the reaction temperature (about 1 to 3 h each); cleaning (for polymer reactors) 0.5 to 1 h.

16.11.6.26 CSTR: Mechanical Mixer (Backmix)

Bd = 0; *Pe* <1. Related topics mixing, 16.11.7.3, and solvent extraction, 16.11.4.10.

Area of Application

Batch, semibatch, and continuous stirred tank reactors: residence time 600 to 15,000 s (10 min to 4 h); heat of reaction: primarily exothermic; reaction rate slow to moderate. High-pressure

autoclaves <100 L. *Unique for CSTR:* phases: liquid, gas-liquid, liquid-liquid, liquid catalytic solid, gas-liquid catalytic solid, gas-liquid bio solid. Capacity 0.0001 to 100 L/s and usually >0.4 L/s; volumes 1 to 1,000,000 L. Autothermal reactions. Usually used if the concentration of reactants is low, and need low concentration of reactants for selectivity. CSTR is larger and more expensive than PFTR. For multiphase, STRs are characterized by high liquid holdups; holdup of the reactive phase is important if the reaction is slow, $Ha < 1$; phase ratio is easy to control. *Liquid:* <300,000 mPa·s; volume <75 m^3. Use for kinetically controlled reactions that require long residence times. *Gas liquid:* surface area 60 to 500 m^2/m^3; surface area gas-liquid per volume of reactor: 200 to 2000 m^2/m^3 volume reactor; surface area gas-liquid per volume of liquid phase: 220 to 2500 m^2/m^3; liquid phase can handle viscous liquids and suspensions, only appropriate for smaller size reactors <10 to 20 m^3. *Liquid-liquid:* surface area 400 to 3500 m^2/m^3 with area increasing with decreasing surface tension and increasing velocity. Drop diameter 4 to 5000 μm; for viscosities <10^4 mPa·s. Phase ratio is easy to control. *Liquid with catalytic solid:* catalyst diameter <0.1 mm; surface area solid 500 m^2/m^3. *Gas-liquid with catalyst solid:* catalyst diameter <0.1 mm; surface area 50 to 1200 m^2/m^3; surface area solid 500 m^2/m^3; surface area gas-liquid 100 to 1500 m^2/m^3. *Gas-liquid bio solid:* aerobic sludge digesters: reduce the volume of and render biologically stable the sludge from a variety of sources: conventional activated sludge and primary clarifier.

Guidelines

Reactor size 8 to 32 m^3, 1.5 MPa, with jacketed heat transfer surface 1.5 to 2.5 m^2/m^3 volume. Heat transfer coefficient U = 0.06 to 0.35 kW/m^2·K for jacket to inside reactor contents; coil 0.7 to 0.8 kW/m^2·K. Power = 0.2 to 2 kW/m^3, see mixing, Section 16.11.7.3, and heat transfer, Section 16.11.3.3. Liquid: power input to promote heat and mass transfer: 1 to 6 kW/m^3 reactor volume. Gas-liquid: holdup: liquid holdup >0.7, gas holdup <0.1; bubble diameter = 2.5 mm regardless of the agitation and has a mean upward velocity of about 0.27 m/s; superficial gas velocity, 0.05 to 1 m/s; backmix; complete; typical liquid mass transfer coefficient = $k_L a$ = 0.02 to 0.2 1/s; volumetric ratio liquid to mass transfer liquid film, $\beta > 100$; power input 0.1 to 4 kW/m^3. Height of liquid = tank diameter or use multiple impellers if height of liquid/tank diameter >2. Impeller diameter 0.3 to 0.5 of tank diameter. *Liquid-liquid:* holdup: volume fraction dispersed liquid 0.01 to 0.5; typical drop diameter is 150 μm; power input 0.2 to 3 kW/m^3. A related topic is solvent extraction (Section 16.11.4.10). *Liquid with catalytic solid:* holdup: volume fraction catalyst 0.01; volume fraction liquid 0.99; power input to facilitate heat and mass transfer, suspend solids, and promote mass transfer: 1 to 4 kW/m^3 reactor volume. *Gas-liquid with catalyst solid:* holdup: volume fraction catalyst 0.01; volume fraction liquid 0.8 to 0.9; volume fraction gas 0.1 to 0.2. Power input 0.05 to 2 kW/m^3. Catalyst activity: variable but often able to avoid diffusion limitations because of small-diameter catalyst. Catalyst selectivity: OK. Catalyst stability: change between batches. Heat exchange: OK. *Gas liquid bio solids:* aerobic sludge digesters: CSTR designed on the basis of VSS reduction. Mixing to keep the solids suspended plus oxygenation. Cell residence time for cells 12 to 22 days, depending on the source of the sludge. Typical organic load 4 to 26 μg VSS/s·m^3; dissolved oxygen concentration 1 to 2 mg/L; air requirement for activated sludge = 0.25 to 0.33 dm^3/s·m^3; mixture of primary plus activated sludge = 0.4 to 0.5 dm^3/s·m^3; 1.42 kg O_2/kg biosolids digested. Oxygen usage 1.4 to 11 mg O_2/s·kg VSS, depending on the source of the sludge. For diffused air 0.33 to 1 dm^3/s·m^3, depending on the sludge; surface aeration = 0.025 to 0.033 kW/m^3. Power = 0.015 to 0.02 kW/m^3.

16.11.6.27 STR: Fluidized Bed (Backmix)

Related topics are heat transfer (Section 16.11.3.4 and Section 16.11.3.8), mixing (Section 16.11.7.1), dryers (Section 16.11.5.5), and size enlargement (Section 16.11.9.5).

Area of Application

Phases: gas with solid catalyst, gas reacting with a solid, liquid reacting with solid catalyst, gas-liquid with solid catalyst: residence time: for gas = seconds; for solids = minutes to hours. Primarily for highly exothermic, very fast reactions where the need is for uniform, closely controlled temperature; need fast reaction that occurs at the bottom of the bed. Not good if have consecutive reactions to produce the product (because of backmixing). Relatively inflexible. Preferred over PFTR for strongly exothermic or endothermic reactions. Easier than fixed bed for catalyst regeneration, excellent heat transfer for high exothermic reactions; lower pore diffusional resistance because of smaller-diameter catalyst particles. Select if catalyst life is <3 months. Catalyst must withstand attrition. *Gas with catalytic solid:* solid residence time, 300 to 15,000 s; gas residence time <1 s; solid particle diameter 0.005 to 7 mm. *Gas with reacting solid:* solid residence time, 300 to 15,000 s; gas residence time <1 s; solid particle diameter 0.005 to 7 mm. *For combustion, gasification, incineration.* Advantages: ease in solids handling, uniform temperature, and thermal stability, even for highly exothermic and endothermic reactions. Cannot be used for solids with partial fusion or softening of particles. *Liquid with catalytic solid:* catalyst diameter 0.1 to 5 mm; surface area solid 500 to 1000 m^2/m^3. *Gas-liquid with catalytic solid:* catalyst diameter 0.1 to 5 mm; surface area solid 500 to 1000 m^2/m^3; surface area gas-liquid 100 to 1000 m^2/m^3.

Guidelines

Gas-solid (catalytic or reacting): operate 10 to 100 × minimum fluidizing velocity; operate in the bubbling regime. Heat transfer coefficient 0.2 $kW/m^2{\cdot}K$. For fast reactions, gas film diffusion may control, and catalyst pore diffusion mass transfer may control if catalyst diameter is >1.5 mm. The fluidization is characterized as "bubbling" (aggregate fluidization). Bubbling consists of two phases: (1) gas bubbles: assume move through in plug flow; superficial gas velocity (0.1 m/s) >> minimum superficial gas velocity to cause fluidization (0.01 m/s); mass transfer coefficient between the bubble and the emulsion phase = 0.01 m/s; the fraction of the volume of the fluidized bed occupied by the bubbles is 0.04, and (2) homogeneous emulsion phase: emulsion phase; reaction occurs in the emulsion phase. Area between the bubble phase and the emulsion phase = 10 m^2/m^3. Diffusivity of the reactant in the emulsion phase = diffusivity in the bubble phase = 10^{-5} to 10^{-4} m^2/s. The six options include (1) single bubbling bed (BFB), (2) BFB/BFB combo with catalyst as the oxygen carrier, (3) circulating fluidized bed (CFB), (4) CFB/BFB combo with catalyst as the oxygen carrier, (5) multistage BFB, and (6) multistage BFB with split air flow and temperature programming. Heat transfer: heat transfer coefficient wall to fluidized bed is 20 to 40 × gas wall at the same superficial velocity, h = 0.15 to 0.3 $kW/m^2{\cdot}K$. Nu = 0.5 to 2. Fluidized bed usually expands 10 to 25%. Superficial fluid velocity is usually 5 to 10 × the minimum fluidization velocity; backmix type reactor, which increases the volume of the reactor and usually gives a loss in selectivity. Usually characterized as backmix operation or, more realistically, as a series of CSTRs if the height/diameter is >2. Usually 1 CSTR for each H/D = 1. *Liquid with catalytic solid:* particulate fluidization: homogeneous with no bubbles. For highly exothermic reactions, consider external recirculation through a heat exchanger. *Gas-liquid with catalytic solid:* holdup volume fraction catalyst 0.1 to 0.5; volume fraction liquid 0.2 to 0.8; volume fraction gas 0.05 to 0.02. Catalyst activity: variable but often reduced because of mass transfer limitation, backmixing is unfavorable. Catalyst selectivity: often reduced because of mass transfer limitation; backmixing is unfavorable. Catalyst stability: must withstand attrition; can be removed for regeneration. Heat exchange; good heat transfer. Isothermal efficiency may be 1, but with larger diameter particles this can decrease. May have lower isothermal efficiency because of diffusion into the pellet and the larger size pellet.

16.11.6.28 Tank Reactor (TR)

Minimal to no internal mixing.

Area of Application

Phases: gas-liquid bio solid; liquid plus bio solid. Liquid plus bio solid: anaerobic digesters: (conventional first stage): batch microbiological treatment of municipal sludge; no mixing: use for <50 m^3/s. Other options include anaerobic ponds, facultative lagoons and ponds, and aerobic ponds.

Guidelines

Liquid plus bio solid: *anaerobic digesters:* (conventional first stage): Residence time 30 to 60 days (35°C); organic loading = 4 to 9 mg VS/s·m^3; circular, diameter 6 to 35 m; depth = 6 to 14 m. *Anaerobic pond:* residence time: 5 days; surface loading 600 to 3500 μg BOD_5/s·m^2 with 150 μg BOD_5/s·m^2 for winter conditions; volumetric loading 3 to 100 kg BOD_5/s·m^3. pH 6.7 to 7.1; depth 1 to 2.5 m. *Facultative lagoon:* residence time = 7 to 20 days, usually 4 to 8 days, longer in cold temperatures; loading 40 to 130 μg BOD_5/s·m^2; depth 2.4 to 4.8 m; surface aeration power to oxygenate. *Facultative pond:* residence time: 7 to 50 days; surface loading 26 to 65 μg BOD_5/s·m^2; depth 1 to 2.5 m; length/width = 3/1. No surface aeration; photosynthesis is source of oxygen; recycle ratio = 0.2 to 8, usually 4 to 8. *Aerobic pond:* residence time: 2 to 6 days; surface loading 130 to 260 μg BOD_u/s·m^2; depth 0.15 to 0.45 m; recirculation ratio = 0.2 to 2. A related topic is aerobic lagoon (Section 16.11.6.23).

16.11.6.29 Mix of CSTR, PFTR with Recycle

Area of Application

Phases: gas-liquid and bio solid. Bio solid removes the soluble organics, COD or BOD_5, from wastewater. Variety of reactor configurations. Related topics are trickling filter (Section 16.11.6.14), CSTR (Section 16.11.6.26), and CSTR in series (Section 16.11.6.23). *Conventional PFTR-activated sludge:* low-strength domestic wastewater, susceptible to shock loads; 85 to 95% removal. *Conventional backmix-activated sludge:* usual-strength domestic wastewater, resistant to shock loads, 85 to 95% removal. *Step aeration, modified aeration PFTR-activated sludge:* higher-strength domestic wastewater, 85 to 95% removal. *Contact stabilization:* PFTR: OK for domestic wastewater; unsuitable for most industrial wastewater, flexible, 80 to 90% removal. *Extended aeration backmix-activated sludge* (oxidation ditch): low organic loadings, small capacity: <40 L/s; flexible, 75 to 95% removal. *High rate aeration backmix-activated sludge:* high-strength domestic wastewater, 75 to 90% removal.

Guidelines

Conventional PFTR-activated sludge: mean cell residence time = 5 to 15 days; food/microorganism ratio = 2.3 to 4.6 mg BOD_5/s·kg MLVSS; volumetric loading = 0.3 to 0.6 kg BOD_5/m^3; MLSS = 1.5 to 3 g/L; residence time = 4 to 8 h; recycle ratio = 0.25 to 0.5. Air requirements = 100 m^3/kg of input BOD_5. Conventional backmix-activated sludge: mean cell residence time = 5 to 15 days; food/microorganism ratio = 2.3 to 7 mg BOD_5/s·kg MLVSS; volumetric loading = 0.8 to 2 kg BOD_5/m^3; MLSS = 3 to 6 g/L; residence time = 3 to 5 h; recycle ratio = 0.25 to 1. Air requirements = 100 m^3/kg of input BOD_5. Step aeration, modified aeration PFTR-activated sludge: mean cell residence time = 5 to 15 days; food/microorganism ratio = 2.3 to 4.6 mg BOD_5/s·kg MLVSS; volumetric loading = 0.6 to 1 kg BOD_5/m^3; MLSS = 2 to 3.5 g/L; residence time = 3 to 5 h; recycle ratio = 0.25 to 0.75. Air requirements = 100 m^3/kg of input BOD_5. Contact stabilization: PFTR with recycle: mean cell residence time = 5 to 15 days; food/microorganism ratio = 2.3 to 7 mg BOD_5/s·kg MLVSS; volumetric loading = 1 to 1.2 kg BOD_5/m^3; MLSS = 4 to 10 g/L; residence time = 3 to 6 h; recycle ratio = 0.25 to 1. Air requirements = 100 m^3/kg of input BOD_5. Extended aeration-activated sludge backmix with recycle: mean cell residence time: = 20 to 30 days; food/microorganism ratio = 0.6 to 1.8 mg BOD_5/s·kg MLVSS; volumetric loading = 0.16 to 0.4 kg BOD_5/m^3; MLSS = 3 to 6 g/L; residence time = 18 to 36 h; recycle ratio = 0.75 to 1.5. Air requirements = 125 m^3/kg of input BOD_5. High rate aeration-activated sludge, backmix with recycle:

mean cell residence time = 5 to 10 days; food/microorganism ratio = 4.5 to 17 mg BOD_5/s·kg MLVSS; volumetric loading = 1.6 to 16 kg BOD_5/m^3; MLSS = 4 to 10 g/L; residence time = 0.5 to 2 h; recycle ratio =1 to 5. Air requirements = 25 to 100 m^3/kg of input BOD_5.

16.11.6.30 STR: PFTR with Large Recycle

Area of Application

Phases: any. Recycle ratio = 20/1 gives backmix. Only exceed this recycle ratio if this is required for heat transfer.

16.11.6.31 Reaction-Injection Molding

Area of Application

Phases: liquid, liquid-liquid. Viscosities <1000 mPa·s; time for reaction to gel under adiabatic conditions >0.1 s; small capacity: 0.150 to 2k g/s.

Guidelines

Viscosity between 10 to 100 mPa·s to prevent bubbles; $Re > 300$; fill time >1 s and less than the reaction time to gel under adiabatic conditions. Mold temperature <100°C (or <200°C for high-temperature operation). Mold temperature plus the adiabatic reaction exotherm must not exceed the degradation temperature. Reaction should be 95% complete in <3 min.

16.11.6.32 Reactive Distillation, Extraction, Crystallization

Gas-liquid reaction with catalytic solid. Include the catalyst with structured packing in a distillation column. A related topic is distillation (Section 16.11.4.2).

Area of Application

Phases: gas-liquid, gas-liquid catalytic solid, gas-liquid plus catalytic solid: minimizes catalyst poisoning, lower pressure than fixed bed. Used for hydrogenation reactions and MTBE and acrylamide production. For example, 90% conversion via reactive distillation contrasted with 70% conversion in fixed-bed option. Liquid with homogeneous catalyst: etherification, esterification. Liquid-liquid: HIGEE for fast, very fast, and highly exothermic liquid-liquid reactions such as nitrations, sulfonations, and polymerizations. Equilibrium conversion <90%. Use a separate pre-reactor when the reaction rate at 80% conversion is >0.5 initial rate. The products should boil in a convenient temperature range. The pressure and temperature for distillation and reaction should be compatible.

Guidelines

Use concentration profiles developed from either equilibrium or nonequilibrium reaction-separation to identify the reactive zone. The reflux ratio for reactive distillation is greater than for distillation. Use 1.2 to 1.4 × minimum. For catalytic structured packing, use liquid loadings up to 14 L/s·m^2 and vapor "capacities," F factor, of 2.5 m/s $(kg/m^3)^{1/2}$ (based on velocity and the root of vapor density).

16.11.6.33 Membrane Reactors

Area of Application

Phases: gas-liquid, gas-liquid catalytic solid. Equilibrium reactions where selective removal via membrane will shift equilibrium or use of membrane as catalyst.

Guidelines

Try to match permeation rate and reaction rate.

16.11.6.34 Process Vessels

Area of Application

Used for a wide range of temperatures, pressures, and uses. Can be decanters, reflux drums, intermediate storage, towers, KO pots, reactors.

Guidelines

Operating pressure and temperature constrain practical size of vessel. Design codes for pressure vessels vary slightly with the country. In general, for operating pressures >10 MPa, vessel volume usually <1 m^3. Pressure decreases as temperatures exceed 250°C. For temperatures above 350°C, consider carbon/molybdenum, and for temperatures >500°C, consider austenitic steels. *Corrosion allowance* 1.5 mm for corrosion rates 0.08 mm/a; 3 mm for rates 0.09 to 0.3 mm/a; 4.5 mm for 0.31 to 0.4 mm/a; 6 mm for >0.4 mm/a. If pressure <400 kPa, use *L/D* of 2 to 3:1. For pressures >400 kPa, use *L/D* of 4 to 5:1. *For surge,* allow 2-min liquid residence time; for draw-off, use 15 min; for reflux, use 5 min, provided this allows sufficient time for controllers to function. Total volume = 1.3 × holdup if the holdup volume is >3 m^3.

16.11.6.35 Storage Vessels and Bins

Guidelines

For liquids, consider floating-head vertical cylinders for pressures <100 kPa; spheres, vertical cylinders with dome ends for pressures <250 kPa; small spheres and horizontal cylindrical tanks for pressures <800 kPa. For gases, consider pressure cylinders and small horizontal cylindrical tanks for pressures >800 kPa. For solids, bins, and hoppers: promote mass flow with cone angle to the vertical related to the wall friction angle of the solid.

Wall Friction Angle	Cone Angle with the Vertical	Wedge Angle with the Vertical
	<	<
30°	10°	20°
20°	25°	38°
10°	35°	48°
0°	45°	60°

Both bottom angle and surface smoothness are important. For a circular cone, the outlet should be at least six to eight times the diameter of the largest particle. For wedge hoppers, the discharge opening should be at least three to four times the diameter of the largest particle. The length of the slot opening should be at least three times the width. The desired mass flow requires the entire discharge opening to be active by the use of: tapered interface belt conveyor, a tapered shaft screw conveyor, a screw conveyor with an increasing pitch (providing the length:screw diameter is <3:1), or a combination of screw conveyor with a tapered shaft plus increased pitch, provided the length:screw diameter is <6:1.

16.11.7 Mixing*

The major situations are gas-solid, gas-liquid, liquid, and solids. Solids blending can include dry solids blenders; extruders for foodstuffs and polymers; and pug mills for clays, thick pastes, and fertilizers.

* Reproduced with permission from Donald R. Woods, *Rules of Thumb in Engineering Practice,* pages 282 to 291, 2007, copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, ISBN: 978-3-527-31220-7. See this book for more details, especially about Good Practice, Trouble shooting and Capital Costs.

16.11.7.1 Gas–Solid

Gas fluidization is used for reactions (Section 16.11.6.26), to facilitate heat transfer (Section 16.11.3.8), dryers (Section 16.11.5.5), and size enlargement (Section 16.11.9.5).

Area of Application

Solid particle diameter 60 to 80 μm, solid particles with ratio of maximum to minimum diameter about 11 to 25.

Guidelines

Minimum gas fluidization velocity of 0.5 mm/s to 15 mm/s or about a factor of 0.01 to 0.1% of the pneumatic conveying velocity. Ratio of height to diameter ≥1. Bed depth usually 0.3 to 15 m. When used for heat transfer: particles and gas tend to leave the bed at the same temperature. Heat transfer from the bed to the walls: U = 0.45 to 1.1 kW/m^2·°C; from bed to immersed tubes: U = 0.2 to 0.4 kW/m^2·°C; from solids to gas in the bed: U = 0.017 to 0.055 kW/m^2·°C.

16.11.7.2 Gas-Liquid

The flow characteristics are given in Section 16.11.2.4. The area and other contacting characteristics are summarized in Sections 16.11.8.1 and 16.11.8.2. A related topic is bubble reactors (Section 16.11.6.11).

Area of Application

Mechanical agitator: viscosity <50,000 mPa·s; volumes <75 m^3. *Air agitation:* viscosity <1000 mPa·s; volumes >750 m^3. See aeration, size reduction, Section 16.11.8.1. Bubble columns: see size reduction, Section 16.11.8.1; a related topic is bubble reactors (Section 16.11.6.11).

Guidelines

Mechanical agitators: see size reduction (Section 16.11.8.1). Air agitation: see aeration, size reduction (Section 16.11.8.1). Bubble columns: see size reduction (Section 16.11.8.1).

16.11.7.3 Liquid

Related to stirred tank reactors (Sections 16.11.6.23 through 16.11.6.25).

Area of Application

Fluid viscosity and volume to be mixed are the most significant factors. *Propellers:* viscosity <3000 mPa·s; volumes <750 m^3. *Turbines and paddles:* viscosity <50,000 mPa·s; volumes <75 m^3. *Liquid jets:* viscosity <1000 mPa·s; volumes >750 m^3. *Air agitation:* viscosity <1000 mPa·s; volumes >750 m^3. *Anchors:* viscosity <100,000 mPa·s; Re <10,000; volumes <30 m^3. *Kneaders:* viscosity 4,000 to 1.5 × 10^6 mPa·s; volumes 3 to 75 m^3. *Roll mills:* viscosity 10^3 to 200,000 mPa·s; volumes 60 to 450 m^3. For viscosity >10^6 consider extruders, Banbury mixers, and kneaders. *Paddle reel/stator-rotor:* gentle mechanical mixing for coagulation, viscosity <20 mPa·s; volumes large. *Motionless mixers:* viscosity ratio <100,000:1; continuous and constant flow rates; residence times <30 min and flow rate ratio of <100:1. Other related sections are size reduction (Sections 16.11.8.1 and 16.11.8.3), reactors (Section 16.11.6.10), and heat transfer (Section 16.11.3.5).

Guidelines

Turbines, propellers, and paddles: power = 0.2 to 1.5 kW/m^3 for mixing liquids with impeller discharge rate >20 × liquid flow rate into tank. Heat transfer, 0.4 to 2 kW/m^3, but don't neglect heat input from the mixer; mass transfer 2 to 4 kW/m^3. *Turbines, propellers, and paddles:* power = 1 to 4 kW/m^3 for mass transfer. *Air agitation:* diffused air: 0.3 to 0.5 Ndm^3/s·m^3; 1.5 to 6 dm^3/s·m

of linear distance along the basin. Diffusers 15 to 30 dm^3 air/s·m^2 diffuser area. For 45-min detention time, 0.6 to 1 dm^3/L. See related topics, flocculation (Section 16.11.9.3) and size reduction, gas in liquid (Section 16.11.8.1). *Anchor:* power = 4 to 9 kW/m^3. *Gentle mechanical mixing, such as paddle reel or stator-rotor for flocculation* (see related topic, Section 16.11.9.3): 0.035 to 0.04 tapering to 0.001 to 0.009 kW/m^3. *Motionless mixers:* for viscosity ratio <100:1 and Reynolds no., *Re* >10,000, use turbulent vortex mixer; for viscosity ratio >100:1 and *Re* <10,000, use helical element. For pipe diameter <0.3 m, element is 1.5 × pipe diameter; for pipe diameter >0.3 m; element = pipe diameter. For *Re* <10, use 18 elements with the number of elements reducing to 2 as Reynolds no. increases to >5000. *Annular sparger:* annular sparger blends liquids of equal viscosity and density in 50 pipe diameters; central injection blends liquids of equal viscosity and density in 80 pipe diameters; in mixing tee after 10 pipe diameters. For viscosity differences <10:1, inject the viscous liquid into the thin liquid. For *blending and heat transfer*, identify viscosity when turbulent mixing occurs. Usually, impeller *Re* of 200.

16.11.7.4 Liquid-Liquid

Related sections are solvent extraction (Section 16.11.4.10), size reduction (Section 16.11.8.3), and reactors (Sections 16.11.6.9 through 16.11.6.16, 16.11.6.23 through 16.11.25, and 16.11.6.30).

Area of Application

Fluid viscosity and volume to be mixed are the most significant factors. Propellers: viscosity <3000 mPa·s; volumes <750 m^3. Turbines and paddles: viscosity <300,000 mPa·s; volumes <75 m^3.

Guidelines

Propellers and turbines: power: 0.2 to 1.5 kW/m^3 for mixing immiscible liquids, with values decreasing as the interfacial tension decreases, and for heat transfer. Power: 1 to 4 kW/m^3 for emulsification and mass transfer.

16.11.7.5 Liquid-Solid

Area of Application

Stirred tank: crystallizers, see Section 16.11.4.6; and reactors, Sections 16.11.6.23 through 16.11.6.25. Liquid fluidized bed: reactors, Section 16.11.6.26; liquid adsorption, Section 16.11.4.12; ion exchange, Section 16.11.4.13; backwash fixed-bed operations such as deep-bed filters, Section 16.11.5.13; liquid adsorbers, Section 16.11.4.12; and ion exchangers, Section 16.11.4.13.

Guidelines

Stirred tank: paddles: power input: suspend solids, 0.2 to 1.6 kW/m^3; *L/D* = 0.7 to 1.05/1. Baffle, four @ 90°; baffle width = 0.08 × tank diameter; off-the-wall distance = 0.015 × tank diameter. Minimum level of liquid = 0.15 × tank diameter for impeller:tank diameter 0.28:1 and minimum level = 0.25 × tank diameter for impeller:tank diameter = 0.4:1. Use a foot bearing plus a single, main axial hydrofoil impeller diameter = 0.28 × tank diameter located 0.2 × tank diameter from the bottom plus a pitched blade impeller diameter = 0.19 × tank diameter located 0.5 × tank diameter from the bottom. *Liquid fluidized bed:* in general, particle diameter 0.5 to 5 mm with density and diameter of the particle dependent on the application. The superficial liquid velocity to fluidize the bed depends on both the diameter and the density difference between the liquid and the particle. Usually, the operation is particulate fluidization. Particle diameter 0.2 to 1 mm reactors; superficial liquid velocity 2 to 200 mm/s. *Fluidized adsorption:* bed expands 20 to 30%; superficial liquid velocity for usual carbon adsorbent = 8 to 14 mm/s. *Fluidized ion exchange:* bed expands 50 to 200%; superficial liquid velocity for usual ion exchange resin = 40 mm/s. *Backwash operations:* fixed-bed adsorption: superficial liquid velocity = 8 to 14 mm/s; fixed-bed ion exchange: superficial backwash velocity = 3 mm/s.

16.11.7.6 Dry Solids

Area of Application

For free-flowing particles that do not segregate, use mixers where outside shell moves (cone, double cone, zigzag). For pastes, plastics, and powders that tend to segregate, use mixers with outside shell fixed (ribbon, edge mill, double arm, Banbury, extruder).

Guidelines

Working capacity is 50 to 60% of total internal volume. Mixing residence times are 3 to 10 min. Mixing time increases with (particle diameter)$^{0.5}$. Rpm 20 to 100. Speed of rotation (rpm) × mixing time (minutes) = 300. *Double cone:* 0.1 to 10 m^3 working capacity; 10 kW/m^3 reducing to 2 kW/m^3 as the working capacity increases. *Ribbon:* 0.02 to 15 m^3 working capacity; 50 kW/m^3 reducing to 4 kW/m^3 as the working capacity increases. *Edge mill:* 1 to 3 m^3 working capacity; 40 to 50 kW/m^3 and relatively independent of working volume. *Double arm:* 0.05 to 3 m^3 working capacity; 100 kW/m^3 and relatively independent of working capacity. Banbury: 0.1 to 0.3 m^3 working capacity; 10,000 kW/m^3 and relatively independent of working capacity.

16.11.7.7 Pastes, Polymers, Foodstuffs, Clay, and Fertilizers

See size enlargement, Section 16.11.9.14. Related topics are size reduction (Section 16.11.8.5) and dewatering rotary press (Section 16.11.5.13).

Area of Application

Use mixers with outer shell fixed.

16.11.8 Size Reduction*

16.11.8.1 Gas in Liquid (Bubbles in Liquid)

Gas-liquid contacting for reactions, separations, mixing. See reactions (Section 16.11.6.11), separations (Sections 16.11.4.8 and 16.11.4.9), and mixing (Section 16.11.7.2) for separate rules of thumb. Flow characteristics are summarized in Section 16.11.2.4.

Area of Application

Aeration: gentle mixing and oxygenation of bio reactors. *Bubble column:* area per unit volume 5 to 70 m^2/m^3; can handle solids, high-pressure drop. *Spray column:* area per unit volume 10 to 100 m^2/m^3; can handle foaming and solid-laden gases, low pressure drop. Reactions: good for reaction with highly soluble gases. *Packed column:* area per unit volume 75 to 200 m^2/m^3; low pressure drop, cannot handle solids, can handle foaming by operating in the cocurrent upflow bubble region. Little flexibility in varying the gas/liquid volumetric flow rates because of flooding. *Tray column:* area per unit volume 75 to 400 m^2/m^3; can handle solids, cannot handle foaming. Some flexibility in varying the gas/liquid volumetric flow rates. *Agitated tank:* area per unit volume 20 to 200 m^2/m^3; can suspend solids, maximum pressure limited by the seal around the rotating mixing shaft. *Motionless mixer:* area per unit volume 1,000 to 7,000 m^2/m^3; cannot handle foaming; see also liquid-liquid, Section 16.11.8.3. *Pipe/tubes, transfer line:* area per unit volume 50 to 2.000 m^2/m^3; high pressure drop, Reactions: use with irreversible reactions and pure gas feed.

Guidelines

Aeration: 0.3 to 0.5 dm^3/s·m^3. Fifteen to 30 dm^3/s·m^3 diffuser area; or 1.5 to 6 dm^3/s·m of linear length of diffuser. Need 75 to 110 m^3 air/kg BOD removed; 0.018 to 0.04 g oxygen absorbed/dm^3

* Reproduced with permission from Donald R. Woods, *Rules of Thumb in Engineering Practice,* pages 291 to 297, 2007, copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, ISBN: 978-3-527-31220-7. See this book for more details, especially about Good Practice, Trouble shooting and Capital Costs.

air sparged into the liquid. k_La = 0.0008 1/s. A related section is mixing (Section 16.11.7.3). *Bubble column:* superficial gas velocity, 0.03 to 0.04 m/s holdup <0.2, k_La = 0.005 to 0.01 1/s. k_La is independent of the diameter if column diameter >0.15 m; k_La is not affected by the type of gas sparger if the gas velocity exiting the orifice is >0.03 m/s. If <0.03 m/s, then use a sintered plate. Height: 3 < height < 12 m; allow 0.75 of diameter or 1 m at the top for foam disengagement. Energy 0.01 to 1 kW/m^3. *Spray column:* superficial gas velocity, 0.75 to 2 m/s; holdup <0.8, energy: high for atomization; k_La = 0.0007 to 0.015 1/s. *Packed column:* superficial gas velocity, 0.75 to 1.5 m/s for atmospheric pressure; 0.2 m/s for pressure operation and 2.5 m/s for high vacuum; holdup <0.95; energy 0.01 to 0.2 kW/m^3; k_La = 0.005 to 0.02 1/s; packing >6 mm; catalyst >3 mm. Column diameter/packing diameter >8 and prefer >30 to prevent liquid channeling. Redistributors every 3 to 4.5 m. Higher mass transfer coefficient, k_La = 0.15 1/s for cocurrent upflow in the bubble regime. *Tray column:* superficial gas velocity, 0.75 to 1.5 m/s for atmospheric pressure; 0.2 m/s for pressure operation and 2.5 m/s for high vacuum; holdup <0.8; energy 0.01 to 0.2 kW/m^3; k_La = 0.01 to 0.05 1/s. *Agitated tank:* superficial gas velocity, 0.05 to 1 m/s; holdup <0.1, energy 0.1 to 4 kW/m^3; k_La = 0.02 to 0.2 1/s. Height of liquid = tank diameter or use multiple impellers if height of liquid/tank diameter is >2. Impeller diameter 0.3 to 0.5 of tank diameter. *Motionless mixer:* superficial gas velocity, 1 to 2 m/s; holdup 0.5, energy 10 to 700 kW/m^3; k_La = 0.1 to 3 1/s. Volumetric flow rate of gas to liquid = 1 at the nozzle. *Pipe/tubes, transfer line:* superficial gas velocity, 0.01 to 0.4 m/s; holdup 0.05 to 0.95; energy 0.1 to 100 kW/m^3. For <10-cm dia. tubes, k_La = 0.01 to 0.7 1/s.

16.11.8.2 Liquid in Gas (Sprays)

Area of Application

Pressure nozzle: spray diameter 70 to 10,00 µm; capacity 0.03 to 0.3 L/s; low viscosity and clean fluids. *Spinning disc:* spray diameter 50 to 250 µm; capacity 0.0015 to 0.4 L/s; for usual fluids and for viscous fluid or fluid containing solids. *Twin fluid:* spray diameter 2 to 80 µm; capacity 0.03 L/s; increasing the ratio of atomizing fluid to liquid from 1 to 10, will decrease the spray diameter by a factor of 10. *Rayleigh breakup* to produce uniform drops of diameter 1.8 × diameter of orifice. A related topic is prilling (Section 16.11.9.14). *Surface aerators:* for activated sludge oxidation (instead of diffused air aeration, Section 16.11.8.1). *Brush aerators:* for oxidation ditches. *Motionless mixers:* spray flow.

Guidelines

Pressure nozzle: pressure 0.45 to 14 MPa; increasing the pressure increases the capacity. *Spinning disc:* increasing the capacity increases the drop size. *Twin fluid:* high energy input. *Surface aeration:* 0.01 to 0.025 kW/m^3 or 0.3 to 1.2 kg O_2/MJ. *Brush aeration:* 0.015 to 0.018 kW/m^3 0.6 to 0.8 kg O_2/MJ. *Motionless mixers:* spray flow: gas superficial velocity 3 to 25 m/s; liquid superficial velocity 0 to 0.6 m/s. Turbulent flow.

16.11.8.3 Liquid-Liquid

Liquid-liquid contacting for reactions, separations, mixing. See reactions, Section 16.11.6.26; separations, Section 16.11.4.10; and mixing, Section 16.11.7.4, for separate rules of thumb.

Area of Application

Mixer in tank: drop diameter 4 to 5000 µm; capacity >0.05 L/s; for viscosities <10^4 mPa·s. *Colloid mill:* drop diameter 1 to 8 µm; capacity 0.01 to 3 L/s; for viscosities <10^4 mPa·s but usually >1000 mPa·s. *Homogenizer:* drop diameter 0.1 to 2 µm; capacity 0.03 to 30 L/s; for viscosities <10^3 mPa·s but usually <200 mPa·s; decrease the drop diameter by increasing the exit pressure. *High shear disperser:* for viscosities 10^3 to 5 × 10^6 mPa·s. *Roller mills:* for viscosities >10^3 mPa·s. *Motionless mixer:* drop diameter 100 to 1000 µm (about 0.15 times drop diameter for fluid velocity in a pipe

without the mixer); capacity 0.3 to 5 L/s. The densities and flow rates of the two phases should be about equal; viscosities <50 mPa·s. See also gas in liquid, Section 16.11.8.1. *Ultrasonic:* drop diameter 1 to 2 μm; capacity 1 L/s.

Guidelines

Mixer in tank: surface area 400 to 10,000 m^2/m^3, with area increasing with decreasing surface tension and increasing velocity. Power 3 kW/m^3. *Colloid mill:* surface area 10,000 to 2,000,000 m^2/m^3, with areas increasing with decreasing drop diameter and increasing volume fraction of dispersed phase. Power 40 to 200 kW·s/L. *Homogenizer:* surface area 20,000 to 10,000,000 m^2/m^3, with areas increasing with decreasing drop diameter and increasing volume fraction of dispersed phase, power 25 to 120 kW·s/L; power increases as exit pressure increases from 3.5 to 55 MPa. *Motionless mixer:* surface area 100 to 20,000 m^2/m^3, depending on the drop diameter and the concentration of dispersed phase. Velocity 0.25 to 2.5 m/s. Turbulent flow. Δp is 100 × Δp in pipe without mixer; *L/D* about 33; power 0.001 to 0.015 kW·s/L. *Ultrasonics:* 18 to 30 kHz for 1 to 2 μm dia. drops.

16.11.8.4 Solids: Crushing and Grinding

Capacities are expressed for open-circuit operation. For closed-circuit with the same size reduction ratio, power, reduce the capacity by a factor of 2. Rod mill product is usually larger in diameter than from a ball mill. Selection depends on the size of feed, the reduction ratio, the target diameter, the capacity, hardness, toughness, fibrosity, and stickiness, and whether wet grinding is OK. Ball and rod mills can be used for most hardnesses including fibrous, friability, and stickiness. Use jaw crushers for hard materials but shift to cone crushers when Mohs hardness is <8, but not for sticky materials. Size reduction is about 1 to 5% efficient; most of the energy generates heat. Very ductile materials are difficult to break mechanically; use cold temperature to make brittle. Impact mills give products with less area per unit mass than ball or rod mills.

Area of Application

Jaw crusher: feed diameter 0.1 to 1.5 m; reduction ratio 5:1 to 10:1; capacity 1 to 300 kg/s; Mohs hardness <9 (reduction by compression). *Gyratory crusher:* feed diameter 0.75 to 1.5 m; reduction ratio 5:1 to 10:1, usually 8:1; capacity 140 to 1,000 kg/s; Mohs hardness <9. More suitable for slabby feeds than jaw crusher (reduction by compression). *Roll crusher:* feed diameter 1 cm; reduction ratio 5:1 to 10:1; capacity 0.3 to 20 kg/s; Mohs hardness <7.5. Suitable for softer, friable, and nonabrasive materials. OK for wet and sticky materials. *Cone crusher and short head cone:* feed diameter <25 cm; reduction ratio 5:1 to 10:1, usually 7:1; capacity 5 to 300 kg/s; Mohs hardness <8. Usually secondary or tertiary crusher. *Impact crusher:* pulverizers, shredders, or smooth roll: feed diameter 1 cm with a reduction ratio of 7:1 to 10:1; capacity 0.3 to 50 kg/s. *Mills, hammer,* feed diameter 10 mm, reduction ratio 10:1 to 50:1, capacity 0.01 to 5 kg/s; Mohs hardness <4.5. Maximum fines; feed not hard or abrasive. *Mills, ball, and rod:* feed diameter 0.5 mm with a reduction ratio of 10:1 to 50:1; Mohs hardness <9. *Mills, autogenous, semiautogenous;* feed diameter 200 mm, reduction ratio 10:1 to 50:1; capacity 0.1 to 100 kg/s; Mohs hardness <6. *Mills, fluid energy:* feed diameter 50 μm; reduction ratio 10:1 to 50:1; capacity <2 kg/s; Mohs hardness <4.5.

Guidelines

Two-stage grinding has lower capital cost but higher operating cost than single-stage primary grinding. Ball mills have lower capital costs but higher operating costs than pebble mills. Semiautogenous usually have lower capital and operating costs than fully autogenous. With breakage by compression, the power needed increases with an increase in hardness of the solid being processed. With breakage by tumbling, the power increases with an increase in the reduction ratio and relatively independent of the hardness. *Jaw crushers:* power 0.5 to 5 MJ/Mg; rpm 300 to 100; maximum

capacity occurs under choke feed; minimum of fines (breakup by compression). Product diameter determined by the adjustment clearance between compressing plates. *Gyratory crusher:* power 3 to 10 MJ/Mg; rpm 450 to 110; minimum of fines (breakup by compression), product diameter determined by the adjustment clearance between compressing plates. *Cone crusher:* selected as secondary and tertiary reducers; power 0.9 to 5 MJ/Mg; rpm 290 to 220; (breakup by compression) product diameter determined by the adjustment clearance between compressing plates. *Short head cone crusher:* power 3 to 12 MJ/Mg; (breakup by compression) product diameter determined by the adjustment clearance between compressing plates. Often, choke fed as tertiary crusher. *Roll crusher:* power 3 to 15 MJ/Mg; (breakup by compression) product diameter determined by the space between the rolls. Speed determines the capacity. *Roller mill:* 50 to 500 kPa, (breakup by compression) product diameter determined by the space between the rolls. Speed determines the capacity. *Shredders:* power 25 to 250 MJ/Mg. *Hammer mill:* power 2 to 80 MJ/Mg, (breakup by impact against a plate traveling at 20 to 60 m/s) product diameter determined by exit screen size. *Cage mill:* (breakup by impact against a plate traveling at 20 to 30 m/s) product diameter determined by exit screen size. Handles amorphous materials. *Pin-disc mill:* (breakup by impact against a plate traveling at 200 m/s) product diameter determined by feed flow rate and speed of the pins. Ideal for soft material. *Impact mill:* (breakup by impact against a plate traveling at 50 to 110 m/s) product diameter determined by exit screen size. *Autogenous mill:* length:diameter 0.2 to 0.5 with 0.33 usual (breakup by impact among particles). *Rod mill:* power 5 to 80 MJ/Mg; length:diameter 1.4:1 to 1.6:1 with length <6.8 m; 35 to 40% v/v rod charge to give total charge of 45% v/v. (Breakup by variety of mechanisms with revolving media.) *Ball mill:* power 30 to 10,000 MJ/Mg; length:diameter 1:1 to 2:1; 50% v/v charge of balls (breakup by variety of mechanisms with revolving media); large balls give coarse particles, small balls give fine particles. *Fluid energy mill:* about 6 to 9 kg air/kg of solid or 1 to 4 kg steam/kg solid; (breakup by impact with other particles traveling at 100 to 300 m/s) product size determined by the feedrate. Power 700 to 1000 MJ/Mg.

16.11.8.5 Solids: Modify Size and Shape: Extruders, Pug Mills, and Molding Machines

See size enlargement, Section 16.11.9.14.

16.11.8.6 Solids: Solidify Liquid to Solid: Flakers, Belts, and Prill Towers

See Section 16.11.9.15.

16.11.9 Size Enlargement*

16.11.9.1 Size Enlargement: Liquid-Gas: Demisters

Area of Application

In general, liquids should not bind to the inserts or walls; they should flow as rivulets or drops along the surface of the insert. *Vane separators:* droplet diameter >20 μm; droplet concentration >0.1 mg/m^3. *Mesh pads:* droplet diameter 3 to 20 μm; droplet concentration 0.01 to 0.1 mg/m^3. *Fiber beds designed for impaction* (usually cylindrical or "candles"): droplet diameter 0.2 to 3 μm; droplet concentration 0.001 to 0.01 mg/m^3. *Fiber beds designed for Brownian motion* (usually cylindrical or "candles"): <0.1 μm; droplet concentration <10^{-3} mg/m^3.

* Reproduced with permission from Donald R. Woods, *Rules of Thumb in Engineering Practice,* pages 298 to 309, 323 to 324, 2007, copyright Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, ISBN: 978-3-527-31220-7. See this book for more details, especially about Good Practice, Trouble shooting and Capital Costs.

Guidelines

For all devices, inlet gas flow rates 80 to 120% of design. *Vane separators:* collecting fiber >300 µm; gas velocity 2.5 to 5 m/s; Δp 0.03 to 0.25 kPa. *Mesh pads:* collecting fiber 100 to 300 µm; gas velocity 2 to 4 m/s with smaller values used as liquid loading increases; Δp 0.1 to 0.75 kPa. *Fiber beds/impact:* collecting fiber 10 to 40 µm; gas velocity 1.25 to 2.5 m/s; Δp 1 to 2.5 kPa. *Fiber beds/Brownian motion:* collecting fiber 8 to 10 µm; gas velocity 0.05 to 0.25 m/s; Δp 1 to 4.5 kPa.

16.11.9.2 Size Enlargement: Liquid-Liquid: Coalescers

Area of Application

Stacked trays: droplet diameter >10 µm; concentration <15% v/v. *Packed bed:* droplet diameter 1 to 10 mm. *Mesh:* droplet diameter 50 to 500 µm. *Fibrous bed:* droplet diameter <20 µm; usually 1 to 9 µm; concentration <1% v/v. *Deep bed:* droplet diameter <1 µm. See Section 16.11.5.13. Ultrafiltration: see Section 16.11.4.21.

Guidelines

Stacked trays: 1 to 25 L/s per pack of trays on 2-cm spacing with 75 m^2 area per pack. Diameter of captured drop increases as the flow rate increases and the density difference and interfacial tension decrease. *Packed beds:* at lower capacities, the exit drop diameter is proportional to the void diameter in the packing. *Mesh:* use mix of high- and low-energy materials in mesh about 100 to 500 µm; flood velocities for mixed high- and low-energy fiber mesh <1.2 m/s; pressure drop 6 to 140 kPa. *Fibrous bed:* select fiber diameter that is about the diameter of droplets, fibers about 10 to 40 µm; typical exit drop diameter two to four times the inlet diameter; flood velocities 1 cm/s; usually design for 0.5 cm/s or 5 $L/s \cdot m^2$ with velocity decreasing as surface tension decreases. Try for surface tension >20 mN/m.

16.11.9.3 Size Enlargement: Solid in Liquid: Coagulation/Flocculation

Area of Application

Particle diameter <1 µm; solids concentration <0.1%. Related to flocculants for thickening (Section 16.11.5.9).

Guidelines

Add coagulant: usually alum in the sweep floc concentration of 20 to 50 mg/L; adjust pH to 6 to 9. *Rapid mix:* 45 s residence time with 1.5 kW/m^3 turbine agitation. *Basin:* velocity gradient, G, at the inlet 150 to 200 s^{-1} reduced to 50 s^{-1} later in the basin. Allow residence time for $Gt = 10^5$. For choice of mixer, see Section 16.11.7.3.

16.11.9.4 Size Enlargement: Solids: Spray Drying

A related topic is dryer (Section 16.11.5.5). For size of spray, see Section 16.11.8.2.

Area of Application

Product diameter: 0.15 to 2 mm.

16.11.9.5 Size Enlargement: Solids: Fluidization

Related topics are gas-solid mixing (Section 16.11.7.1) and reactors (Section 16.11.6.27).

Area of Application

Product diameter: 0.6 to 2.5 mm; batch process. For spouted bed with feed diameter >1 mm, gives product diameter of 3 to 3.5 mm.

Guidelines

Fluidized bed: 30 to 50 min for batch of 200 to 700 kg. Shallow bed, 0.3 to 0.6 m deep; gas velocity 0.1 to 2.5 m/s or 3 to 10 × minimum fluidization velocity. Evaporation rates 0.005 to 1 kg/s·m^2 cross-sectional area.

16.11.9.6 Size Enlargement: Solids: Spherical Agglomeration

Area of Application

Product diameter: 2 to 3 mm; batch; tensile strength of agglomerate: 10 to 100 kPa.

Guidelines

Power 10 to 40 kW/m^3. Mixing time 30 to 300 s.

16.11.9.7 Size Enlargement: Solids: Disc Agglomeration

Area of Application

Product diameter: 10 mm, fertilizer 1.5 to 3.5 mm; ore 10 to 25 mm. Capacity <25 kg/s. Tensile strength of agglomerate 10 to 200 kPa, depending on the binder. Produces more nearly uniform granules than drum (Section 16.11.9.8).

Guidelines

Rotational speed about 50% of critical speed or 30 rpm decreasing to 6 rpm as diameter increases. Disc area = 0.1 to 200 m^2. L:D = 0.1 to 0.22; angle of inclination with the horizontal 40 to 70°. Power = 7 to 9 kW·s/kg or MJ/Mg.

16.11.9.8 Size Enlargement: Solids: Drum Granulator

Area of Application

Product diameter 2 to 5 mm; capacity 0.001 to 30 kg/s. Tensile strength of the agglomerate: 10 to 200 kPa, depending on the binder.

Guidelines

Drum volume: 5 to 100 m^3. L:D = 2 to 4; angle of inclination with the horizontal, 10°. For fertilizer: 5 to 7 kW·s/kg or MJ/Mg. For iron ore: 2 kW·s/kg. 10 to 20 rpm. Product diameter controlled by speed, residence time, and binder.

16.11.9.9 Size Enlargement: Solids: Briquetting

Use of pressure to create agglomerate.

Area of Application

Product diameter 15 to 80 mm; capacity 1 to 30 kg/s. Crushing strength of agglomerate 1 to 10 MPa.

Guidelines

Constant product volume; operating pressure <50 MPa. Power 2 to 50 MJ/Mg.

16.11.9.10 Size Enlargement: Solids: Tabletting

Use of pressure to create agglomerate.

Area of Application

Product diameter 15 to 100 mm; capacity 0.011 to 1.5 kg/s. Crushing strength of agglomerate 1.5 to 10 MPa.

Guidelines

Operate either as *constant volume machine:* mechanical tabletter with operating pressure <50 MPa, or *constant mechanical tensile strength (constant pressure) machine:* hydraulic tabletter with operating pressure 150 to 250 MPa. Power: 50–60 MJ/Mg.

16.11.9.11 Size Enlargement: Solids: Pelleting

Use of pressure to create agglomerate.

Area of Application

Product diameter 2 to 30 mm; capacity <6 kg/s. Cylindrical-shaped product; used primarily for foodstuffs. Feed is usually a viscous paste.

Guidelines

Power 18 to 70 MJ/Mg.

16.11.9.12 Size Enlargement: Solids: Sintering/Pelletizing

Use of high temperature to create strong agglomerates. Related sections are reactors (Sections 16.11.6.19 and 16.11.6.20), and kilns (Section 16.11.3.7).

Area of Application

Product diameter 80 to 150 mm; capacity 15 to 300 kg/s; product crush strength >10^4 kPa.

Guidelines

Capacity 0.015 to 0.04 kg/s·m^2 traveling grate; 0.012 kg/s·m^3 volume of rotating kiln.

16.11.9.13 Size Enlargement: Solids: Crystallization

See Section 16.11.4.6.

16.11.9.14 Solids: Modify Size and Shape: Extruders, Pug Mills, and Molding Machines

See related topic dewatering press (Section 16.11.5.13).

Area of Application

Batch: injection molding machine: thermoplastics: commodity resins, polyolefins (LDPE, HDPE, PP), styrenics (PS, PMMA. polycarbonates, ABS, PET), and engineered resins for higher impact strength. *Continuous: extruder:* thermoplastics. *Casting:* PP: fine film: 10 to 50 μm; *cast film:* 100 to 400 μm; *thermoformable sheet:* 200 to 2500 μm. *Film blow:* LDPE, HDPE, PP. *Pug mill:* clay materials for bricks, tiles, and ceramics.

Guidelines

Batch: cycle: fill, cool, unload. *Injection molding machine:* cycle: injection fill, 1/4 cycle or about 3 s; cooling time 3/4 cycle cool such that a release in pressure does not cause distortion, 17 to 30 s; machine open close, 7 s. Feed temperature = heat distortion temperature + 55°C; example temperature 200°C; mold temperature for commodity resins = 25°C. Viscosity 0.1 to 100 kPa·s; injection pressure 100 MPa. Clamping force 38 MN per m^2 of projected area surface part for polyolefins; 25 to 30 MN/m^2 for styrenics. Cooling time: for polyolefins, 1 s/0.1 mm wall thickness; for styrenics, × 1.3 to 1.8 longer. Cooling time also dependent on type of machine; toggle takes longer than hydraulic, which takes longer than electric. *Continuous: extruder:* for processing polymers: 0.4 to 1 kW·s/g or 400 to 1800 kJ/kg. *Casting:* polyproylene: sheet 0.6 m × 50 μm; extrude at 200°C; drum diameter 0.45 m. Film velocity 1 m/s. *Film blow:* LDPE, PP, HDPE: draw

velocity 0.35 m/s; draw ratio 4:1; extrude at 180°C; mass flow 0.2 g/s; thickness 34 μm. *Extruders for dewatering:* 1 to 4 kW·s/g or 1000 to 4000 kJ/kg. Related to rotary press (Section 16.11.5.13). *Extruders for foodstuffs:* rpm 30 to 40; shear 5 to 10 1/s; power 200 kJ/kg or 0.1 to 0.4 kW·s/g with values increasing with shear. *Extruders and cookers:* for foodstuffs: rpm 60 to 500; shear 20 to 180 1/s; power 75 to 500 kJ/kg. *Pug mills* for clays, thick pastes, and fertilizers: 0.004 kW·s/g or 3 to 12 kJ/kg.

16.11.9.15 Solids: Solidify Liquid to Solid: Flakers, Belts, and Prill Towers

Related topics are size decrease (Section 16.11.8.6) and dryers (Section 16.11.5.5), but use refrigeration (instead of steam) to solidify liquid.

Area of Application

Flaker: liquid feed: product: flakes about 1 cm × 1 cm × 1 mm thick; capacity <10 kg/s. *Chilled belt:* liquid feed: product: pastilles, flakes, pellets; capacity usually <10 kg/s per unit. *Prilling tower:* liquid feed, product diameter: spheres 1 to 3 mm. Capacity <5 kg/s per unit.

Guidelines

Flaker: 20 to 300 g/s·m^2. Heat transfer coefficient 350 W/m^2 C; power: 1 to 50 MJ/Mg, depending on the material; lower values for ammonium nitrate, benzoic acid, tetrachlorobenzene, sodium hydroxide; higher power usages for waxes and resins. *Chilled belt:* feeder: heated overflow weir, viscosities <1000 mPa·s, produces flakes 1 to 3 mm thick; overhead double roll, viscosities <10^8 mPa·s, produces flakes; rotoformer to produce pastilles 1 to 10 mm diameter; heated strip former (for brittle products). Heat transfer coefficient 350 W/m^2 C; 20 to 300 g/s·m^2. Power 1 to 50 MJ/Mg, depending on the material. *Prilling tower:* gas velocities less than the terminal velocity of the prill, <1 to 2 m/s; gas-to-solids ratio 10 kg air/kg solids. Assume solid surface temperature = solidification temperature, volumetric heat transfer coefficient 5 W/m^3 C. Height <60 m.

17.1 INTRODUCTION

Chemical engineers are faced with a variety of safety concerns, from both federal and state authorities as well as management at the corporate and local levels. At the federal level, the "Process Safety Management" standard of the Occupational Safety and Health Administration (OSHA) [1] and the "Risk Management Program" rule of the U.S. Environmental Protection Agency (EPA) [2] present comprehensive requirements for the control of processes to prevent releases of hazardous materials. Similarly, several states (notably, New Jersey, Delaware, and California) require chemical plants and other facilities that handle chemicals to protect the public and employees. Further, many companies and insurers have even stricter requirements for process control and for preventing and reporting of process incidents, including those that do not cause injury or property loss.

This chapter presents methods for meeting the requirements of the federal regulations concerning public and employee safety. Additional information is provided for some aspects of process safety that are not included in this legislation but can affect the safety of operations in facilities handling hazardous materials. There are other resources for analysis and control of general industrial hazards [3, 4].

Calculation procedures presented here help to evaluate the consequences of leaks or spills of hazardous material. However, the methodology and equations can be used for other calculations that are frequently encountered in chemical engineering studies.

17.2 PROCESS SAFETY MANAGEMENT

Table 17.1 shows the aspects of process safety for which actions are required by OSHA in Title 29 of the Code of Federal Regulations, Part 1910, Section 119 (29 CFR 1910.119) [1] and by the EPA in Title 40 of the Code of Federal Regulations, Part 68 (40 CFR 68) [2]. This "Chemical Process Safety" section concentrates on the engineering aspects of "Process Safety Information"—on the "consequences of failure of engineering and administrative controls" and the "qualitative evaluation of a range of the possible safety and health effects of failure of controls" requirements of the OSHA and EPA "Process Hazards Analysis" and the "Off-Site Hazard Assessment."

Appendices B and C of the OSHA Process Safety Management standard provide some guidance concerning the elements of the OSHA standard and, therefore, of similar elements of the EPA standard. To assist in compliance with the Offsite Consequence Analysis element of the EPA standard, dispersion-analysis Reference Tables 1 through 22 and calculation-methods Appendices A through E are provided in the accompanying rule [9].

The type and extent of the EPA requirements depend on the placement of a "stationary source" in Programs 1, 2, or 3. Program 1 eligibility is limited to sites having good histories and presenting no off-site hazards. Program 3 applies to sites subject to OSHA requirements and sites that are identified with the following North American Industrial Classification System [NAICS] codes: 32211, 32411, 32511, 325181, 325188, 325192, 325199, 325211, 325311, and 32532 [2]. Thus, program 3 applies to most large chemical-handling plants. Program 2 applies to other sources.

Additional guidance concerning management systems and calculation methods are provided in the following sections. Pertinent references are presented in Appendices C and D and are indicated by brackets [ ] in the text.

17.3 ELEMENTS OF THE PROCESS SAFETY MANAGEMENT STANDARDS

17.3.1 Management System

The OSHA standard indicates the need for a Process Safety Management (PSM) system by the following statements:

1. Employers need to develop the necessary expertise, experiences, judgement, and proactive initiative within their workforce to properly implement and maintain an effective process safety management program [1, Appendix C].
2. Employers may wish to form a safety and health committee of employees and management representatives to help the employer meet the obligations specified by this standard [1, Appendix C].
3. Employers shall consult with employees and their representatives on the conduct and development of the elements of process safety management in this standard [1, (c2)].

The EPA standard is more specific in its requirement for a Process Safety Management system [2, 68.15]:

1. The owner or operator of a stationary source shall develop a management system to oversee the implementation of the risk management program elements.
2. The owner or operator shall assign a qualified person or position that has the overall responsibility for the development, implementation, and integration of the risk management program elements. When responsibilities for implementing individual requirements of this part are assigned to other persons, the names or positions of these people shall be documented, and the lines of authority shall be defined through an organization chart or similar document.

A PSM system has been defined as the "comprehensive sets of policies, procedures, and practices designed to ensure that barriers to episodic incidents are in place, in use, and effective" [6(G20)], and "the set of formal and informal procedures and activities used by a facility to control and direct process safety" [6(G20)].

The PSM system involves planning, organizing, implementing, and controlling activities at the corporate and site-management ("strategic") levels, at the middle ("managerial") level and at the employee ("task") level [6(G8)]. It depends on the inherent and demonstrated hazards of the processes, their complexity, the numbers and potential exposures of employees, and many other factors, and guidance for PSM system design and implementation is available [6(G25); 6(G8); 6(G10)] (Table 17.2).

Each of the above aspects should normally be assigned to one or more persons in the organization, with periodic (e.g., monthly) reports concerning the success in implementation.

17.3.2 EPA Off-Site Hazard Assessment

Important aspects of process safety are minimizing the frequency and size of releases of hazardous materials and minimizing the exposure of persons to the toxicity, fire, and explosion consequences of hazardous-materials releases. To evaluate the potential hazards of such releases, it is necessary to estimate the rates and durations (or quantities) of possible releases, and then evaluate the consequences of such releases. The following sections provide methods for estimating the rates of releases from process containers and piping.

The EPA standard requires that—for the "worst case" evaluations—the total quantity of toxic or flammable material is released from the vessel that contains the greatest amount, over a 10-min period, and a liquified gas is assumed to be released as a gas (that is, 100% "flashing" to gas or vapor). If the largest container contains liquid or a gas maintained as a liquid by refrigeration, it is assumed that a pool is formed instantaneously (1 cm deep), with evaporation of the hazardous

TABLE 17.2
Factors That Should Be Addressed in the PSM System

Elements of the PSM System	Some Components of the PSM System
New-project design review	Process design, siting, and hazards reviews
Legislation, standards/codes, and internal	Design, construction, operation, and maintenance guidance
Process knowledge	Process design, operating conditions, and protective systems
Training	Orientation, initial, and refresher
Human factors	Operator interactions with controls and equipment
Process and equipment integrity	Materials of construction, and maintenance procedures
Process risk management	Hazards identification and reduction of risk
Management of change	Procedures and authorizations
Incident investigation	Injury, loss, and near-miss, and communication
Audits and corrective actions	Self-examination and third-party studies of practices
Continuous improvement	Updating of control and safety system and practices
Accountability at all levels	Continuity of operations and protection against injury/loss

vapor from the surface of the pool. For evaluation of "alternative" scenarios, the release rates may be calculated as shown in the following sections.

17.3.2.1 Release Source Terms (Gas or Vapor Flow Rates)

The rate of gas or vapor flow through a "hole" in process equipment is a function of (in descending order of importance) the diameter of the hole, the pressure within the equipment, the molecular weight of the gas or vapor, the temperature of the gas or vapor within the equipment, and the specific-heat ratio.

17.3.2.1.1 Hole in Piping or Equipment

The following simplified equation estimates the rate of gas or liquid flow through a hole for "critical-flow" (sonic) conditions (for pressures above about 13 pounds per square inch, gauge [psig]):

$$w_{vapor/gas} = 0.035\, D_{hole}^{2}\, P_o\, [M/T_o]^{0.5} \text{ pounds/second} \tag{17.1}$$

where P_o and T_o are the absolute pressure and absolute temperature upstream of the hole (in pounds per square inch, absolute [psia] and °K, respectively), D_{hole} is the diameter of the hole (in inches), and M is the molecular weight of the gas or vapor. If the pressure is less than 13 psig (thus, subsonic flow), the pressure P_o can be replaced by a "virtual" pressure P_o' (to account for zero flow when the container pressure equals the ambient pressure), as given by

$$P_o' = 14.7\, \{[(P_g + 14.7)/14.7]^{2.5} - 1\}^{0.4} \text{ psia} \tag{17.2}$$

where P_g is the gauge pressure, in psia.

17.3.2.1.2 Guillotine Failure of Piping

The following simplified equation can be used to estimate the rate of gas or vapor flow from the open end of a pipe, for "unchoked" (sub-sonic) conditions [10]:

$$W_{vapor/gas} = 0.15\, D_{hole}^{2}\, P_o\, [M/T_o]^{0.5}\, [D/L]^{0.5} \text{ pounds/second} \tag{17.3}$$

where D and L are the pipe diameter and pipe length (in inches and feet, respectively). Because the above equation would give an "infinite" flow for zero pipe length, it should not be used if the pipe length is less than approximately 40 pipe diameters, and an orifice-flow equation should then be used to estimate the flow.

17.3.2.1.3 Time to Empty a Gas-Filled or Vapor-Filled Container

The quantity of gas or vapor in a container is a function of (in descending order of importance) the container volume, including the connected piping and other nonisolated equipment, the pressure, the molecular weight of the gas or vapor, the temperature, and the "compressibility factor" for the gas or vapor. The following equation can be used with sufficient accuracy for hazards evaluations:

$$W_{vapor/gas} = P_o V_T M / Z_v R T_o \text{ pounds} \tag{17.4}$$

$$T_f = T_o\, (P_f/P_o)^{(k-1)} \text{ °K} \tag{17.5}$$

$$W_{lost} = [V_T M P_o/19.32 T_o][1/Z_o) - (14.7^{(1/k)}/[Z_f P_o^{(1/k)}])] \text{ pounds for ideal gases} \tag{17.6}$$

where V_T is the volume of the container, in cubic feet; Z_o and Z_f are the initial and atmospheric-pressure compressibilities of the vapor or gas (typically near 1.0); R is the ideal-gas constant (19.32 psia-cu.ft./lbmol °K); P_f is the final pressure (14.7 psia, for discharge to the atmosphere); and k is the specific-heat ratio (about 1.4 for air)

$$W_{lost} = [V_T M P_o\ 19.32\ T_o][(14.7/[Z_o P_o])] \text{ pounds for real gases} \quad (17.7)$$

$$t_c = (\text{In } [P_o t_c/14.7])/(0.035\ D_H^2\ [19.32/V_T][T_O/M]^{0.5)} \text{ seconds for ideal gases} \quad (17.8)$$

$$t_c = (\text{In } [P_O t_C/14.7])/(0.23\ D_P^{\ 2}\ [19.32/V_T][T_O/M\}^{0.5}\ [D_P/L]^{0.5)} \text{ for real gases} \quad (17.9)$$

The preceding equations assume that the temperature of the gas or vapor remains constant (isothermal conditions), and this would apply only if the initial temperature was near-ambient and the duration of leakage was very long.

The EPA standard states that the total quantity of gas or vapor is to be divided by 10 min, to obtain a rate of flow that could then serve as input to the dispersion tables.

17.3.2.2 Release Source Terms (Liquid Flow Rates)

The rate of liquid flow through a "hole" in process equipment is a function of (in descending order of importance) the diameter of the hole, the pressure within the equipment (including the "head" of liquid above the hole), the density of the liquid, and the viscosity of the liquid within the equipment.

17.3.2.2.1 Hole in Piping or Equipment

The following simplified equation can be used to estimate the rate of liquid flow through a hole [8, 10]:

$$w_{liquid} = 0.31\ D_{hole}^2\ [dP_g]^{0.5} \text{ pounds/second} \quad (17.10)$$

where P_g is the pressure upstream of the hole, and d is the density of the liquid (in psig and pounds/feet^3, respectively).

17.3.2.2.2 Guillotine Failure of Piping

The following equation can be used to estimate the rate of liquid flow from the open end of a pipe:

$$w_{liquid} = 0.31\ D_{hole}^2\ [dP_g/(1 + [0.08\ L/D])]^{0.5} \text{ pounds per second} \quad (17.11)$$

where L and D are the pipe length and diameter (in feet and inches, respectively).

17.3.2.2.3 Time to Empty a Container of Liquid

The time required to empty a tank of liquid is given by [10]

$$t_{empty} = 1.0\ [D_{tank}/D_{hole}]^2\ H_{liquid}^{0.5} \text{ minutes} \quad (17.12)$$

where D_{tank} and D_{hole} are the tank and hole diameters (in feet and inches, respectively), and H_{liquid} is the initial height of liquid above the hole. The above equation applies only if the pressure in the tank is atmospheric. If other conditions apply, a more complicated procedure should be used [11].

17.3.2.3 Release Source Terms (Two-Phase Flow)

A sudden release of pressure in a container of liquified gas or a liquid that is at a temperature above the atmospheric-pressure boiling point can result in a rapid conversion of some of the liquid to vapor, with a consequent swelling of the now two-phase fluid. Since this fluid is not totally gas or liquid, the equations that are used to calculate flow rates for these phases do not apply. Similarly, venting of a liquified gas or a liquid at a temperature above the atmospheric-pressure boiling point

can result in a conversion of some of the liquid to vapor, with a consequent reduction in flow through a restriction, such as a relief valve, a rupture disk, or piping.

For flow through an orifice, the following equation can be used [10]:

$$W_{two\text{-}phase,hole} = 0.3D_{hole}^{2}\ [d_{liquid}(P_o - P_{vapor})]^{0.5} \text{ pounds/second} \tag{17.13}$$

where d_{liquid} is the liquid density (in pounds/feet^3), P_o is the pressure upstream of the hole, and P_{vapor} is the saturated vapor pressure (both in psia).

For flow through a pipe that is of moderate length (but more than about 4 in. long), the following equation can be used [10, 12]:

$$W_{two\text{-}phase,hole} = 0.08(D_{hole}^{2}P_oMH_{vaporization})[T_o^{1.5}C_{liquid}^{0.5}] \text{ pounds per second} \tag{17.14}$$

where M is the molecular weight of the liquid and vapor, $H_{vaporization}$ is the heat of vaporization (in BTU/pound), T_o is the upstream temperature (in °K), and C_{liquid} is the heat capacity of the liquid (in BTU/pound/°F).

17.3.2.4 Vapor Formation as a Result of Adiabatic Flashing

If a liquid is released while its temperature is above the atmospheric-pressure boiling point, some of the liquid will adiabatically and instantaneously "flash" to vapor; that is, the energy that is released as the liquid temperature drops to the boiling point is utilized in vaporizing some of the liquid. The fraction of liquid that is flash-vaporized often can be obtained from a thermodynamic diagram (such as a pressure-enthalpy plot [8, 13]) for the material of interest, where values of "x" (if shown) indicate the weight-fractions of vapor ("quality") in the two-phase mixture.

If tabulated thermodynamic data are available, the isenthalpic (irreversible adiabatic) "flashing fraction" can be calculated from [10]

$$f = (H_{liquid,Po} - H_{liquid,14.7})/(H_{vapor,14.7} - H_{liquid,14.7}) \tag{17.15}$$

where H is the enthalpy of the liquid or vapor at the initial pressure P_o or at 14.7 psia.

A similar isentropic (reversible adiabatic) calculation yields a smaller flashing fraction.

If thermodynamic data are not available, the "flashing fraction" can be approximated by [14]

$$f = 1 - e^{-2.63(C_{liquid}/H_{vaporization})(T_c - T_b)(1-[(T_c - T)/(T_c - T_b)0.38)} \tag{17.16}$$

where T_o, T_c, and T_b are the initial temperature; the critical temperature and the atmospheric-pressure boiling point, respectively, are in the same dimensions as the liquid heat capacity C_{liquid} and the heat of vaporization $H_{vaporization}$.

The preceding equation is based on an energy balance, with "Watson"-type corrections [8] for (1) the approach to zero of the latent heat of vaporization at the critical temperature and (2) the approach to infinity of the heat capacity at the critical temperature [15].

Some of the escaping liquid is carried with the "flashing" vapor as mist or aerosol, which then vaporizes as it mixes with warmer air and enters the cloud as vapor. It is usually assumed that, if the pressure in the container is the vapor pressure of the liquid, the amount of mist or aerosol is equal to that of the amount of vapor that results from "flashing," except that if the flashing fraction exceeds 33%, the amount of mist or aerosol would be half of the remaining liquid [16], with "rain-out" of the rest of the cold liquid. If, however, the pressure in the vapor space above the liquid is substantially above the vapor pressure, discharge of the contents may result in entrainment of all of the liquid, with no "rain-out" or deposition of liquid [16].

17.3.2.5 Pool Formation from Liquid Spills

The hazards of a spill of a volatile toxic or flammable liquid are primarily dependent on the size of the spill, in terms of its diameter or area, since the rate of evaporation depends primarily on the surface area. If the spill is into a dike or curbed area, the area of the spill that is exposed to evaporation is the area of the confinement. If the spill is onto a surface without confinement, the spill area is related to the viscosity and is limited by the rate of evaporation at the outside edge of the spill.

The area of a confined pool would be governed by the dike area (or curbed area, if the spill can be contained by the curbing). The area of an unconfined spill on an essentially flat surface depends on the average depth of the pool. The following equation gives the approximate pool depth:

$$h_{pool} = 0.3W_{pool}^{0.5}/d_{liquid} = 0.1\ G_{pool}^{0.5}/d_{liquid}^{0.5} \text{ inches} \tag{17.17}$$

where W_{pool} is the weight of liquid in the pool (in pounds), and G_{pool} is the volume of liquid in the pool (in gallons).

For the purposes of the EPA "worst case" evaluation, the pool is assumed to be 0.39 in. (1 cm) deep [2]. The above equation assumes that no vaporization occurs as the pool is developing.

17.3.2.6 Evaluation of Toxicity Hazards

17.3.2.6.1 Toxicity Hazards Analysis

Of the many routes of toxic-material entry into humans, inhalation is the most likely to occur and is the route specified in current legislation. Toxicity data have been developed for most of the important industrial chemicals [19] and form the basis for "threshold" or "allowable" concentrations to which persons cam be exposed with no significant physiological effect. Evaluation of toxicity hazards is then based on the duration of exposures to concentrations above these "threshold" levels. The concentrations of toxic materials in air are primarily functions of vapor pressure and temperature (for toxic liquids); the rate of gas, vapor, mist, or dust release or generation; and distance from the source.

After the rate of toxic material entry into a cloud has been determined (using the equations in the preceding section), the effects of atmospheric conditions on the dispersion (dilution) of the material—particularly gas or vapor—can be evaluated.

Computer programs are available for calculating (1) gas and vapor concentrations; (2) concentration × time products (doses); (3) cloud lengths, widths, and heights; and (4) travel times, as functions of (in decreasing order of importance) wind speed, atmospheric stability, surface roughness, and averaging time. Evaluation and listing of these programs are outside the scope of this publication, but resources are available [6(G40)].

The EPA has selected conservative models for (1) neutrally buoyant gases and vapors and (2) dense gases and vapors. For compliance with the EPA standard [2], the values of the variables that are shown in Table 17.3 were specified by the EPA and should be used [9].

For evaluation of flash-fire hazards involving dispersion of flammable gases and vapors, an averaging time of 0.1 min was used in the EPA tables. Only "passive" mitigation (such as a dike or a confining building) is to be considered for the "worst-case" evaluation, but "active" mitigation (such as valves, transfers, and operator responses) can be considered for the "alternative" evaluations.

Each of the EPA tables can be represented by one or two "exponential" equations, having the form

$$X = Kw_{vapor}^{a}/[MCv_{wind}]^{b} \text{ feet} \tag{17.18}$$

where w_{vapor} is the rate of vapor release to the atmosphere (in pounds per minute); M is the molecular weight of the vapor; C is the concentration of the vapor in air (in mg/L); v_{wind} is the wind speed

TABLE 17.3
EPA Values for Gases and Vapors

Property	Condition	Value
Toxic endpoint	No irreversible effects	Emergency Response Planning Guide–2 or the EPA Level of Concern: 0.1 IDLH (which is about 0.1 LCLo, or 0.01 LC50), or the TWA/TLV
Gas/vapor density	Buoyant or neutral	M < 28 or (vp)M < 500 mm Hg
	Dense	M > 30 or (vp)M > 500 mm Hg
Wind speed	Reference height	10 me
Stability	"F" stable atmosphere	1.5 me/s (3.4 MPH)
	"D" neutral atmosphere	3.0 m/s (6.7 MPH)
Surface roughness	Urban environment	Urban: 1 m; Rural: 3 cm
Averaging time	Short-duration releases	Short: up to 10 minutes; Long: 30 minutes or more
Environment	Ambient	25°C (77°F); 50% relative humidity

(in meters/second), and K, a, and b are functions of the vapor density, atmospheric stability, "surface roughness" (urban, or rural), and the duration of the release. The EPA guidance document provides tables for 10-min releases and for 60-min releases (for release durations that exceed 10 min).

Each of the EPA tables show a "break" in the exponential relationships, and it is necessary to solve each of the pair of equations to determine the distance that could be attained by "toxic endpoint" concentrations. If the distance exceeds the "break point," the "long-distance" equation would apply.

Table 17.4 provides values of K, a, and b for the equations for neutral and dense gases and vapors, rural and urban environments, short-duration releases (10 min), long-duration releases (30 min), and short distances and great distances. Values of EPA toxic endpoints for the EPA listed materials are presented in Appendix A. Also shown are values of toxic endpoints for OSHA-listed materials, based on (in order) ERPG-2 values, 1/10 of the IDLH, or 1/100 of the 4-hour LC50.

TABLE 17.4
EPA Values of *K*, a, and *b* for Gases and Vapors

Gas/Vapor Density	Atmos. Stability	Release Duration (min.)	Ref. Table	Short Distances *K*	Short Distances *a*	Short Distances *b*	Long Distances *K*	Long Distances *A*	Long Distances *b*	Break (feet)
Neutral	"F" stable;	10	1	455,000	1.0	0.48	800,000	1.0	0.60	55,000
	rural	60	2	500,000	1.0	0.50	4,500,000	1.0	0.76	7500
	"F" stable;	10	3	200,000	1.0	0.46	220,000	1.0	0.49	40,000
	urban	60	4	255,000	1.0	0.50	700,000	1.0	0.63	4500
Dense	"F" stable;	10	5	670,000	0.50	0.53	370,000	0.43	0.45	$6800/w_v^{0.5}$
	rural	60	6	3,600,000	0.63	0.66	930,000	0.48	0.49	$22{,}000/w_v^{0.2}$
	"F" stable;	10	7	720,000	0.50	0.58	540,000	0.47	0.54	35,000/*wv*
	urban	60	8	3,000,000	0.64	0.69	1,000,000	0.51	0.55	$30{,}000/w_v^{0.4}$
Neutral	"D" neutral;	10	14	340,000	1.0	0.55	210,000	1.0	0.46	15,000
	rural	60	15	185,000	1.0	0.49	770,000	1.0	0.69	6000
	"D" neutral;	10	16	97,000	1.0	0.46	97,000	1.0	0.46	None
	urban	60	17	70,000	1.0	0.44	235,000	1.0	0.65	5000
Dense	"D" neutral;	10	18	350,000	1.0	0.55	300,000	0.53	0.52	$20{,}000/w_v^{0.4}$
	rural	60	19	500,000	0.61	0.59	500,000	0.61	0.59	None
	"D" neutral;	10	20	460,000	1.0	0.60	240,000	1.0	0.53	$2600/w_v^{0.1}$
	urban	60	21	510,000	0.61	0.62	510,000	0.61	0.62	None

The equations in Table 17.4 thus can be used in "spreadsheet" calculations, with "logic" statements to determine which of the short-distance or long-distance equations applies, to interpolate between values in the EPA Reference Tables [9].

In the above equations, w_v is the rate of vapor release (as gas or vapor, or as vapor from the surface of a pool) in pounds per second, M is the molecular weight of the gas or vapor, C is the concentration of interest in parts per million by volume, and v_w is the wind speed in feet/second.

17.3.2.6.2 Consequence Analysis for Toxicity Hazards

The EPA standard requires that the consequences of a toxic-material release be described in terms of

1. The population within a circle with its center at the point of the release and a radius determined by the distance to the endpoint as determined from the dispersion analysis (release rate, gas or vapor properties, toxic endpoint, and atmospheric conditions). The population is to be estimated to two significant digits. U.S. Census data are available on CD-ROM disks individually, by section of the country, or as a set of 11 from the U.S. Bureau of the Census [301-457-4100].
2. The presence of institutions (such as hospitals, nursing homes, retirement centers, schools, day-care centers, and prisons); parks and recreational areas (such as stadiums and swimming pools); and major commercial, office, and industrial buildings (such as shopping malls and industrial parks) within the circle. Some schools and hospitals are shown on U.S. Geological Survey maps, and the locations of other concentrations of population generally may be found on local street maps. The EPA standard does not require a determination of the population at these locations.
3. The presence of environmental receptors (such as national or state parks, forests, or monuments, wildlife sanctuaries, preserves, refuges, or areas, and Federal wilderness areas) within the circle and as identified on U.S. Geological Survey maps.

The current EPA standard does not require an estimation of the number of persons that might be injured, the types or severity of injuries, the areas of environmental receptors that might be damaged, or the types or severity of damage that might result from a release of hazardous material.

17.3.2.6.3 Risk-Mitigation Methods for Toxic Materials

Mitigation efforts can take several forms [6(G4), 6(G24), 20]. However, the EPA standard allows consideration only of "passive" mitigation systems (that function without human, mechanical, or other energy input) when evaluating "worst case" scenarios. For "alternative" scenarios, the proper functioning of both "passive" and "active" mitigation devices or equipment can be assumed. Typical "post-release" mitigation methods for the protection of personal are as follows, in an approximate decreasing order of effectiveness in each category:

1. Lower "source strength" (reduction in toxic vapor/gas concentration)
   a. "Passive" methods for liquids [2]
      (1) Reducing both the evaporation rate and out-of-doors concentration (by design, so that a spill would be within a confining building)
      (2) Minimizing the surface area of a spill pool (by confining the spill in a diked area)
   b. "Passive" methods for gases or vapors
      (1) Reducing the out-of-doors concentration (by design, so that a release would be within a confirming building)
   c. "Active" methods for liquids [9]
      (1) Dilution of spilled liquid, if miscible
      (2) Neutralization/detoxification of spilled liquid
      (3) Spill-area-limitation devices
   d. "Active" methods for gases or vapors [9]

(1) Water or chemical sprays
(2) Dispersion with air curtains, fans, etc.

2. Lower "source duration" (reduction in duration of release)
   a. "Passive" methods for gases, vapors, or liquids
      (1) Excess-flow valves, to limit the duration of a high-rate leak
      (2) Check valves, for protection against back-flow toward a leak
   b. "Active" methods for gases, vapors, or liquids
      (1) Leak-sensor-actuated block or shutoff valves
      (2) Leak-sensor-actuated de-inventory valves
      (3) Operator-controlled remote-operated shutoff valves
      (4) Operator-controlled de-inventory to a scrubber, absorber, adsorber, or condenser
      (5) Applying spill-covering materials to liquid spills: foam; sheeting; floating granular materials; water (if less dense); adsorbent or reactive
      (6) De-inventory to a stack
      (7) Leak-stopping: patching, plugging, freezing
      (8) Deliberate ignition of flammable vapors or gases
3. Reduced off-site effects of a toxic-material release
   a. "Passive" methods
      (1) Walls or nonporous fences (for dense or cold gases and vapors)
   b. "Active" methods
      (1) Off-site alarms (audible, radio, television, local authorities) to "shelter in place" by entering structures, shutting-off air inlets and exhaust systems, closing doors and windows, etc.
      (2) Evacuation of persons where long-duration exposure would be likely
      (3) Providing self-contained breathing protection to potentially exposed persons

Toxic materials ordinarily would not be expected to cause significant structural damage or property loss, unless the toxic material was also flammable (as addressed in the following section) or corrosive (such as HCl or SO_3).

Prerelease methods for minimizing the size of a hazardous-material release (rate and duration, or quantity) and/or the frequency of any such release involve recognition of potential hazards early in the design of a facility and then incorporating appropriate mitigation features in the design [6(G4), 7, 20, 21].

17.3.2.7 Explosion-Hazards Evaluation

The EPA standard lists 46 flammable materials that are gases at 25°C (77°F) and atmospheric pressure, and 17 "Class IA" flammable liquids (that have flash points below 22.8°C/73°F and have boiling points below 37.8°C/100°F). This standard requires an evaluation of at least one "worst case" explosion involving a listed flammable gas, vapor, or liquid and one or more "alternative" explosions. It may be necessary to evaluate several possible explosions to determine which of them would give the greatest distance to the "endpoint" of 1.0 psig overpressure, and this scenario would then be the "worst case" incident.

17.3.2.7.1 Explosion Hazards Analysis (Unconfined Vapor Cloud Explosion)

The distances attained by a "side-on" blast overpressure of 1.0 psig are given in Reference Table 9 of the Risk Management Program Guidance [9]. A 1.0-psig overpressure was chosen as an explosion-hazards endpoint because this pressure can cause window breakage and damage to houses.

The relationships shown in Table 9 can be described by the following equation:

$$X_{1psig} = 3.4[eW_{flammable}H_{combustion}]^{1/3} \text{ feet} \quad (17.19)$$

where e is the vapor cloud explosion efficiency (0.1, for 10%), $W_{flammable}$ is the weight of flammable vapor (in pounds) in the vapor/air cloud, and $H_{combustion}$ is the heat of combustion (in BTU/pound).

Heats of combustion for the materials that are listed in the EPA guidance are given in Appendix A. Also included in Appendix A are the heats of combustion for several of the materials that are listed in the OSHA standard.

For the "worst case" evaluation, the weight of flammable material in a vapor cloud is assumed to be the total quantity of the substance that could be released from a vessel or pipeline. For liquids, this assumption infers that the liquid is above its atmospheric-pressure boiling point and that 100% flashing to vapor occurs. Also, the entire quantity of vapor is assumed to have concentrations between the lower and upper flammability limits and that the entire quantity explodes, with an energy-conversion efficiency e of 0.10. For mixtures, the weight-average heat of combustion would be used in the above equation.

For "alternative" evaluations, the weight of flammable material in a vapor cloud can be calculated as the gas-release or vapor-release rate multiplied by the estimated time required to stop the release. For liquid releases, the vapor-release rate would be calculated from the liquid-release rate multiplied by twice the flashing fraction (to account for aerosol vaporization) or, for liquids released below the boiling point, as the rate of vaporization from a pool multiplied by the estimated time required to cover or dilute the pool. Also, a lower energy-conversion efficiency (such as 0.03) can be used in the calculation.

The EPA guideline for evaluation of the "far-field" (distant) explosion hazards is based on a "TNT" [TriNitro Toluene] model. Evaluation of the "near-field" (within the vapor cloud, or near the explosion center) requires departure from the blast-pressure and blast-impulse curves for TNT or modification of the distance/quantity relationship [22].

17.3.2.7.2 Consequence Analysis for Explosion Hazards

The EPA standard requires that the consequences of a flammable material release be described in terms similar to those listed for toxicity hazards in Section 17.3.2.6.2 above.

17.3.2.7.3 Risk-Mitigation Methods for Flammable and Explosive Materials

Mitigation of the effects of releases of flammable gases or vapors, or liquids above the boiling point, at high rates is very limited. Further, the EPA standard allows consideration only of "passive" mitigation systems (that function without human, mechanical, or other energy input) when evaluating "worst case" scenarios. For "alternative" scenarios, the proper functioning of both "passive" and "active" mitigation devices or equipment can be assumed.

Typical "post-release" mitigation methods are as follows, in an approximate decreasing order of effectiveness in each category:

1. Lower "source strength" (reduction in vapor concentration)
   a. "Passive" methods
      [None would apply to releases of flammable gases, vapors, or liquids]
   b. "Active" methods [6(G4)]
      (1) Dispersion with existing fans or air curtains, etc.
      (2) Water or chemical sprays
2. Lower "source duration" (reduction in vapor-cloud size)
   a. "Passive" methods
      (1) Excess-flow valves, to limit the duration of a high-rate leak
      (2) Check valves, for protection against back-flow toward a leak
   b. "Active" methods
      (1) Leak-sensor-actuated block or shutoff valves
      (2) Leak-sensor-actuated de-inventory valves
      (3) Operator-controlled remote-operated shutoff valves
      (4) Operator-controlled de-inventory to a scrubber, absorber, adsorber, or condenser
      (5) De-inventory to a stack, for high-elevation release

3. Reduced off-site effects of release
   a. "Passive" methods
      [None would apply to releases of flammable gases, vapors, or liquids]
   b. "Active" methods
      (1) Minimize the probability of ignition by shutting off all ignition sources: welding; vehicles; sparking electrical tools and other "non-explosionproof" electrical equipment; flares; incinerators and boilers (unless protected with flame arresters in the air inlets), actuated by a site-wide alarm
      (2) Off-site alarms (audible; radio; television; local authorities) to "shelter in place" by taking refuge in interior rooms or basements, closing drapes, curtains, and shades over windows, to minimize injury from flying glass [12]

Pre-release methods for minimizing the size of a hazardous-material release (rate and duration, or quantity) and/or the frequency of any such release involve recognition of potential hazards early in the design of a facility and then incorporating appropriate mitigation features in the design [6(G4), 7, 20, 21].

17.3.2.8 Flash-Fire Hazards Evaluation

The hazards of a flash fire, which involves ignition of a cloud containing a mixture of flammable gas or vapor and air, usually are limited to locations where the concentration of gas or vapor exceeds the lower flammable limit (LFL). Because of the relatively short duration of the "flash," persons or combustible materials outside the LFL boundary of the cloud are subjected to a low "dose" of thermal radiation. Somewhat in contrast, persons within the cloud and wearing combustible clothing may be at great risk of serious injury, because the clothing might be ignited by the flash fire [23].

OSHA has recently extended the Personal Protective Equipment standard [24] and its hazard-assessment requirement [25] to include an assessment of flash-fire and jet-fire hazards, with a requirement to consider the wearing of noncombustible clothing where a flash fire (or a jet fire) might occur.

17.3.2.8.1 Flash-Fire Hazards Analysis

The distances attained by LFL concentrations define the hazardous region around a flammable liquid spill or a flammable gas or vapor release. The distances are given in Reference Tables 18, 19, 20, and 21 of the Risk Management Program Guidance [9].

The relationships shown in these tables can be described by the following equations given in Table 17.5.

The dispersion analyses that yielded the EPA tables were based on an averaging time of 6 s as compared with the 10 min and 60 min used for the toxic gas and vapor dispersion analyses. As with toxic materials, the neutral density equations would be used for listed gases and vapors that have a molecular weight <28 or where the product of vapor pressure and molecular weight is <500 millimeters of mercury (mm Hg). In contrast, the dense vapor equations would be used for listed

TABLE 17.5
EPA Equations for Gas or Vapor Lower Flammable Limits

Gas/Vapor Density	Stability; Environment	CAA Table	Distance Equation (feet)
Neutral	"D" neutral; rural	18	$R_{LFL} = 3{,}200[w_v/M(\text{LFL})v_w]^{0.58}$
Neutral	"D" neutral; urban	19	$R_{LFL} = 1{,}800[w_v/M(\text{LFL})v_w]^{0.53}$
Dense	"D" neutral; rural	20	$R_{LFL} = 5{,}500[w_v^{0.54}/M(\text{LFL})v_w^{0.71}]$
Dense	"D" neutral; urban	21	$R_{LFL} = 19{,}000[w_v^{0.53}/M(\text{LFL})v_w]$

vapors that have a molecular weight >30 or where the product of vapor pressure and molecular weight >500 mm Hg.

17.3.2.8.2 Consequence Analysis for Flash-Fire Hazards

The EPA standard does not require an offsite consequence analysis for flash fires unless the flammability endpoint (LFL) is outside the property boundary, or unless there are locations within the property boundary to which the public has routine and unrestricted access during or outside business hours.

If either of these situations could exist, the EPA standard recommends that the consequences of a flash fire be evaluated as an “alternative” scenario for a flammable-liquid release and be described in terms similar to those listed under Toxicity Hazards.

17.3.2.8.3 Risk-Mitigation Methods for Flash Fires

Mitigation efforts can take several forms [6(G4), 6(G24), 20]. For “alternative” scenarios, the proper functioning of both “passive” and “active” mitigation devices or equipment can be assumed.

Typical “post-release” mitigation methods are as follows, in an approximate decreasing order of effectiveness in each category:

1. Lower “source strength” (reduction in concentration)
    a. “Passive” methods for liquids [2]
        (1) Minimizing the surface area of a spill pool (by confining the spill in a diked area)
        (2) Designing so that spills would occur in a building, which would have “explosion-proof” electrical equipment and no other ignition sources
    b. “Passive” methods for gases or vapors
        [None would apply to releases of flammable gases or vapors]
    c. “Active” methods for liquids [9]
        (1) Dilution of spilled liquid, if miscible
        (2) Spill-area-limitation devices
        (3) Ventilating a building in which a spill had occurred [The concentration above a spill would decrease approximately as the 0.22 power ($v^{0.78}/v$) of the air velocity over the spill]
    d. “Active” methods for gases or vapors
        (1) Water or chemical sprays
        (2) Dispersion with air curtains, fans, etc.
2. Lower “source duration” (reduction in duration of release)
    a. “Passive” methods for gases, vapors, or liquids
        (1) Excess-flow valves, to limit the duration of a high-rate leak
        (2) Check valves, for protection against back-flow toward a leak
    b. “Active” methods for gases, vapors, or liquids
        (1) Leak-sensor-actuated block or shutoff valves
        (2) Leak-sensor-actuated de-inventory valves
        (3) Operator-controlled remote-operated shutoff valves
        (4) Operator-controlled de-inventory to a scrubber, absorber, adsorber, or condenser
        (5) Applying spill-covering materials to liquid spills: foam; sheeting; floating granular materials; water (if less dense); adsorbent or reactive
        (6) De-inventory to a stack for elevation above ignition sources
        (7) Leak-stopping: patching, plugging, freezing
3. Reduced off-site effects of a flammable-material release
    a. “Passive” methods
        [None would apply to releases of flammable gases, vapors, or liquids]
    b. “Active” methods

(1) Minimize the probability of ignition, by shutting off all ignition sources: welding; vehicles; sparking electrical tools and other "non-explosionproof" electrical equipment; flares; incinerators and boilers (unless protected with flame arresters in the air inlets), actuated by a site-wide alarm
(2) Off-site alarms (audible; radio; television; local authorities) to "shelter in place" by entering structures, shutting off air inlets and exhaust systems, closing doors and windows, taking refuge in interior rooms or basements [12]

Pre-release methods for minimizing the size of a hazardous material release (rate and duration, or quantity) and/or the frequency of any such release involve recognition of potential hazards early in the design of a facility and then incorporating appropriate mitigation features in the design [6(G4), 7, 20, 21].

17.3.2.9 Pool-Fire Hazards Evaluation

The hazards of a fire above a pool of flammable liquid can be described in terms of thermal radiation intensity and duration of exposure. The EPA standard specifies a radiant-heat endpoint of 5 kilowatts per square meter (or 0.12 calorie per second per square centimeter) and a duration of 40 seconds. The thermal "dose" thus corresponds to 20 joules/cm^2 or 4.8 calories/cm^2 and could cause second-degree burns on unexposed skin, but is unlikely to ignite clothing [26, 27].

17.3.2.9.1 Pool-Fire Hazards Analysis

The EPA standard recommends use of the following equation to determine the hazard distance from pool fires [9], converted to English units:

$$X_{pool} = 0.004H_{combustion}[\varepsilon\tau\, A_{pool}/q_{hazard}/H_{vaporization} + C_{liquid}[T_{boiling} - T_{ambient}])]^{0.5} \text{ feet} \quad (17.20)$$

where $H_{combustion}$ and $H_{vaporization}$ are the heats of combustion and vaporization, respectively (in BTU per pound), q_{hazard} is the hazardous thermal-radiation intensity, A_{pool} is the pool area (in square feet), C_{liquid} is the heat capacity of the liquid in the pool (in BTU/lb/°F), and $T_{boiling}$ and $T_{ambient}$ are the boiling points and ambient temperature, respectively (in °F).

For the EPA evaluations, it is to be assumed that the hazardous intensity of thermal radiation q would be 5 kilowatts per square meter (0.44 BTU/sec/ft^2) and that the duration of exposure would be 40 seconds. Thus, if the exposed person(s) retreated from the pool fire or took refuge in the "shadow" of a structure, the hazard of thermal-radiation exposure could be reduced significantly. It was also assumed that the fraction of heat ε that would be radiated from a pool fire would be 0.4 and that the atmospheric transmittivity τ would be 1.0. Values for ε, τ, and q are available in the literature [26, 27, 28].

17.3.2.9.2 Consequence Analysis for Pool-Fire Hazards

The EPA standard does not require an off-site consequence analysis for pool fires unless the thermal-radiation endpoint (5 kilowatts/m^2) is outside the property boundary, or unless there are locations within the property boundary to which the public has routine and unrestricted access during or outside business hours. If either of these situations could exist, the EPA standard recommends that the consequences of a pool fire be evaluated as an "alternative" scenario for a flammable-liquid release and be described in terms similar to those listed under Toxicity Hazards.

17.3.2.9.3 Risk-Mitigation Methods for Pool Fires

Mitigation efforts can take several forms [6(G4), 6(G24), 20]. For "alternative" scenarios, the proper functioning of both "passive" and "active" mitigation devices or equipment can be assumed.

Typical "post-release" mitigation methods are as follows, in an approximate decreasing order of effectiveness in each category:

1. Lower "source strength" (reduction in concentration)
   a. "Passive" methods for liquids or liquified gases [2]
      (1) Minimizing the surface area of a spill pool (by confining the spill in a diked area)
      (2) Designing so that spills would occur in a building, which would have "explosion-proof electrical equipment and no other ignition sources
   c. "Active" methods for liquids and liquified gases [9]
      (1) Dilution of spilled liquid, if miscible
      (2) Spill-area-limitation devices (personnel wearing flash suits over Level A protective clothing)
      (3) Ventilating a building in which a spill had occurred [The concentration above a spill would decrease approximately as the 0.22 power ($v^{0.78}/v$) of the air velocity over the spill]
      (4) Water or chemical sprays
      (5) Dispersion with air curtains, fans, etc.
2. Lower "source duration" (reduction in duration of release)
   a. "Passive" methods for liquids or liquified gases
      (1) Excess-flow valves, to limit the duration of a high-rate leak
      (2) Check valves, for protection against back-flow toward a leak
   b. "Active" methods for liquids or liquified gases
      (1) Leak-sensor-actuated block or shutoff valves
      (2) Leak-sensor-actuated de-inventory valves
      (3) Operator-controlled remote-operated shutoff valves
      (4) Operator-controlled de-inventory to a scrubber, absorber, adsorber, or condenser
      (5) Applying spill-covering materials to liquid spills: foam; sheeting; floating granular materials; water (if less dense); adsorbent or reactive
      (6) De-inventory to a stack for elevation above ignition sources
      (7) Leak-stopping: patching, plugging, freezing
3. Reduced off-site effects of a flammable-material release
   a. "Passive" methods for pool fires involving flammable liquids or liquefied gases
      [None would apply to releases of flammable liquids or liquified gases]
   b. "Active" methods for pool fires involving flammable liquids or liquified gases
      (1) Minimize the probability of ignition, by shutting off all ignition sources: welding; vehicles; sparking electrical tools and other "non-explosionproof" electrical equipment; flares; incinerators and boilers (unless protected with flame arresters in the air inlets), actuated by a site-wide alarm
      (2) Off-site alarms (audible; radio; television; local authorities) to "shelter in place" by taking refuge in structures and avoiding exposure to the thermal radiation.

Pre-release methods for minimizing the size of a hazardous-material release (rate and duration, or quantity) and/or the frequency of any such release involve recognition of potential hazards early in the design of a facility and then incorporating appropriate mitigation features in the design [6(G4), 7, 20, 21].

17.3.2.10 Pressure-Vessel-Burst Hazards Evaluation

The explosive bursting of a pressure vessel is not at present identified by the EPA as a likely cause of off-site injury or property damage. However, if a pressure vessel is large and the pressure within the vessel is very high, explosive rupture of the vessel can create blast pressures and impulses at considerable distances from the vessel. The following evaluation is for pressure vessels that contain gas or vapor, or where most of the volume is occupied by gas or vapor; evaluation of the explosive-

rupture hazards of pressure vessels containing superheated liquid (resulting in a "BLEVE") is presented in a later section.

17.3.2.10.1 Pressure-Vessel-Burst Hazards Analysis

17.3.2.10.1.1 Non-Flammable Contents

If the gas or vapor that is confined in a pressure vessel is not flammable, the chief hazards of vessel burst would be blast effects and missiles or shrapnel. The TNT [TriNitro Toluene] equivalent of a pressure-vessel burst is a function of the burst pressure of the container, its volume, and the specific-heat ratio of the vapor.

An approximate TNT equivalent for the bursting of a gas-filled or vapor-filled container can be obtained from an isentropic-expansion equation [10]:

$$W_{TNT} = [0.0001P_{burst}V_{tank}/(k - 1)][1 - (14.7/P_{burst})^{(k-1)/k}] \text{ pounds of TNT} \tag{17.21}$$

where V_{tank} and P_{burst} are the volume and bursting pressure (typically, four times the design pressure) of the container or tank, respectively (in cubic feet and psia), and k is the specific-heat ratio.

If a possible cause of vessel bursting is explosion of a mixture of combustible material and an oxidant (such as flammable vapor and air, or combustible dust and air), the maximum TNT equivalent (for a "stoichiometric" mixture) of the explosion can be calculated from

$$W_{TNT} = 0.0005W_{combustible}H_{combustion} \text{ pounds of TNT} \tag{17.22}$$

The approximate pressure that results from an explosion of a near-stoichiometric mixture of flammable gas or vapor and air can be calculated from

$$P_{max} = 8P_{initial} + 103 \text{ psig} \tag{17.23}$$

where $P_{initial}$ is the initial pressure of the fuel/air mixture (in psig).

As a general rule, a container will not burst unless the energy equivalent of an internal explosion (expressed as a TNT equivalent) exceeds the energy equivalent of the container bursting (also expressed as a TNT equivalent), and it will not burst unless the explosion pressure (based on the initial pressure) exceeds the burst pressure of the container.

The EPA hazard distance, for a "side-on" or "incident" overpressure of 1 psig, can then be obtained from

$$X_{1psig} = 43W_{TNT}^{1/3} \text{ feet} \tag{17.24}$$

Approximate values for the "far-field" surface-burst reflected blast pressure and blast impulse [29] can be obtained as functions of TNT equivalent and distance (from pressures of ~20 psig down to zero) from

$$P_{reflected} = [60/Z][1 + (30/Z)] \text{ psig} \tag{17.25}$$

where Z is the "scaled distance" and is equal to $X/W_{TNT}^{1/3}$ (feet/pound of TNT)$^{1/3}$ and

$$I_{reflected} = [125/Z][W_{TNT}^{1/3}][1 + (1.6/Z^{0.5})] \text{ psig/milliseconds} \tag{17.26}$$

The consequences of exposure to blast pressures and impulses are discussed in the next section.

TABLE 17.6
Probability Relationships for Hazard Distances

	Probability of Injury		
Type of Injury	**1%**	**50%**	**99%**
First-degree (sunburn)	[Not determined]	$X_{fireball} = 5.6W_f^{0.49}$	[Not determined]
Second-degree (blisters)	[Not determined]	$X_{fireball} = 5.3W_f^{0.48}$	[Not determined]
Third-degree (fatality)	$X_{fireball} = 5.0W_f^{0.46}$	$X_{fireball} = 3.6W_f^{0.46}$	$X_{fireball} = 2.5W_f^{0.46}$

17.3.2.10.1.2 Flammable Contents

If the gas or vapor that is confined in a pressure vessel is flammable, there may be a fireball hazard in addition to the explosion hazard, particularly if the cause of vessel rupture is fire exposure or impact.

The EPA equation for the second-degree burn hazard distance at which the combination of thermal-radiation intensity and duration of exposure would correspond to 5000 watts/m^2 and 40 seconds, respectively, is (approximately)

$$X_{fireball} = 0.10H_{combustion}{}^{0.5}W_{flammable}{}^{0.43} \text{ feet} \tag{17.27}$$

where $H_{combustion}$ and $W_{flammable}$ are the heat of combustion and weight of flammable material, respectively, in BTU per pound and pounds.

The preceding equation was developed for fireballs in which some of the flammable material was in the form of aerosol and in which the mixing of flammable material with air might be significantly slower (thus, "rich" conditions within the fireball) as compared with that of a flammable gas or vapor. The energy effects would be similar, although the cloud burning time might be shorter, and the maximum diameter of the cloud might occur at a lower elevation (as a result of faster mixing of the gas or vapor with air).

Relationships for hazard distances as a function of probability of injury are listed in Table 17.6 [26].

The equations in Table 17.6 were developed for propane (which has a heat of combustion near 12,000 calories/gram). For other materials, the weight of flammable material would be multiplied by the ratio of the heat of combustion (in calories/gram) to 12,000.

17.3.2.10.2 Consequence Analysis for Pressure-Vessel-Burst Hazards

The extent of injury and property damage from an explosion depends on both the blast overpressure and the blast impulse at the point of interest [30]. Table 17.7 presents examples of overpressure and impulse combinations as a function of distance for an explosion having an energy equivalent of 10,000 pounds of TNT, together with the approximate limits of various types of injury and property damage.

The EPA standard requires that the consequences of a flammable material release be described in terms similar to those listed under Toxicity Hazards.

17.3.2.10.3 Risk-Mitigation Methods for Pressure-Vessel-Burst Hazards

There are no "passive" or "active" methods for mitigating the blast or missile effects of an explosion after an explosion has taken place, other than the self-preservation actions of persons turning and running away if there is any visual (speed of light) warning. For this reason, all practical measures should be taken to prevent explosions in the design and operation of high-pressure and exothermic processes; thus, "pre-release" mitigation. This could include barricading, both to reduce the pressure effects outside the barricade and to limit the number, size, and range of missiles [6(G4), 7, 20, 21].

TABLE 17.7
Examples of Overpressure and Impulse Combinations

Distance (feet)	Value of "Z" (feet/$lb_{TNT}^{1/3}$)	Reflected Properties: Pressure (psig)	Reflected Properties: Impulse (psig-ms)	Personal Injury	Property Damage
115	5.3	76	4,000	100% Fatal	Reinf. conc. demolished
135	6.3	27 (s.o.)	265 (s.o.)	99% Fatal	Reinf. conc. unusable
210	9.7	10 (s.o.)	175 (s.o.)	1% Fatal	Panel on steel demolished
310	14.5	13	975	50% Eardrum rupture	Residences demolished; reinf. masonry usable
520	24	5.6	475	10% Eardrum rupture	Residences unusable; tall columns toppled
750	35	1.2 (s.o.)	55 (s.o.)	1% Eardrum rupture	Masonry block demolished; tall columns undamaged
930	43	2.1 1.0 (s.o.)	190 50 (s.o.)	Flying glass	Masonry block repairable; panel on steel usable
2000	94	0.8	75	Flying glass	Residences usable
3000	142	0.5	45	Flying glass	50% Windows broken
3400	155	0.4	40	None	1% Windows broken

s.o. indicates "side-on" blast pressures and impulses as contrasted with "reflected" values.

17.3.2.11 BLEVE Hazards Evaluation

A boiling-liquid expanding-vapor explosion (BLEVE) can occur if a container of liquid or liquified gas at temperatures above their atmospheric-pressure boiling points were to rupture. Sudden loss of containment and reduction in pressure can result in explosive vaporization of some of the liquid, and the sudden increase in volume can propel parts of the container to great distances and create blast effects (pressure and impulse). Further, if the superheated liquid or liquified gas is flammable, a fireball involving the ejected vapor, aerosol, and liquid can result, particularly if the cause of the overpressure and rupture is exposure to fire.

17.3.2.11.1 BLEVE Hazards Analysis

17.3.2.11.1.1 BLEVE Involving Nonflammable Contents

If the superheated material is not flammable, the hazards of a BLEVE would be blast effects and missiles or shrapnel. The TNT equivalent of a BLEVE is a function of the burst pressure of the container, its volume, and the specific-heat ratio of the vapor.

An approximate TNT equivalent for a liquid-full container can be obtained from [14]

$$W_{TNT} = \{0.0019 f V_{tank} d_{liquid} T_{burst}/[M(k-1)]\}\{1-(14.7/P_{burst})/^{(k-1)/k} \text{ pounds TNT} \quad (17.28)$$

where d_{liquid}, M, T_{burst}, and f are the density of the liquid (in pounds/feet^3), the molecular weight of the material, the temperature of the liquid (in °K) at the burst pressure, and the flashing fraction, respectively. The resulting blast pressures, impulses, and effects can then be determined as described in previous sections.

17.3.2.11.1.2 BLEVE Involving Flammable Contents (Fireball)

If the liquid or liquefied gas that is confined in a pressure vessel is flammable, there may be a fireball hazard in addition to the explosion hazard. Ignition of the ejected contents is almost a certainty if the cause of the BLEVE is fire exposure, and ignition is likely if the BLEVE cause is

impact or a runaway reaction. Ignition simultaneous with release of flammable contents is less likely if the cause of container rupture is a liquid-full condition and solar or ambient heating.

The consequences of exposure to a fireball resulting from a BLEVE can be determined as described in the previous section.

17.3.2.11.2 Risk-Mitigation Methods for BLEVEs

There are no "passive" or "active" methods for mitigating the blast or missile effects of a BLEVE-type explosion after the BLEVE has taken place, other than the self-preservation actions of persons turning and running away if there is any visual (speed of light) warning. However, the primary cause of BLEVE is fire exposure, and several precautions can be taken during fire-fighting to minimize the risk of injury from BLEVE:

1. Provide water-spray cooling of fire-exposed containers either by remote-operated "monitors" or "water cannons" or by mobile "water cannons" placed near the fire-exposed containers "early" in the fire, with fire-lighters then retreating to a safe distance. The time available to set up and aim mobile "water cannons" would depend on the size of the container, its design pressure, the size of relieving devices, and the volatility of the contents.
2. Ensure that there are no fire-fighters or spectators in the "axial" directions for horizontal cylindrical containers, and evacuate buildings in the axial directions, since a BLEVE frequently projects parts to great distances (up to a quarter mile) in an axial direction.
3. Ensure that there are no fire-fighters or spectators within a radius of about 1000 feet (for a 55-ton tank car) to minimize exposure to a BLEVE fireball.

Because there are no reasonable methods for mitigating risk following the occurrence of a BLEVE, all practical measures should be taken to prevent the causes of a BLEVE. This could include fixed water-spray systems over process vessels containing flammable liquids or which could be exposed to flammable-liquid fire, ensuring that relief devices do not direct vented flammable vapors onto the container, systems for diverting spilled flammable liquid to locations that would not expose process vessels, and public-address systems to warn persons to evacuate locations where loss of process control could lead to a BLEVE [14].

17.3.2.12 Jet-Fire Hazards Evaluation

It is unlikely that a release of flammable fluid could result in a jet fire that would cause an off-site thermal-radiation hazard, and the EPA guidelines [9] do not provide guidance concerning jet-fire hazards assessment. However, the length of a jet flame can be calculated from [7]

$$L_{jet} = 0.37[W_{flammable}H_{combustion}]^{0.46} \text{ feet} \tag{17.29}$$

where $W_{flammable}$ is the rate of release of the flammable material (in pounds/second).

The hazard radius is usually assumed to be twice the jet-flame length [12].

There are no "passive" methods for mitigating the risk of exposure to a jet fire other than the self-preservation action of turning and running away from the fire or taking refuge in the "shadow" of intervening equipment or a structure. "Active" methods would include stopping the flow of flammable fluid to the leaking equipment and de-inventorying the equipment to another container or to a stack or flare.

17.3.2.13 "Condensed-Phase" Detonation Hazards Evaluation

Detonation of a self-reactive material or mixture of materials results in blast effects that can be related to an energy-equivalent weight of TNT, for which there are good blast-effects data. The

heat of detonation (and, thus, the TNT equivalent) is related to the oxygen balance, being a maximum when the oxygen balance is near zero (except for strongly "endothermic" compounds, such as acetylene, ethylene, and lead azide).

Oxygen balance (OB) can be calculated from the molecular structure (or the relationships between combustible materials and oxidants, in a mixture) by [31]

$$\text{OB} = -100\{8(4[C] + [H] - 2[O])/M\} \text{ percentage} \tag{17.30}$$

An approximate relationship between oxygen balance and heat of detonation is

$$H_{detonation} = 1550\{1 - [1 - e^{K(OB\wedge 2)})]^{0.5}\} \tag{17.31}$$

where K is the slope of the line on probability graph paper, and is ~0.00003 for negative OB and ~0.0007 for positive OB.

Thus, an approximate value for the TNT equivalent of a detonation-type explosion can be obtained from chemical structure (or, in many cases, from [29, 31]) for assessing blast effects. Similarly, the TNT equivalent for explosion of a mixture of a combustible material in air (vapor-cloud explosion) can be obtained from the heat of combustion (when multiplied by an "explosion-efficiency" factor, which may be of the order of 10%).

The OSHA standard includes the manufacture, storage, transportation, and use of explosives, blasting agents, and pyrotechnics, with no threshold or minimum quantity. The EPA standard includes all Division 1.1 explosives, as listed and defined in the U.S. DOT regulations [36]. The threshold quantity is set at 5000 pounds, based on the potential to detonate and yield a blast wave overpressure of 3 psi (gauge) at a distance of 100 meters (~328 feet) [5]. It should be noted that many explosives are listed in 49 CFR 172.101 as "forbidden" rather than "1.1," and these materials include "Type A" peroxides and particularly ketone peroxides [36].

Fragments frequently are projected to great distances by explosions. The hazards to personnel and property depend on the number of fragments or missiles, and their weight and velocity [8]. There are no "passive" or "active" methods for "post-release" mitigation of the blast or missile effects of an explosion (after an explosion has taken place), other than the self-preservation actions of persons turning and running away if there is any visual (speed of light) warning. For this reason, all practical measures should be taken to prevent explosion in the design and operation of explosives-handling operations, particularly to avoid friction, impact, flame, spark, or other thermal or mechanical sources of initiation. "Pre-release" mitigation measures also would include barricading, both to reduce the pressure effects outside the barricade and to limit the number, size, and range of missiles [6(G4), 7, 20, 21].

17.3.3 Incident Identification/History

The OSHA standard requires a study of previous incidents involving listed chemicals, to determine which had "a likely potential for catastrophic consequences in the workplace" [1(e)]. The EPA standard further requires a listing of incidents that had occurred during the previous 5 years, with details concerning the incident and, particularly, the on-site and off-site impacts (if any) of the incidents [2(42)]. This is particularly important in establishing "Program 1" eligibility, which requires that the process not have had an incident involving a regulated substance that led to off-site injury or restoration of the environment. Also, the EPA standard requires a statement concerning any operational or process changes that resulted from investigation of the incident.

During analysis of a process for hazards, it may be helpful to review the descriptions of incidents that have occurred at other locations worldwide and in other industries. There are several compilations of incidents that may be useful [7, 37–39].

17.3.4 Employee Participation

The OSHA regulations require employee participation in several aspects of process safety [l(c)]:

1. Specifically, the conduct and development of Process Hazard Analyses
2. Generally, the development of the other elements of the Process Safety Management Standard, which would include
   a. Compilation of Process Safety Information, particularly concerning the evaluation of the consequences of deviations from safe upper and lower limits of operating conditions
   b. Development and review of Operating Procedures
   c. Development of the Training program and, specifically, the frequency of refresher training
   d. Development of the Contractor Safety program, particularly concerning the evaluation of the performance of contractors in training employees to safely perform their jobs, in following the safety rules of the facility, and unique hazards presented by contract employer's work
   e. Participation in Pre-Startup Safety Reviews
   f. Development of Mechanical Integrity (maintenance) procedures, including inspections and tests and the frequencies of such inspections and tests
   g. Development of safe work practices, including lockout/tagout, confined space entry, opening process equipment, facility-entrance procedures, and hot-work procedures
   h. Development of the Management of Change procedure
   i. Participation in Incident Investigations
   j. Development of Emergency Plans
   k. Participation in Compliance Audits

A written plan of action concerning Employee Participation is required. Also, all of the information and the results of analyses, investigations, and audits are to be made available to employees and their representatives.

17.3.5 Process Safety Information

The OSHA and EPA require a compilation of Process Safety Information concerning the regulated chemicals and the processes in which they are employed [1(d), 2(65)]. Although Material Safety Data Sheets (MSDS) may serve as resources for this information, it should be recognized that some of the quantitative data that may be important to hazards analysis are not at present required by the pertinent standard [40]. In particular, quantitative thermal-stability (self-reactivity), incompatibility, and corrosivity data are frequently not found in the MSDS publications shipped with chemicals; further, some materials that are considered to be "stable" by manufacturers and distributors are not stable (can decompose, polymerize, form peroxides, auto-oxidize, or auto-ignite) at the temperatures that are frequently employed or accidentally occur in chemical processes [33]. Under the "general duty" clause [41], the employer would be responsible for determining the degree of stability or regions of instability of chemicals used in processes.

17.3.6 Process Hazards Analysis

A Process Hazards Analysis (PHA) is described as [1(C)]:

1. "An organized and systematic: effort to identify and analyze the significance of potential hazards associated with the processing or handling of highly hazardous chemicals."

2. "Directed toward analyzing potential causes and consequences of fires, explosions, releases of toxic or flammable chemicals, and major spills of hazardous chemicals."
3. "Focused on equipment, instrumentation, utilities, human actions (routine and nonroutine), and external factors that might impact the process."
4. "Provides information which will assist employers and employees in making decisions for improving safety and reducing the consequences of unwanted or unplanned releases of hazardous chemicals."

Several types of PHAs are suggested by the OSHA and EPA standards (Table 17.8). They include the following (in approximate order of increasing complexity), with pertinent references indicated for details concerning their application [5, 42].

TABLE 17.8
OSHA and EPA Standards for Process Hazards Analysis

Method	Description	References
Checklist	The PHA team is guided by a checklist previously prepared by an experienced, knowledgeable person to identify potential causes of incidents and to determine the adequacy of existing incident-prevention systems.	CCPS [6(G18)]: 48, 54, 77, 99, 204, 318; Lees [7]: 8/11
"What if..?" checklist	The PHA team formulates "What if.. ?" questions, as guided by a checklist of process-equipment components and possible causes of component failure, such as inadequate design, construction, or maintenance, or unsafe operation, to determine the adequacy of existing incident-prevention systems.	CCPS [6(G18)]: 62, 77, 122, 204, 383
"What if..?"	The PHA team formulates "What if.. ?" questions, as guided by their cumulative experience with a process and the existing design, construction, maintenance, and operating practices at the site, and external factors, to determine the adequacy of existing incident-prevention systems.	CCPS [6(G18)]: 48, 60, 77, 117, 204, 253, 257 Lees [7]: 8/57
Failure modes and effects	Each component in a process is listed, together with possible modes of failure and the effects of such failures on the process, to determine the adequacy of existing incident-prevention systems.	CCPS [6(G18)]: 66, 77, 151, 204, 377 Lees [7]: 8/77
Hazard and operability (HAZOP)	At each "node" in a process (vessel or pipe section), possible deviations in process variables (such as temperature) from the design intent are formed by combinations of variables and "guide words" (such as "more" or "high"), to determine the adequacy of existing systems to prevent hazardous deviations.	CCPS [6(G18)]: 48, 64, 77, 131, 204, 289, 330, 351 Lees [7]: 8/59 to 8/77; 8/80
Fault tree	The PHA team constructs a "tree" that has as its starting point an unwanted hazardous event. Causes of this "top event" are identified, together with precursor causes, to develop the "tree" downward to basic causes, for which occurrence frequencies are available. Calculation procedures yield a "top event" frequency that, if not "tolerable," can be reduced by adding safety systems to minimize the effects of component or human failures.	CCPS [6(G18)]: 67, 77, 160, 205, 304 CCPS [6(G6)]: 22, 192 to 211

The employer is obliged to determine a priority order for the analysis of processes involving regulated materials and to use an appropriate method [1(e), 2(67)]. The prioritizing should consider (1) the potential severity of an incident, (2) the number of potentially affected employees, (3) the operating history of the process (such as the frequency of incidents), and (4) the age of the process. The method selection should consider (1) the amount of existing knowledge about the process, (2) type of operation (batch, semi-batch, or continuous), (3) size and complexity of the process, and (4) previous operating experience with the process (length of time, and frequency of hazardous or "near-miss" incidents).

In addition to the Process Hazards Analysis, the following are to be addressed in the PHA report:

1. Previous incidents with potential for catastrophic consequences.
2. Applicable engineering and administrative controls.
3. Setting of the facility.
4. Human factors.
5. A qualitative evaluation of safety and health effects of failure of controls.

Updating and revalidation of Process Hazards Analyses is required at least every 5 years after May 26, 1997, for OSHA and after June 21, 1999, for the EPA.

17.3.7 Operating Procedures

The OSHA and EPA require that written operating procedures be developed and implemented for processes in which regulated chemicals are used. These procedures are to provide guidance for operators for each step of operation, including [1(f), 2(69)]:

1. Initial startup of a process, following construction.
2. Startup following a normal shutdown, a shutdown for maintenance, or an emergency shutdown.
3. Normal operations.
4. Temporary operations, with modified materials, equipment, or conditions.
5. Emergency operations, to regain control of a process.
6. Emergency shutdown, if control of a process is not recoverable.
7. Normal shutdown.

These procedures are to describe the steps to be performed, how the steps are to be performed, the desired values of the operating variables at each step, the limits for process variables, the reasons why the limits are not to be exceeded, steps to be taken to correct deviations from the desired operating conditions, the data to be recorded, the samples to be collected, and the safety and health precautions to be taken. Of particular importance are the conditions under which emergency shutdown is required, and the assignment of shutdown responsibility to qualified operators to ensure that emergency shutdown is executed in a safe and timely manner.

The operating procedures also should include precautions to ensure quality control and inventory control, and descriptions of safety systems and their functions. The operating procedures should be reviewed and corrected to reflect current operating practices or validated at least annually.

17.3.8 Training

Initial and periodic refresher re-training (at least every 3 years) are required by the OSHA and EPA standards. This training is to ensure that each employee involved in operating a process (1) understands and adheres to the current operating procedures of the process (including emergency shutdown); (2) understands the specific safety and health hazards; (3) can perform the safe work

practices applicable to the employee's job tasks; and (4) has the required knowledge, skills, and abilities to safely carry out the duties and responsibilities as specified in the operating procedures [1(g), 2(71), 5, 42]. All training should be documented.

17.3.9 Contractor Safety

The safety of contractors who may be exposed to process hazards has become a great concern since the occurrence of very serious incidents at Pasadena, Texas (October 23, 1989), and Channelview, Texas (July 5, 1990). Employers are now required to (1) evaluate the safety performance of contractors; (2) inform contract employers concerning fire, explosion, and toxicity hazards; (3) ascertain that contractor employees understand the site's emergency plan; (4) control the presence of contractors in process areas; and (5) maintain an injury and illness log related to a contractor's work in process areas [1(h), 2(87), 5, 42].

17.3.10 Pre-Startup Safety Review

Prior to startup of a new or significantly modified facility, a pre-startup review is required by the OSHA and EPA standards. This review is to ascertain that (1) construction and equipment are in accordance with design specifications; (2) safety, operating, maintenance, and emergency procedures are in place and are adequate; (3) a process hazards analysis has been performed on new processes, and recommendations have been resolved, or a management-of-change procedure has been performed for modified processes; and (4) training of each employee involved in operating a process has been completed [1(i), 2(77), 5, 42].

17.3.11 Mechanical Integrity (Equipment Maintenance)

Written procedures to ensure the integrity of process equipment (such as storage tanks, piping systems, valves, pumps, pressure vessels, process controls, emergency shutdown systems, and relief and vent systems) are required by OSHA and EPA. This includes inspections and tests following recognized and generally accepted good engineering practices at frequencies consistent with manufacturers' recommendations and good engineering practices. The results of such inspections and tests are to be documented with names, dates, test descriptions, and serial numbers. Also, equipment deficiencies are to be corrected either (1) before further use, or (2) "in a safe and timely manner when necessary means are taken to assure safe operation" in the interim.

Newly installed equipment is to be checked to assure that it is suitable for the intended process application and that the equipment is installed properly. Spare parts and equipment are to be checked to assure that they also are suitable for the intended processes [1(j), 2(73), 5, 42].

17.3.12 Safe Work Practices; Safety Procedures for "Non-Routine" Work

The development and implementation of safety procedures for "non-routine" work are required by OSHA and EPA. These specifically include "hot work" (such as welding), lockout or tagout, line-breaking, and confined-space entry. Other examples of non-routine work for which procedures should be developed would be excavation, electrical hot work (on energized conductors), hot-tapping (on pressurized piping), and, in some instances, personal protective equipment.

17.3.12.1 Specified Safety Procedures

References to pertinent regulations and examples are shown in the Table 17.9.

The following sections provide some guidance concerning the other "non-routine" tasks, for which "open-literature" guidance may not be available.

TABLE 17.9
"Non-Routine" Work Regulations

Nonroutine Work	References	Examples
Hot work (welding, etc.)	[25] 29 CFR 1910.252	Lees [7], p. 21/28
Lockout/tagout	[25] 29 CFR 1910.147	"Hazards in the Workplace" [41], p. 39
Confined-space entry	[25] 29 CFR 1910.146	"Hazards in the Workplace" [41], p. 17
Hot work (electrical)	[25] 29CFR 1910.269(j; 1); 333(a)(2); (c)(ii); 335	"Hazards in the Workplace" [41], p. 97
Personal protective equipment	[25] 29 CFR 1910.132; 120	"Personal Protective Equipment" [41], p. 5

17.3.12.2 Opening Process Equipment or Piping

It is often necessary to open process equipment or piping for cleaning, maintenance, or modification. The "work-permit" procedure should address the following:

1. Establishing the levels and areas of authorizations (operations, maintenance; landlord, supervisor, site manager) required for the work to proceed.
2. Evaluating the hazards of the material(s) that might be in the equipment or piping.
3. Positively identifying the equipment or piping to be opened.
4. Determining whether the equipment or piping (a) can be and has been drained and depressurized, or (b) cannot be or has not been drained or depressurized, including a study of piping to identify undrained low points, unvented high points, and potential syphons.
5. Determining whether the equipment or piping has been flushed, purged, or evacuated.
6. Locking shut and tagging valves, using blind-flanges, or disconnecting sources of hazardous material associated with the equipment or piping to be opened, locking open vent valves, and locking off energy sources such as pumps, compressors, and electrical tracing.
7. Safeguarding against external hazards, such as ignition sources if the piping or equipment could contain flammable material, and sealing off drains or other possible sources of noxious liquids, vapors, or gases.
8. Preparing a safe working position, through proper use of platforms, scaffolds, ladders, safety harness, ventilation, etc.
9. Isolating the area, by barricades or shields, to exclude inadequately protected persons, particularly at lower elevations.
10. Preparing or maintaining exits from the work area, in event of a release of hazardous material.
11. Preparing for accidental releases or spills from the equipment or piping to be opened, by establishing spill control, having fire extinguishers ready, etc. ("contingency planning").
12. Ensuring the presence and testing of safety showers, eyewash fountains, or other washing or flushing facilities.
13. Establishing the types and degree of protection that should be worn for "drained" and "undrained" equipment or piping, considering the flammability, corrosivity, toxicity, thermal, and pressure hazards and quantity of material that might remain in the equipment or piping.
14. Providing for one or more standby "buddy" persons, who is equally protected, at a safe distance from the work area but maintaining visual contact with the worker.
15. Developing and implementing the procedure for gradually loosening bolts or connections, with periodic tests for "residual" pressure, to avoid exposure from unexpected sprays, pressure impacts, or other discharges.

16. Determining when protective clothing can be removed, after the equipment or piping has been opened.
17. Establishing a "turnover" procedure, which documents flow isolation and electrical lockout locations and protective equipment requirements, if the equipment or piping is to remain open for more than one shift.

17.3.12.3 Excavation

Removal of earth, concrete, asphalt, or other ground cover is often necessary prior to, or as part of, construction activities. The "work-permit" procedure should address the following [43]:

1. The depth that can be excavated without completing a permit, such as 2 inches in concrete and 6 inches in earth.
2. The types of underground hazards or facilities (such as electrical, gas, and telephone utilities; process or steam piping; drains and sewer lines; spilled or buried hazardous materials; etc.) that might be encountered during excavation. Identifying such hazards with the assistance of site maps and plans, utility companies, and knowledgeable employees.
3. De-energizing electrical services in the area to be excavated, particularly those over 50 volts AC or 100 volts DC.
4. De-pressurizing and/or emptying all piping in the area to be excavated.
5. Barricading or isolating the work site, to prevent close approach by unauthorized persons.
6. Placement locations for earth or other materials that are removed from the excavation.
7. Protection provided against cave-in or collapse of trench or excavation walls, using shoring and/or sloping.
8. Protecting the excavation from surface water, and ensuring that water or other liquids do not accumulate in the excavation.
9. Periodically testing the atmosphere in the excavation, to ensure the proper concentration of oxygen and absence of hazardous contaminants, such as hydrogen sulfide, methane, and carbon dioxide, and providing forced fresh-air ventilation.
10. Procedures for working above, near, and around obstructions, wiring, conduit, or piping that is expected in the area to be excavated, including manual/hand excavation (with high-voltage gloves and nonconductive paddles, if wiring is encountered) instead of using powered digging equipment.
11. Procedures for protecting exposed equipment, piping, conduit, and wiring that is exposed during excavation, to avoid damage during subsequent work activities.
12. Procedure for correcting maps or plans if unexpected lines or piping are discovered or are not found at the expected locations, and for adding equipment or piping that is being installed in the excavation.
13. Marking or physically protecting (with creosoted boards, for example) electrical cables and process piping that is laid within an excavation, for protection against future excavations.

17.3.12.4 Entrance Control

Unauthorized or unexpected entry of employees, contractors, employees of service organizations (such as postal and utilities), or other visitors, and the activities of these persons, could cause process upsets, could aggravate the consequences of hazardous incidents, and could interfere with emergency or rescue activities. A procedure should be established to control the entry and document the exit of persons from areas in which hazardous materials are handled.

The entrance-control procedure should address the following:

1. Sign-in and sign-out of visitors, with dates, times, printed name, and signature.
2. A warning statement concerning the hazardous materials that are used in the area to be visited.
3. Protective-equipment requirements (such as eye and head protection).
4. The layout of the area (using, for example, a map of the area).
5. Whether or not an authorized employee is required to escort the visitor at all times in the area.
6. An alarm provided to initiate evacuation, and the desired response to such an alarm.

17.3.12.5 Hot-Tapping

Hot-tapping is the drilling of a hole into, and fitting a branch on, a pipe while it is still on line, by welding or "strapping" a sleeve on the pipe. The "work-permit" procedure for hot-tapping should address the following [7, 44]:

1. Establishing the levels and areas of authorizations (operations, maintenance; landlord, supervisor, site manager) required for the work to proceed.
2. Establishing the pipeline fluid conditions: liquid at temperatures below the atmospheric-pressure boiling point; liquified gas at temperatures above the atmospheric-pressure boiling point; or gas, temperature, and pressure.
3. Establishing the pipe material, the wall thickness, and the condition of the pipe (particularly internal or external corrosion); and the effect of welding on the pressure-resistance strength of the pipe, if welding is to be performed.
4. Establishing the type of fitting to be placed on the piping and the attaching method(s), and whether or not reinforcing pads are required.
5. Positively identifying the piping to be hot-tapped.
6. Preparing a safe working position, through proper use of platforms, scaffolds, ladders, safety harness, ventilation, etc.
7. Isolating the area, by barricades or shields, to exclude inadequately protected persons.
8. Eliminating external hazards, such as ignition sources if the piping contains flammable material, and sealing off drains or other possible sources of noxious liquids, vapors, or gases.
9. Preparing and maintaining access to and exits from the work area, in the event of a release of hazardous material.
10. Preparing for accidental releases or spills from the piping to be hot-tapped, by establishing spill control, having fire extinguishers ready, etc. ("contingency planning").
11. Ensuring the presence of, and testing of, safety showers, eyewash fountains, or other washing or flushing facilities.
12. Establishing the types and degree of protection (eye, face, head, hands, feet, and body) that should be worn for the work, considering for flammability, corrosivity, toxicity, thermal, and pressure hazards.
13. Providing for one or more standby "buddy" persons, who is equally protected, at a safe distance from the work area but maintaining visual contact with the worker.

17.3.13 Management of Change

The development and implementation of a procedure for the control of changes in process chemicals, technology, equipment, and procedures are required by OSHA and EPA [1(1), 2(75)]. Replacement of a defective component "in kind" (same manufacturer, model, and size, and other characteristics) would not require following the procedure. Replacement of a defective, obsolete, or obsolescent device with a "similar" device would require a "minimal" procedure, with limited authorizations.

Changes in chemicals, operating conditions, process equipment, instrumentation, repairs to damage, and other facets of process technology require the following prior to the change:

1. The technical basis for the proposed change, such as laboratory study, purchased technology, or desired change in production rate.
2. An evaluation of the impact of the proposed change on safety and health of employees and the population in the area surrounding the site, and the environment.
3. Revision of the operating procedures, to correspond to the proposed change in chemicals, operating conditions, process equipment, or technology.
4. The date on which the proposed changes would become effective and, if a temporary change, the date on which the modified process would revert to the original process. If the changes are to be permanent, the Pre-Startup Review procedure should be implemented. Many companies require that the modified process be analyzed for hazards, prior to startup, using a Process Hazards Analysis method that would be consistent with the inherent or demonstrated hazards.

Temporary changes should be authorized by knowledgeable members of the site staff (such as the operations and maintenance managers, the research director or process engineer, and the safety, health, and environmental staff members). Operating, maintenance, and contractor employees who will be affected by the proposed change should be informed of, and trained in, the changed process prior to startup. The operating procedures and safety information should be revised to correspond to the proposed change.

17.3.14 Incident Investigation

Investigation of incidents that resulted in, or could reasonably have resulted in, a catastrophe (a major uncontrolled emission of a highly hazardous chemical, a fire, or an explosion) is required by OSHA and EPA [1(m), 2(81)]. The investigation should be initiated within 48 hours, and the investigation team should include (1) at least one person knowledgeable in the process involved, (2) a contract employee if contractors were involved, and (3) other persons having appropriate experience.

A written report is required. The contents of the report are to be reviewed with all affected personnel, and the report is to be retained for 5 years. The report is to address the following: (1) the date and time of the incident, (2) the date on which the investigation began, (3) a description of the incident, (4) the factors that contributed to the incident, and (5) recommendations resulting from the incident.

The employer is required to establish a system to promptly address and resolve the recommendations and to document the resolutions and corrective actions.

17.3.15 Emergency Planning and Response

The EPA and OSHA require development of an emergency plan and training in the implementation of the plan [l(n), 2(95), 25]. Because the requirements differ, a site's plan should include the requirements of both standards, as shown in Table 17.10.

17.3.16 Compliance Audits

The EPA and OSHA require self-audits every 3 years by at least one person who is knowledgeable in the process(es) that involve regulated chemicals, beginning June 21, 1999, and May 26, 1995, respectively, to determine conformance. The employer shall promptly determine and document appropriate responses to the findings of the audit and document that the deficiencies have been corrected [1(o), 2(58)].

TABLE 17.10
OSHA and EPA Emergency Requirements

Requirement	OSHA Standard	EPA Standard
Procedures and measures for emergency response	Emergency escape procedures (types of evacuation) and routes	Provide to the local emergency planning committee
Procedures for employees who remain to operate critical operation before they evacuate	Required	Not required
Procedures to account for all employees after emergency evacuation	Required	Not required
Rescue and medical duties for those employees who are to perform them	Required	Not required
First-aid and emergency medical treatment of persons exposed to regulated substances	Required [29 CFR 1910.119(f)(1)(iii)(C)]	Documentation required (for off-site treatment)
Preferred means of reporting fires and other emergencies	Required (to other employees)	Required (to public and local emergency response agencies)
Names or titles of persons who can be contacted for further details	Required	Required [40 CFR 68.15(b)]
Establish an alarm system, with distinctive signals for brigade members and other purposes	Required [29 CFR 1910.165]	Not required
Training for evacuation aides	Those employees who are to assist in safe and orderly emergency evacuation	Not required
Training for all employees	Initially and following any changes	Required
Procedures for handling small releases	Required	Not required
Hazardous waste operations and on-site emergency response requirements	Required unless releases are "incidental" and can be absorbed, neutralized, or otherwise controlled at the time of release by employees, and where there is no "reasonable possibility" for employee exposure to safety or health hazards.	Not required
Emergency response equipment	Required: Annual testing of alarm (or every two months if not a "supervised" system)	Required: Inspection, testing, and maintenance of emergency response equipment
Procedures to review and update the emergency response plan	Not specifically required	Required
Ensure that employees are informed of changes to the plan	Required	Required

The EPA requires, in addition, periodic audits by the implementing agency, such as the state or local air permitting agency. The frequency of such audits would be based on (1) accident history, (2) quantities of regulated substances, (3) proximity to public receptors, and (4) hazards identified in the Risk Management Program [2(220)].

17.3.17 Trade Secrets

The OSHA standard requires that all pertinent information be provided to employees involved in (1) compiling Process Safety Information, (2) performing Process Hazards Analysis, (3) developing

Operating Procedures, (4) performing Incident Investigations, (5) preparing the Emergency Response Plan, and (6) performing the Compliance Audit, without regard to possible trade secret status [1(p)]. However, employers can require such employees to enter into confidentiality agreements. Further, employees and their designated representatives shall have access to trade secret information contained within the Process Hazard Analysis and other documents required to be developed under the OSHA standard. There are no similar requirements or stipulations in the EPA standard.

17.4 OTHER ASPECTS OF PROCESS SAFETY MANAGEMENT

Several other pertinent aspects of Process Safety Management are not directly addressed by the OSHA or EPA standards. They are listed in the Table 17.11, with pertinent references.

TABLE OF SYMBOLS

English units, with °K.

A_p	Area of the pool (the area of a dike, or [π/4] D_P^2 for an unconfined pool, in feet²).
C	Concentration of interest, in parts/million, by volume.
$[C]$	Number of carbon atoms in the molecule.
C_d	Coefficient of discharge, which is a function of Reynold's number (~0.62); dimensionless.
C_L	Heat capacity of the liquid or liquified gas or vapor, in BTU/pound/°F.
C_p	Specific heat of a fluid at constant pressure, in BTU/pound/°F.
D_h	Diameter of the hole, in inches.
D_P	Diameter of the pool, in feet.
D_p	Inside diameter of the pipe, in inches.
D_T	Diameter of the vertical cylindrical tank, in feet.
f	Fanning friction factor; dimensionless.
g_c	Conversion constant (32.2 $ft/lb_m/lb_f/sec^2$).
G_P	Volume of the liquid in the pool, in gallons.
$[H]$	Number of hydrogen atoms in the molecule.
H_c	Heat of combustion of the flammable material, in BTU/pound.
$H_{L,Pb}$	Enthalpy of the liquid at the container-burst pressure, in BTU/pound.
$H_{L,14.7}$	Enthalpy of the liquid at atmospheric pressure, in BTU/pound.
$H_{V,14.7}$	Enthalpy of the vapor at atmospheric pressure, in BTU/pound.
H_v	Latent heat of vaporization, in BTU/pound.
K	Slope of a line on probability graph paper.
k	Specific-heat ratio; dimensionless.
L	Length of the pipe from the source container to the open end, in feet.
LFL	Lower flammable limit, in volume-percentage.
M	Molecular weight of the gas or vapor.
N_M	Mach number for gas or vapor flow; dimensionless.
N_{Re}	Reynold's number; dimensionless.
$[O]$	Number of oxygen atoms in the molecule.
OB	Negative or positive oxygen balance.
P_a	Pressure outside the equipment (usually 14.7 psia).
P_b	Bursting pressure of the container, in psia.
P_f	Final pressure (usually 14.7 psia).
P_g	Gauge pressure in the vapor space above the liquid, in psig.
P_o	Initial absolute pressure within the equipment, in psia.
P_o	"Virtual" absolute pressure, for subsonic flow, in psia.
P_s	Saturation vapor pressure of the flashing liquified gas at the temperature of interest, in psia.
q	Thermal-radiation intensity, in BTU/second/feet².
R	"Ideal gas law" constant, which is equal to 19.32 psia/feet³/lb-mole/°K.
r_c	Critical pressure ratio, given by $(2/[k + 1])^{(k/[k\ l])}$.
RH	Relative humidity, in %.
S	Entropy value (similar to values of enthalpy H), in BTU/lb/°F.
$[S]$	Number of sulfur atoms per molecule.
$[Si]$	Number of silicon atoms per molecule.
t	Time required to empty a container of fluid, in seconds.
T_a	Ambient temperature, in °K (typically about 298°K [25°C/77°F]).
T_b	Atmospheric-pressure boiling point, in °K.
T_c	Critical temperature, in °K.
T_f	Final temperature, in °K.
T_P	Temperature of the liquid in the pool, in °K.
T_o	Initial temperature, in °K.
v	Velocity of liquid or gas through a pipe, in feet/second.
vp	Vapor pressure, in mm Hg.

$V_{L,Pb}$	Specific volume of the liquid at the container-burst pressure, in feet³/pound.
$V_{L,14.7}$	Specific volume of the liquid at atmospheric pressure, in feet³/pound.
$V_{V,14.7}$	Specific volume of the saturated vapor at atmospheric pressure, in feet³/pound.
V_T	Volume of a container, in feet³.
vw	Wind speed over the pool, in feet/second.
W_c	Burning rate, in pounds/second.
W_f	Weight of flammable material in the vapor cloud or vessel, in pounds.
W_L	Liquid flow rate, in pounds/second.
W_P	Weight of the liquid in the pool, in pounds.
W_{TNT}	TNT equivalent of the gas-filled or vapor-filled vessel burst, in pounds.
W_V	Weight of gas or vapor in a container, in pounds.
W_v	Rate of vapor release (as gas or vapor, or as vapor from the surface of a pool), in pounds/second.
W_2	Rate of two-phase release, in pounds/second.
$[X]$	Number of halogen (chlorine, bromine, fluorine, etc.) atoms per molecule.
X	Hazard distance from the center of the source to the receptor, in feet.
Z	"Scaled distance" $R/W_{TNT}^{1/3}$, in feet/pound of $TNT^{1/3}$.
Z_f	Compressibility of the vapor phase at the final temperature and pressure conditions; dimensionless.
Z_L	Compressibility of the liquid phase ($PM/RT\rho_L$), dimensionless.
Z_o	Compressibility of the vapor phase at the initial temperature/pressure conditions; dimensionless.
Z_S	Elevation of the liquid surface above the hole, in feet.
Z_V	Compressibility of the gas or vapor, dimensionless.
ρ_G	Density of the gas or vapor, in pounds/feet³.
ρ_L	Density of the liquid or liquified gas, in pounds/feet³.
ε_p	Roughness of the internal surface of piping, in inches.
ε_B	Fractional energy-conversion efficiency of the flammable-vapor explosion, as compared to TNT.
ε_T	Fractional conversion of energy to thermal radiation.
μ	Viscosity of the gas or vapor, in centipoises.

CONVERSION FACTORS

Symbol	Value	Metric	per	English
A	0.093	Square meters	per	Square foot
C_L; S	1.00	Calories per gram-°C	per	BTU per pound-°F
D; L; X	0.305	Meters	per	Foot
D	2.54	Centimeters	per	Inch
G	0.0038	Cubic meters	per	Gallon
g_c	30.5	Centimeters per second²	per	Foot-lb_{mass}/lb_{force}-second²
H	0.555	Calories per gram	per	BTU per pound
P	6,895	Pascals	per	pound per square inch
q	11.3	Kilowatts per square meter	per	BTU per second per square foot
R	0.848	Kilogram-meters per g-mol-°K	per	psia-cuft per lb-mol-°K
R	0.00424	Liter-atma per gmol-°K.	per	psia-cu.ft. per lb-mol-°K
T	0.55	C° [$T_C = (T_F - 32)/1.8$]	per	F° [$T_F = (1.8\ T_C) + 32$]
V	0.0283	Cubic meters	per	Cubic foot
v	0.305	Meters per second	per	Foot per second
vp	133	Pascals	per	Millimeter of mercury [mm Hg]
W; (w)	0.453	Kilograms (per second)	per	Pound (per second)
ρ	16.0	Kilograms per cubic meter	per	Pound per cubic foot
μ	0.001	Pascal-seconds	per	Centipoise (0.000672 lb_m/ft-sec per cp)

APPENDIX A
OSHA AND EPA LISTED CHEMICALS

The EPA and OSHA regulations [A-l, A-2, and A-3] apply to facilities from which a release of hazardous material could occur, at or above the quantities specified, as shown in **bold** in Table 17.A.1. Also shown are the Immediately Dangerous to Life and Health [IDLH] concentrations (for 30-minute exposure) [A-4]; the Lower Flammable Limits and Heats of Combustion for combustible materials; and the EPA toxic, thermal-radiation, and overpressure "endpoints" for public-exposure evaluations. "N/L" indicates that the chemical is not listed in the pertinent document. Estimated values are shown with a superscript ([e]). Where no inhalation-toxicity data were available, the oral dose that caused 50% fatalities is shown only to indicate qualitatively the systemic toxicity (for example, an oral LD50 of 1000 mg/kg would be considered relatively nontoxic). The data are for pure chemicals, except where otherwise indicated, that is, without added diluents. Additional hazardous-properties information can be obtained via the "Sax No." [A-6].

Ca: The compounds for which "Ca" [carcinogenic] is shown in the above table have been characterized by the National Institute for Occupational Safety and Health [NIOSH] as "potential occupational carcinogens" [A-4].

[a] Flammable liquids or gases and meet the definition of the OSHA "Hazard Communication" standard [A-7] as a liquid having a flash point <100°F or a gas having a lower flammable limit of 13% by volume or having a flammable range that is wider than 12% by volume. The OSHA Threshold Quantity for flammable liquids and gases is 10,000 pounds.

[b] Not specifically listed in the OSHA standard and are flammable liquids or gases, but a 10,000-pound Threshold Quantity probably would be considered excessively hazardous because of the toxicity hazard, as indicated by low values for the EPA "Toxic Endpoint" [A-9] or for the IDLH.

[c] Estimated values that were obtained by first calculating the "stoichiometric" concentration in air (for combustion to carbon dioxide, water, silicon dioxide, sulfur dioxide, and halogen acids) and then multiplying by 0.55 for nonhalogen materials and by 0.60 for halogen-containing materials. The "stoichiometric" concentration can be calculated from:

$$C_{st} = 83.8/\{4[C] + 4[Si]\ 4[S] + [H] - [X] - 2[O] + 0.84\}$$

where lower flammable limits data are not given in the EPA Guidance, the data were obtained from NFPA 325 or NFPA 49 [A-8].

[d] The IDLH concentrations for flammable (and relatively nontoxic) materials are 10% of the lower flammable limits [A-8].

[e] Estimated values, based on the "stoichiometric" concentrations, for flammable and combustible materials.

[f] Calculated, from (MW × PPM)/(1000 × 24.4).

[g] Emergency Response Planning Guide [ERPG-2] values obtained from the current listing of the American Industrial Hygiene Association [A-10].

[h] One-tenth of the Immediately Dangerous to Life and Health [IDLH] value [A-4].

[i] One-hundredth of the concentration that was lethal to 50% of the exposed population [LC50], or one-tenth of the lowest observed lethal concentration [LCLo], for exposure durations of 4 hours.

[j] Threshold limit values or time-weighted average values, for 8-hour exposures.

APPENDIX B
FIRE-HAZARD PROPERTIES OF OSHA AND EPA LISTED HAZARDOUS MATERIALS

Flammable Liquid	Liquid Density (g/ml)	Boiling Point (°C)	Heat of Combust. (cal/g)	Heat of Vapor (cal/g)	Specific Heat (cal/g/°C)	$H_c/H_v+C_L(T_b\text{-}T_a)$ for T_a=25°C (dimensionless)	Burning Rate (kg/sec-m²)	Rate/Ratio (kg/sec-m²)
Ammonia	0.82	33.3	5400	328	1.10	16.5	Not Determined	—
Butane	0.57	0.5	10,970	92	0.55	119	0.078	0.00065
Carbon Disulfide	1.26	46	3240	85	0.24	36	Not Determined	—

18.1 BACKGROUND

Increased attention to both local and global environmental issues over the past few decades has resulted in heightened focus on these issues. This new attention has increased the workload, knowledge base, and responsibilities of environmental professionals. Issues ranging from the impact of pollution on human health, global climactic change, national security risks, and nuclear fuel processing pose serious concerns.

As with any issue within our society, consideration to health and environment is made with attention to economics and commerce. Known cases exist where deleterious financial impact resulted from negative consumer perceptions of a corporation's environmental or human health–related policies. "Green marketing" wears a friendly neighbor label and instills a barrier-to-entry against competitive products.

The costs associated with environmental and personal safety policies (the "compliance burden") pose real challenges to corporations. However, these costs serve as prudently invested dollars when weighed against the ramifications of environmental policy inaction, whether as regulatory fines or market share loss. Adherence to the various Code of Federal Regulations (CFR) that apply to a large number of U.S. industries can prevent public embarrassment and help maintain customer loyalty.

This chapter will focus on statutes and mandates of the U.S. Environmental Protection Agency (EPA) enforceable by various federal regulations, as well as discuss the state of engineering and management tools available for managing corporate compliance, and provide numerous online resources suitable for in-depth investigation of each topic.

As a quick reference, government agencies that have important bearing on the environment can be contacted via the following sites:

- The U.S. Environmental Protection Agency (EPA) www.EPA.gov
- The U.S. Nuclear Regulatory Commission (NRC) www.nrc.gov
- The U.S. Department of Energy (DOE) www.doe.gov
- Occupational Safety & Health Administration (OSHA) www.osha.gov
- U.S. Department of Health and Human Services (HHS) www.hhs.gov

18.2 THE CLEAN AIR ACT (http://epa.gov/air/caa/)

18.2.1 Background and Pollutant Types

The Clean Air Act (CAA) establishes monitoring and reporting mechanisms, air pollution inventories and reporting thresholds, and economic incentives for controlling and/or reducing pollutant

emissions from manufacturing sectors of all types. The CAA monitors the National Ambient Air Quality Standards (NAAQS) via State Implementation Plans (SIP) to ensure consistent air quality for all U.S. residents. Each SIP adheres to the requirements of the CAA by assigning applicable air pollutants to one of two categories:

- Criteria Pollutants: Pollutants for which a primary (personal safety threshold) or secondary (environmental threshold) limit exists. These limits reflect the efforts of experimental science, with criteria pollutants including common pollutants and those that are harmful based on long-term cumulative exposure, or that typically occur in very low amounts.
- Hazardous Air Pollutants (HAPs): Pollutants possessing known carcinogenics or exhibiting other extreme pathological symptoms in humans and/or in the environment.

18.2.1.1 Criteria Pollutants

U.S. regions that exhibit criteria pollutant concentrations at or below defined threshold levels receive "attainment zone" classification. Roughly 90 million Americans currently live in nonattainment zones.

18.2.1.2 Criteria Pollutants and Smog

The adverse effects on human health due to smog include shortness of breath in those with compromised pulmonary function, and may include increased asthma frequencies in young children. Long-term exposure often permanently impairs human respiratory and immune system function, and can lead to death; historical records indicate that 4000 Londoners died in December 1952 due to exposure to unsafe smog levels.

Smog contains high concentrations of ground level ozone (O_3). Ozone naturally exists at high (stratospheric) altitudes, but volatile organic compounds (VOCs) and other criteria pollutants found in gasoline, organic solvents, and paints promote increases at ground level.

Criteria pollutants include combustion products, participates (of various sizes), and volatile organics. Of significance, the EPA includes some slow evaporating, low-vapor pressure compounds such as butyl cellosolve as volatile organic materials. A full list of such pollutants is at the EPA site, http://epa.gov/oar/oaqps/peg_caa/p/egcaa11.html.

18.2.1.3 Hazardous Air Pollutants

Many chemicals pose serious risk to humans and to the ecosystem if not controlled. Many VOCs are within this group, and are regulated within the National Emissions Standards for Hazardous Air Pollutants (NESHAP). They often are carcinogens at low exposure levels, impact reproduction efficiency and fetal development, or yield serious injury or death upon even slight exposure. A current list of such pollutants is located under Section (b)(1) at the EPA site, http://epa.gov/air/caa/caa112.txt.

Since HAP chemical lists often change, this site and its related links need to be revisited periodically. Delisting of certain chemicals (e.g., acetone) can have significant regulatory and fiscal ramifications.

Listed HAP materials may appear as pure compounds, as components of a chemical mixture, or as a by-product of a chemical reaction. Regardless of a facility's pollutant type, the pollutant must be categorized, its levels quantified and then compared to regulatory listings and *de minimis* reporting levels. If a facility emits criteria or other regulated pollutants in excess of specified levels, it is classified as a major source (see description below). The major source threshold varies by location and pollutant.

Material Safety Data Sheets (MSDS) are needed for all materials utilized and/or produced within a facility, whether as a raw material, an intermediate, or a by-product, and must be available

to assist in determining a chemical's standing relative to its level of hazard within several categories. When available, even more detailed information is preferred.

18.2.1.4 Maximum Achievable Control Technology Standards

To limit the risk of hazardous air pollutant exposure over time, the EPA mandates that all major sources of HAP emissions operate under Maximum Achievable Control Technology (MACT) standards. The EPA intends to augment and add to the current list of MACT standards; additionally, there are "catch-all" regulations for all major sources of HAPs. One such example is the "MACT Hammer," which allows states to implement MACT standards for industries not currently addressed by EPA definitions. A list of such MACT standards, including the Miscellaneous Organic NESHAP (MON), can be referenced at http://www.dep.state.pa.us/dep/deputate/airwaste/aq/permits/neshaps/hammer_table.pdf.

18.2.2 Compliance Requirements

To implement the CAA, the EPA administers regulations via six discrete "Titles." These titles are defined as follows (courtesy of the EPA):

Title I – Air Pollution Prevention and Control (http://epa.gov/air/caa/title1.html)

- Part A – Air Quality and Emission Limitations
- Part B – Ozone Protection (replaced by Title VI)
- Part C – Prevention of Significant Deterioration of Air Quality
- Part D – Plan Requirements for Nonattainment Areas

Title II – Emission Standards for Moving Sources (http://epa.gov/air/caa/title2.html)

- Part A – Motor Vehicle Emission and Fuel Standards
- Part B – Aircraft Emission Standards
- Part C – Clean Fuel Vehicles

Title III – General (http://epa.gov/air/caa/title3.html)
Title IV – Acid Deposition Control (http://epa.gov/air/caa/title4.html)
Title V – Permits (http://epa.gov/air/caa/title5.html)
Title VI – Stratospheric Ozone Protection (http://epa.gov/air/caa/title6.html)

Requirements associated with Title V are of vital importance to industry, state, and local agencies. A facility's air permit defines the air pollutant threshold limits available to it. The permit declares essential operational parameters of the holder's facility with regard to product and raw material throughputs, and establishes the basic relationships between those throughputs and regulated pollutant emissions amounts.

18.2.3 Source Delineations under Title V

The EPA applies NESHAP, as well as other classifications, in defining an emitter's standing under the Title V program. Where new sources of emissions are created, or where existing sources are modified, other regulations (including both new source review (NSR) and new source performance standards [NSPS]) must be considered.

Agencies grant permits to manufacturers or distributors generally based on one of three regulated emitter definitions, as follows:

- Major Source
  - A stationary source having the potential to emit 25 tons of total HAPs to the air per annum
  - A stationary source having the potential to emit 10 tons of a single HAP to the air per annum
  - A stationary source having the potential to emit 100 tons of any criteria pollutant to the air per annum
  - A stationary source having the potential to emit HAPs in greater quantities than regionally established thresholds. This addresses nonattainment zones, such as the "extreme nonattainment" zone in the Los Angeles basin (10 TPY)
- Synthetic Minor Source
  - A stationary source that accepts federally enforceable limitations on their operations (production) to maintain their emissions below major source thresholds
- Minor Source
  - A stationary source with potential to emit, for all pollutants, less than major source threshold limits

Local and state regulations may further restrict emissions. Details concerning the requirements involved with applying for Title V permits are explained at the EPA site, http://epa.gov/air/caa/title5.html.

18.2.4 Methodologies for Determining Air Emissions

The EPA allows both simple conservative estimation as well as more precise and advanced approaches to emissions estimation. For example, facilities involved in the manufacture of limited products via a continuous process may obtain emission factors from experimental observation (e.g., stack testing) or via continuous emissions monitoring systems (CEMS).

When experimental data are sought, the EPA regulates testing methods. A list of approved methods and their descriptions is available at the Technology Transfer Network Emission Measurement Center (http://www.epa.gov/ttn/emc/tmethods.html).

Facilities unable to implement CEMS or to derive suitable experimental emission factors for their operations can utilize the factors and methods available at the EPA's Clearinghouse for Inventories & Emissions Factors, commonly referred to as CHIEF. A listing of the emission factors, free software, and other useful information is located at http://www.epa.gov/ttn/chief.

In all cases, the emission factors and methods outlined in AP-42 (a compendium of industry-specific EPA emission factors available at the CHIEF site) provide conservative estimates, thereby yielding an auditable "worst case" inventory of air pollutants nationally and regionally. Manufacturers adhering to AP-42 likely overestimate (and over report) air emissions.

The added expense attributable to an increased compliance burden resulting from inaccurate estimation of emissions, whether through administrative headcount or capital equipment, likely far exceeds the costs of implementing advanced methods for estimating air emissions. AP-42 can usually be excelled, and the variance between estimated emissions and actual emissions reduced considerably.

Available environmental management information systems (EMIS) may or may not provide advanced methods for emissions estimation, and should be reviewed versus their use of AP-42 or better.

18.2.5 New Source Reviews and Modifications

The Clean Air Act requires a revised permit for any change to a major source facility's "emissions fingerprint" resulting from the addition of physical emission points or the change of a facility's

mode of operation (NSPS). All new and modified major sources of HAPs must comply with MACT standards.

These modifications may be positive or negative with regard to Title V permitted emission levels, but such a change requires an update to the air pollutant inventory under SIP rules. In many cases, a net zero change in emissions will be sought by combining parallel activities—one positively divergent, one negatively divergent. Substituting non-HAP for a HAP classified solvent in cleaning operations is a simple example whereby reduction of use in one area may allow for increased use, or possibly retooling, in another.

18.2.6 New Regulations

The Miscellaneous Organic NESHAP (MON) is structured to reduce the floor levels of major sources and to reassess the definitions of and methods by which MACT standards and levels are achieved (http://www.epa.gov/ttn/atw/mon/monpg.html)

Certain sites currently classified as minor emissions sources will find themselves classified as major sources under MON, and adherence to the requirements of the MACT guidelines posed by the major source classification will likely be costly. It is recommended that manufacturers of VOC-related products acquaint themselves with the MON and make necessary preparations. Costs associated with major source classification within MON often range upwards of $5–10 million per facility.

18.2.7 Title IV (Acid Rain) and Title VI (Stratospheric Ozone) Considerations

18.2.7.1 The Title IV (Acid Rain) Permit (http://epa.gov/air/caa/title4.html)

The environmental, health, and cultural impacts of acid rain were well documented in the late 20th century. Acid rain results from combustion of the sulfur and nitrogen contents of fossil fuels. Sulfur and nitrogen oxides combine with atmospheric water to form acids. The prevalence of mobile (e.g., automotive and aircraft) sources globally hints at the requirement for control of Title IV compounds and precursors.

Automotive catalytic converters (http://www.all-catalytic-converters.com/techtip1.html) alleviate this issue (as well as those associated with smog formation) within the mobile source category; however, they are not the perfect solution to emissions problems.

Within the stationary source category, acid rain forming compounds primarily result from combustion-based power plant facilities.

18.2.7.2 Permitting Requirements

Title IV addresses "affected sources," which comprise "affected units." These affected units are subject to emissions reductions or limitations under Title IV, and are granted allowances per annum, with each allowance equal to 1 ton of SO_2 per year.

Under Title IV, facilities must document and report annually regarding the aggregate amount of acid-rain precursors in the form of SO_2 and $NO_{X.}$ Determination of these amounts are traditionally handled by stack testing, with the emissions factor subsequently calculated in units of pound of species emissions per pound of fuel combusted, per hour of operation, or other. Title IV thresholds are subject to penalty when exceeded. Additionally, in the case of violation, the EPA can enforce a mandatory emissions reduction in the subsequent year to offset the excess emission value.

Power generation facilities are evaluated within the Title IV requirements versus baselines established within the National Acid Precipitation Assessment Program (NAPAP) Emissions Inventory. Descriptions of source and unit types applicable under Title IV can be found at http://epa.gov/air/caa/caa402.txt.

18.2.7.3 Emissions Trading

Emission allowances under Title IV are eligible for trading and/or carry forward contingent upon adherence to EPA administrative and regulative rules. A summary discussion of such activity is provided at http://www.epa.gov/airmarkets/progsregs/arp/docs/clearingtheair.pdf.

18.2.8 The Title VI (Stratospheric Ozone) Permit (http://epa.gov/air/caa/caa602.txt)

Decreasing levels of stratospheric ozone (O_3) over the polar caps have lead to the speculation that a reduction in high-atmospheric (stratospheric) ozone levels will lead to increased skin cancers rates (caused by excessive, nonhistorical UV-band radiation exposure).

Chlorine or other halogen bearing hydrocarbons (typically chlorofluorocarbons) defined as either class 1 or class 2 substances comprise the major stratospheric ozone depleting substances. EPA has established a midterm objective of an atmospheric chlorine content <2 parts per billion (ppb).

Glacial ice core samples indicate pre-industrial-age levels of atmospheric chlorine at <1 ppb. By the late 20th century, the concentration had reached 3.6 ppb. Continuation of current efforts may return the Earth's atmosphere to <1 ppb levels shortly after year 2100. The following link provides a summary analysis of CFC/HCFC atmospheric conditions compiled by the Canada Chemical Producers Association: http://en.wikipedia.org/wiki/ozone_layer.

18.2.8.1 Permitting Requirements

Operators must report all class 1 and class 2 compounds whether imported, exported, or manufactured. Additionally, users of nonessential (as determined by administrator review) class 1 or class 2 substances are prohibited from sale or transfer of such substances.

18.2.9 Control Technologies: Hardware Options

See examples of pollution control devices at http://www.epa.gov/ebtpages/treapollutioncontrol.html or http://cn.wikipedia.org/wiki/air_polution/control_devices.

Numerous control technology hardwares are available for the reducing airborne emissions. Several types are reviewed below with general comments applied to each.

1. Oxidizers. Thermal oxidizers rely on high temperature combustion of VOC/HAP species to reduce emissions levels. Although often expensive, they provide high destruction efficiencies, often >99.8%. Hence, they often prove a useful asset with high measurable return.
2. Condensers. Condensers condense volatile species present in the vapor stream resulting in sidewall condensation and reflux to the liquid phase. Vapor pressure data are used to predict control efficiencies as functions of condenser temperature.
3. Scrubbers and absorbers. Scrubbers capture particles, gases, and/or acidic vapors. In treating particulate matter, scrubbers remove particulates in mists of liquid (typically water) and transport the particles away from the vapor stream. In these cases, high flow rates of liquid mist droplets increase the removal efficiency of the solids. In the treatment of gases, it is essential to select a liquid in which the gas is soluble and to use liquid and vapor flow rates that match the targeted capture percentage based on the system's solubility information. In both cases, the liquid to vapor ratio is an important operating variable.
4. In acid gas removal, the scrubber employs a solid alkaline "sorbent" material mixed with water. The gas phase acid adsorbs onto the sorbent surface, and then forms a salt.

Available sorbent surface area, vapor-liquid stream mixing, and reactivity will dictate the effectiveness of such "dry sorbent injector" scrubbers.

5. Biofilters. Although relatively new, biofiltration has been used in some instances for reduction of emissions and odors. Biofilters consist of microbes grown on porous media, and in small-scale implementations, they provide >90% reduction in emissions levels.
6. Cogeneration. Several new technologies combine destructive oxidation technologies with cogenerative site-based power facilities. The energy utilized in emissions oxidation can sometimes be reclaimed to yield economic benefits.

18.2.10 Consultation

In general, numerous professional consulting service providers can help prepare Title V permits, annual emissions inventory reports, and other state-specific documents. An Internet search can identify potential regional candidates.

The EPA expects that EMIS systems be implemented at all major categorization facilities, and site implementation of such systems typically constitutes the first requirement of an EPA corrective action plan. As stated above, more accurate systems of emissions estimation can lead to reduced compliance burden and potentially eliminate the need for source classification adjustment.

In all cases, adherence to the full range of Federally Applicable Requirements, the crux of which are provided above, combined with the goal of maintaining operational flexibility, should be the objective of any permit-focused environmental engineer.

18.3 THE CLEAN WATER ACT (http://www.epa.gov/r5water/cwa.htm)

The Clean Water Act (CWA) provides water quality standards (WQS) for surface waters in the United States. The CWA gives the EPA the authority to implement pollution control and regulatory strategies.

Water quality criteria (WQC) provide chemical-specific numerical values of amount (magnitude), interval of test, and frequency of occurrence that must be met in tandem to meet the requirements of the WQS. For chemicals with WQC documented at EPA, states and Indian tribes must also assign WQC (not necessarily of identical values per the EPA metrics).

The EPA typically allows exemptions from the WQS for locations downstream of point source discharges ("stream mixing") as well as for relatively rare conditions where a significant increase in flow diminishes water quality (for example, storm sewer flooding). Waivers based on mixing are regulated and require that mixing zones do not extend throughout a body of water or from bank to bank of a river or stream. Additionally, waivers will not allow deleterious impact to designated use (DU) zones. A contiguous region meeting WQS must be maintained.

18.3.1 Existing Use

Designated use nomenclatures indicate the level of quality to which a community aspires; the "existing use" establishes a benchmark. The intent of the existing use delineation assures that no commercial, public, or private activity reduces water quality to subexisting use levels, and regulating bodies will not authorize subexisting use conditions ("Tier I rule").

The EPA protects zones that significantly exceed current WQS from negative impacts, thus making it difficult to impact a water body while ensuring the quality remains above its minimum. Prior to initiation of such an adverse activity, several criteria must be met as defined under the "Tier II rule."

Certain waterways are designated as outstanding national resource waters, and no significant degradation in water quality is permitted for any significant period of time ("Tier III rule"). These

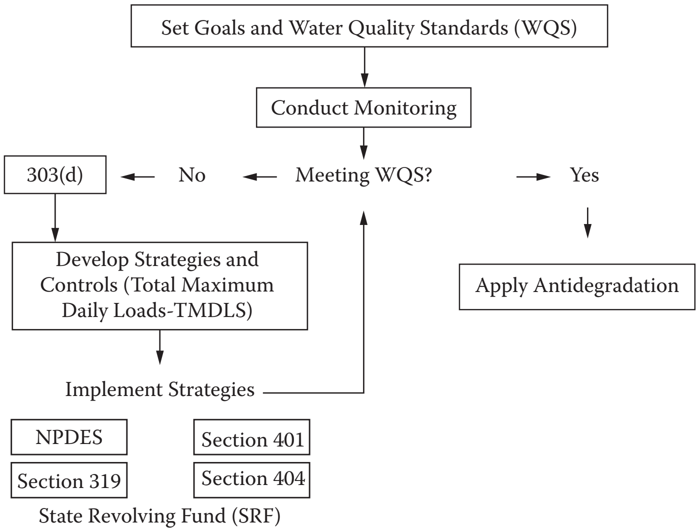

FIGURE 18.1 The EPA chart "Introduction to the Clean Water Act."

three "anti-degradation rules" provide high-level management metrics to regulating and enforcement bodies within the state, national, or regional level.

18.3.2 Total Daily Maximum Load Levels

Infrequent measurements of water quality result in large statistical errors in estimation of performance versus WQS. When the available evidence indicates achieving WQS standards unlikely or impossible via application of source control technologies, the EPA imposes total maximum daily load (TDML) levels of individual pollutant discharge from point sources.

Unfortunately, application of TMDL rules does not typically result in achievement of WQS due to the large impact of nonpoint sources (e.g., soil runoff). Nonetheless, TMDLs for such defined pollutants as clean sediments, nutrients (nitrogen and phosphorus), pathogens, acids/bases, heat, metals, cyanide, and synthetic organic chemicals are enforced.

Caps are established, with margins of safety, and completed facility TDML plans and strategies are provided to the EPA for approval or disapproval. The time defined within a TDML plan does not necessarily have to equal 1 day, and a reserve for future polluting activities is typically comprehended. Approved agencies or parties will regularly audit site performance against a facility's TMDL plan.

The EPA chart "Introduction to the Clean Water Act" (Figure 18.1) highlights the key focus areas of the CWA (http://www.epa.gov/watertrain/cwa/cwa1.htm).

18.3.3 National Permit Discharge Elimination System

Although the CWA states the illegality of pollution discharge from point sources, it does allow for controlled discharges via the *National Permit Discharge Elimination System* (NPDES). NPDES permits limit the levels of point source pollutant discharge allowable over defined periods (some sectors of industry are exempt; see http://www.epa.gov/watertrain/cwa/cwa37a.htm). Indirect discharges, i.e., those treated by a publicly owned treatment works (POTW) facility prior to release, are not covered under the NPDES permit program (see below).

The EPA defines waste load allocations (WLA) to point source pollution sources (generally or specifically), which are then regulated against the defined TMDL (if applicable) established in the NPDES permit site. A useful example of the administration of Waste Load Allocations within the State of California can be found at http://www.swrcb.ca.gov/rwqcb2/Agenda/03-19-03/03-19-

TABLE 18.1
General Publicly Owned Treatment Works Water Allowance Limits

Pollutant	Effluent Limit/7-Day Average	Effluent Limit/30-Day Average
5-day BOD	45 mg/L	30 mg/L
TSS	45 mg/L	30 mg/L
pH	N/A	6–9
Removal specification	N/A	85% of BOD 5 and TSS

BOD, biochemical oxygen demand; TSS, total suspended solids.

5bmou.doc. This example provides an historical review of the environmental performance of the waterway in question, with focus on mercury contamination. Additional information on waste quality is available at http://en.wikipedia.org/wiki/water_quality.

Often, NPDES permits are either granted as individual or general permits, and contain specific mass amounts of defined pollutants eligible for discharge (effluent limits at pipe end) from the permitted operation. To ensure compliance, internal auditing plans and quality control policies are defined. Further requirements for using best management practices, monitoring, and reporting are included.

Detailed information on NPDES permits is available at http://www.epa.gov/watertrain/cwa/cwa40.htm.

As with the CAA, the CWA establishes performance standards (the maximum effluent concentrations allowable) and control technology guidelines applicable to various industries and sectors. These guidelines reflect data compiled from numerous industry sources, and define expected discharge levels as a function of best available technology economically achievable (BAT or BATEA). More information on effluent streams is at http://www.epa.gov/waterscience/guide/.

For cases where application of BAT to effluent stream discharges will not meet the requirements of a water source's DU, and for which TMDL limits are not established, the permitting agency will apply water quality–based effluent limits (WQBEL). WQBEL includes an analysis of the level of effluent stream dilution required to retain DU levels. Where WQBEL is employed, a high risk has been assigned to the water source, and economics will often be secondary to technology.

18.3.4 Publicly Owned Treatment Works

Both primary and secondary levels of sequential treatment specifications exist for POTW plants. The former involves the settling and filtering of solids (activated sludge). Table 18.1 provides typical limits imposed on secondary treatment criteria.

The EPA offers supplemental information regarding activated sludges involving biosolids, including rules and standards (see http://www.epa.gov/watertrain/cwa/cwa42.htm).

18.3.5 "Wet Weather Flow" Conditions

Due to heavy rainfall, wastewater overflows from sewers or industrial facilities may result in underperformance versus WQS. Nevertheless, affected sewer systems, typically combined sewer overflow (CSO) or municipal separate storm sewer systems (MS4), remain subject to NPDES regulations. CSO systems, found in older residential or municipal areas, allow transportation of both rainwater and raw sewage within a common stream; MS4 systems separate the two flows.

Attention to the public health challenges posed by CSO sewers focus on control of pathogen dispersion. From NPDES perspectives, CSO systems are restricted from discharging untreated sewage during periods of dry weather.

NPDES regulates MS4 sewers that discharge to surface waters because of the potential for the water line to contain various levels of contaminants such as metals, oils, and pesticides. Permits for MS4s tend to focus on response planning and "design against failure" rather than on actual effluent stream concentrations. More information is available at http://www.epa.gov/watertrain/cwa/cwa46.htm.

Industrial sites may or may not require individual NPDES permits for storm water runoff pertaining to overflow drainage into surface water or MS4 sewage systems. Frequently, these conditions will be covered under NPDES documentation via the site's storm water pollution prevention plan (SWPPP) (see http://cfpub.epa.gov/npdes/stormwater/indust.cfm).

SWPPP phase I applies to industrial facilities and to construction sites affecting more than 5 land acres, while SWPPP phase II regulations affect those construction sites affecting between 1 and 5 acres. SWPPPs are expected to provide plans for minimization of soil erosion, protect vegetation and wetlands, and define runoff source points to standing water.

Additionally, a spill prevention control and countermeasure (SPCC) plan may be required at facilities where oil materials are stored. Importantly, edible oils are often included in this designation. SPCC is discussed in more detail in Section 18.9.

18.3.6 CWA Section 319: Nonpoint Source Pollution

Nonpoint source runoff is the major source of water pollution in the United States. Topsoil runoff from farms and pastures represents the major source of this pollution.

Contrasting the federal position on point sources, the EPA provides grants ("319 funds") and other modes of assistance and incentive to such polluting states. The EPA's objective is to curtail pollution from such erosion sources and to define auditable levels of watershed TMDL. For more on nonpoint pollution, see the EPA CWA Web site, http://www.epa.gov/watertrain/cwa/cwa52.htm.

18.3.7 CWA Section 404: Wetland Protection

The "wetland protection program" (administered by the Army Corps of Engineers) addresses the displacement of dredged or fill-material into defined wet areas such as bottomland hardwood swamps, intermittent streams, or oceans (http://www.epa.gov/owow/wetlands/facts/fact10.html). The Army Corps of Engineers has ultimate authority for defining a Section 404 wetland, and for assuring compliance within Section 404 boundaries.

The wetland protection program requires that any commercial activity requiring the destruction of existing wetlands be essentially dependent on the presence of water. If not, the activity will be relocated to an unprotected area. Prior to construction on a protected wetland area, demonstration of destruction mitigation plans along with a wetland replacement strategy and/or a plan for improving an existing wetland must be presented.

18.3.8 Final CWA Notes: Sections 303, 305, and Section 401 Certification

Special attention is given waters that are directly threatened or do not meet WQS. These receive Section 303(d) or Section 305 (threatened or impaired waters) classification. Section 303(d) includes those surface water sources impacted by pollutants, whereas "nonpollutants" impair Section 305 waters. Where the source of aquatic life impairment is unclear, the source receives Section 303(d) classification. Waters classified as threatened or impaired require biennial progress reporting, with prioritization of TMDL levels and WQC established accordingly.

Section 401 certification ensures that all states indicate compliance status under the CWA. By requiring such a certification, states downstream of the discharge can become involved in the certification and permitting processes (http://www.epa.gov/watertrain/cwa/cwa58.htm).

The hydropower dam presents an interesting case study, as dams by definition cause great variance between existing and DU classifications and the final state of the dammed water.

18.4 NUCLEAR POWER GENERATION

Currently, nuclear energy serves as the second largest source (behind coal) of electrical power in the United States. Nuclear sources are inherently clean, but significant risks and therefore governmental regulations apply to the waste disposal methods.

The Nuclear Regulatory Commission (http://www.nrc.gov/) oversees all permitting, guidelines, and definition of operational requirements via the Office of Nuclear Reactor Regulation.

18.4.1 Hazardous Waste Disposal

Nuclear reactor facilities undergo hazardous waste management procedures every 12 to 24 months. Older fuel rods are removed, generating approximately 2000 metric tons of used radioactive material annually (the National Energy Institute presents the analogy of one football field covered to the depth of 5 yards during the past 40 years).

Based on laws against the proliferation of nuclear weapons, nuclear waste cannot be recycled, and is assigned a once-through single use designation. Department of Energy policies as administered by the U.S. Department of Energy Office of Health, Safety, and Security can be consulted at http://www.hss.energy.gov/NuclearSafety/techstds/standard/standard.html.

The Office of Environmental Management maintains the DOE's waste management policies. Two discrete levels of nuclear wastes are considered:

1. Low-Level Waste
   a. Radioactive by-products of NRC-licensed or DOE-permitted activities that are not high-level waste.
   b. Radioactivity, containing mostly beta and gamma emissions, persists for 5 to 50 years; contains elements with atomic numbers less than that of uranium (92), and is eligible for disposal via authorized independent or government-approved facilities, as determined by the Low-Level Waste Disposal Facility Federal Review Group (LFRG).
2. High-Level Waste
   a. Irradiated nuclear fuel ("spent fuel"), plus both liquid products of reprocessing and the solids into which such liquids have been incorporated.
   b. Contains numerous radioactive materials of high levels of radiation and with long half-lives. Such materials are generated either through nuclear power generation or Department of Defense activities. In general they are assigned for disposal at the U.S. Government Yucca Mountain National Depository.

For the centralized disposal of high-level nuclear wastes, Yucca Mountain, Nevada, was selected in large part because of national security concerns.

18.4.2 Lessons Learned: 3-Mile Island and Chernobyl

The incident at Unit 2 of the 3-Mile Island (Pennsylvania) reactor during March 28 to April 1, 1979, led to the formation of the Institute of Nuclear Power Operations (INPO). The INPO sets objectives, guidelines, and criteria for all U.S.-based nuclear power generating facilities. In 1985, this group established the National Academy for Nuclear Training, which accredits all plant operators and supervisors.

In April 1986, fundamental flaws in Soviet reactor designs, combined with procedural human error, resulted in a steam explosion and the expulsion of 5% of the Chernobyl-4 (Ukraine, USSR)

reactor core into the atmosphere. This disaster sparked a review of (especially Russian) reactor designs and further emphasized the need for strictly enforced operational standards, guidelines, and policies. Differences between current “East” and “West” reactor designs can be reviewed at the site http://www.insc.anl.gov/neisb/neisb4/NEISB_1.1.html.

18.4.3 Next Generation Designs: VHTR Reactors

Very high temperature reactors (VHTR), currently being developed, not only address energy generation but also provide a relatively cheap source of molecular hydrogen. Hydrogen is currently proposed as an alternate fuel source for vehicular power, but current methods for obtaining it pose severe environmental problems.

In a VHTR cogeneration scheme, a fraction of the energy generated acts to produce and store hydrogen. When combined with an adequate logistics system, hydrogen can serve as a clean, renewable combustion energy source for personal or industrial use. Health and safety concerns, combined with economics considerations, will dictate the future of VHTR reactors. For further review of this and other nuclear power generation roadmap technologies, consult the site http://energy.inel.gov/gen-iv/default.shtml.

18.5 OSHA

The Occupational Safety and Health Act has the objective of protecting workers’ lives and health by the enforcement of policies, regulations, and guidelines defining working and workplace conditions. OSHA lists regulations and compliance at the following sites:

http://www.osha.gov/comp-links.html
http://www.osha.gov/html/comp-guides.html

Employers must operate within these guidelines except for rare exceptions (variances). Variance types include:

1. Temporary
   a. Issued when an employer-operator cannot meet the requirements of an OSHA regulation due to a lack of available staff, equipment, or materials. Employers governed by a state-run worker protection program must contact their local plan representative for such a variance, but operators that span geographic areas or states that include OSHA-regulated regions must apply directly through OSHA.
2. Permanent
   a. Issued to an employer that demonstrates pre-existing methods superior to OSHA requirements. In attaining a permanent variance, the employer must inform the employee workforce of the intention to seek a variance, and allow for an employee hearing if requested.
   b. At any time within 6 months of the award of a permanent variance, employees and employers maintain the right to petition for the rescinding of the variance. OSHA may also follow this course at its own volition.
3. Experimental and Other Variances
   c. Granted by the Secretary of Health and Human Services to ascertain the impact of operations changes that require variances. These experimental variances are intended to improve existing OSHA methods.
   d. Because of National Security reasons, the Department of Defense may hold other variances.

Variances are not retroactive. During the period of operation prior to receipt of a variance, if issued, OSHA may provide an interim order, allowing continued activity based on current methods. Details of such an interim order are subject to site publication and employee-employer review.

18.6 THE "SUPERFUND" LAW

The "Superfund" law derives from citizen concerns over the health impacts of decades of accumulated hazardous wastes within or near communities. More accurately labeled the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), the Superfund governs the removal and destruction of toxics and also establishes disposal procedures through the Office of Superfund Remediation Technology Innovation (OSRTI). Prioritization activities are within the jurisdiction of the OSTRI.

18.6.1 Amendment to the Superfund Law: SARA

The Superfund Amendments and Reauthorization Act (SARA) provides guidelines to improve Superfund enforcement methods and criteria. SARA also refines the Hazardous Rankings System, and by OSTRI prioritizes remediation activities. Rules and regulations under the Superfund and its SARA amendment are accessible at http://www.epa.gov/superfund/action/index.htm.

18.7 EPCRA (EMERGENCY PLANNING AND COMMUNITY RIGHT TO KNOW ACT)

EPCRA, also known as "Title III of SARA," protects local communities from the hazards of toxic pollutant discharge (http://www.epa.gov/region5/defs/html/epcra.htm). EPCRA mandates regulations surrounding the maintenance and site availability of such forms as MSDS, toxic chemical release forms, and emergency and hazardous chemical inventory forms (see http://www4.law.cornell.edu/uscode/html/uscode42/usc_sup_01_42_10_116_20_II.html

Under EPCRA, state emergency planning commissions and local emergency planning councils must be formed. EPCRA ensures the documentation of quantity and location of hazardous materials present in excess of Toxic Substance Controls Act (TSCA) thresholds. SARA Title III information must be submitted to state and local (including fire) agencies under SARA Sections 312 and 313.

EPCRA, in combination with the Pollution Prevention Act (PPA), administers the toxic release inventories (TRI) program. Industry and federal facilities emitting toxic materials must report on annually released quantities under SARA Section 313 (Form R). Although the EPA does not host a site containing all TRI materials, versions of this document can be obtained via the Government Printing Office (http://www.access.gpo.gov/). An executive summary, including requirements for submittal to the TRI via Form R submittals, is available at http://www.epa.gov/tri/tridata/tri01/press/executivesummarystandalone.pdf.

18.8 TOXIC SUBSTANCES CONTROL ACT (TSCA)

More than 75,000 chemicals enter, are manufactured within, and/or are consumed within the United States each year. The TSCA (http://www.epa.gov/region5/defs/html/tsca.htm) provides methods for categorizing newly created and existing chemicals, and supplements the Clean Air Act and the Toxic Release Inventory portion of EPCRA. The TSCA assists in quantifying types and amounts of chemicals both produced and released to the environment annually.

Commercial activities that result in the creation of new chemicals must receive authorization from the EPA prior to production or distribution. To receive such authorization, a pre-manufacture notice (PMN) must be filed with the EPA's Office of Pollution Prevention and Toxic Substances.

For a listing of toxic substance categories as defined within the Chemicals on Reporting Rules database, access https://www.unh.edu/ehs/pdf/TSCA-CORR-By-CAS.pdf.

18.8.1 TSCA General Sections References

Lead exposure reduction:

http://www4.law.cornell.edu/uscode/html/uscode15/usc_sup_01_15_10_53_20_IV.html

18.9 RESOURCE CONSERVATION AND RECOVERY ACT (RCRA)

Administered by the Office of Solid Wastes, the RCRA establishes regulations regarding the effective handling of spilled, leaked, or otherwise improperly disposed wastes (http://www.epa.gov/rcraonline/). The RCRA also manages hazardous wastes from their origin to disposal, and oversees garbage and industrial waste handling. Example wastes not covered under RCRA are nuclear (see above), medicinal, and animal.

The site http://www.epa.gov/epaoswer/osw/topics.htm provides an information source addressing those wastes covered under the RCRA, including regulations surrounding underground storage tanks.

18.10 SPILL PREVENTION CONTROL AND COUNTERMEASURES (SPCC) ACT

The SPCC, ultimately a component of the Clean Water Act, focuses on prevention of oil spills into U.S. waters or shorelines. To minimize the impact of spills, the SPCC requires filing of facility response plans (FRP) under its oil pollution regulations.

The SPCC addresses owners or operators that drill, produce, gather, store, use, process, refine, transfer, distribute, or consume oil and oil products. With such a broad classification, de minimis standards are established that set maximum vessel or throughput quantities. The SPCC defines threshold EPA reportable event levels as:

- Two spills in excess of 42 gallons each within any given 12-month period
- One spill in excess of 1000 gallons

Highlights, de minimis standards, and additional information including FRP guidelines, are available at http://www.epa.gov/oilspill/spccrule.htm.

18.11 GREENHOUSE GASES AND (GLOBAL WARMING) CLIMACTIC CHANGE

No regulations currently apply to greenhouse gas (GHG) emissions. The United States and other nations are conducting research on global warming while establishing the current air inventory of GHG. (For a review, see http://yosemite.epa.gov/oar/globalwarming.nsf/content/emissions.html.)

Although few dispute that current industrial processes, automobiles, power production, etc., impact GHG levels, there is still much debate regarding human-induced and naturally occurring variations. Recently excavated ice core samples indicate that CO_2 levels are rising at a much faster rate than at any time in the past 400,000 years. Such cores show current atmospheric CO_2 levels of 380 ppmv, exceeding previous cyclical highs by roughly 18%. The following links to graphical data can assist in drawing conclusions:

- http://www.grida.no/climate/vital/02.htm (400,000-year CO_2 atmospheric measurements, Vostok ice sheet, Antarctica)
- http://www.grida.no/climate/vital/06.htm (recent data from Mauna Loa test site, altitude 4000 meters)
- http://www.grida.no/climate/vital/07.htm (CO_2 levels, 1870 to 2000)

Although the scientific community generally believes that decreasing polar ice cap size and commensurate rising ocean levels correlate with increased GHG levels and global warning, the full ramifications of the evidence remain contested.

18.11 SUMMARY

The daily tasks of compliance management in the face of potentially changing government regulations are facilitated by a strong industry complement of consulting expertise. Additionally, software packages of varied types are available to assist in automating difficult compliance tasks.

Environmental engineering issues span a wide gamut of technologies and requirements both mundane and essential. Ensuring compliance with government regulations, though never a glorified chore, nonetheless provides a necessary function that ensures the protection of interests ranging from the economic to the vital.

The roles of environmental engineers in ensuring and monitoring the healthy progress of developing nations, assisting in defining the directions of new and necessary technologies, and in protecting our children and ecosystems cannot be underestimated.

The economic impact of a dearth of environmental stewardship is too great to gamble.

19.1 INTRODUCTION

Biochemical engineering involves the scale-up of biological processes. One of the earliest examples of the successful scale-up of a biological process was the production of penicillin during World War II. Industrial microbiologists used stirred-tank fermenters to culture molds on a large scale. During the 1960s and 1970s, biochemical engineering grew rapidly with the increased needs for the development of biological processes in the food, beverage, and pharmaceutical industries. The activities in bioprocessing grew even further as Arab oil embargos prompted the use of renewable energy sources, such as biomass. For example, cellulose, a major component of wood, can be broken down enzymatically to glucose, hence producing ethanol via yeast fermentation.

The research for the utilization of renewable resources dwindled in the early 1980s because of the reduction in energy prices. However, the area found another opportunity to grow as biologists discovered a way to manipulate genes of living organisms. The manipulation of genes is known as genetic engineering or biotechnology.

19.1.1 Biotechnology

Biotechnology is broadly defined as "commercial techniques that use living organisms, or substances from those organisms, to make or modify a product, including techniques used for the improvement of the characteristics of economically important plants and animals and for the development of microorganisms to act on the environment" [1]. This very broad definition includes not only the newly developed recombinant DNA technology, but also the traditional areas involving agriculture, animals, human heath, and industrial microbiology. Since ancient days, people utilized microorganisms to produce fermented beverages (alcohol, sweet refreshments) and food (cheese, soy sauce, fermented vegetables, sweets, and bread), though they did not understand those biological changes. People crossbred plants and animals for better yields.

However, in recent years, the term biotechnology is being used to refer to novel techniques such as recombinant DNA. This technique is also known as genetic engineering, a misleading description of scientific endeavors. The applications are numerous, as listed in Table 19.1. Previously expensive and rare pharmaceuticals (such as insulin for diabetics, a human growth hormone to treat children with dwarfism, interferon to fight infection, vaccines to prevent diseases, and monoclonal antibody for diagnostics) are now produced from genetically modified microbial cells or hybridoma cells inexpensively and in large quantities. Disease-free seed stocks and healthier, higher-yielding food animals have been developed. Important crop species can be modified to have traits that resist stress, herbicides, and pests. Furthermore, recombinant DNA technology can be applied to develop genetically modified microorganisms so that they will produce various chemical compounds with higher yields than available from unmodified microorganisms.

19.1.2 Biochemical Engineering

In order to cultivate genetically modified cells in large quantities, we need to develop a large-scale process that is technologically efficient and economically viable. A typical biological process (bioprocess) involving microbial cells can be illustrated as in Figure 19.1. Raw materials are treated and mixed with other ingredients that are required for cells to grow well. The liquid medium,

TABLE 19.1
Applications of Biotechnology

Area	Products or Applications
Pharmaceuticals	Antibiotics, antigens, neurotransmitters, gamma globulin, growth hormone, serum albumin, immune regulators, insulin, interferon, interleukins, lymphokines, monoclonal antibodies, neuroactive peptides, tissue plasminogen activators, vaccines
Animal agriculture	Development of disease-free seed stocks; healthier, higher-yielding food animals
Plant agriculture	Transfer of stress-, herbicide-, or pest-resistance traits to crop species; development of biological insecticides
Specialty chemicals	Amino acids, enzymes, vitamins, lipids, hydroxylated aromatics, biopolymers
Environmental applications	Mineral leaching, metal concentration, pollution control, toxic waste degradation, enhanced oil recovery
Commodity chemicals	Acetic acid, acetone, butanol, ethanol
Bioelectronics	Biosensors, biochips

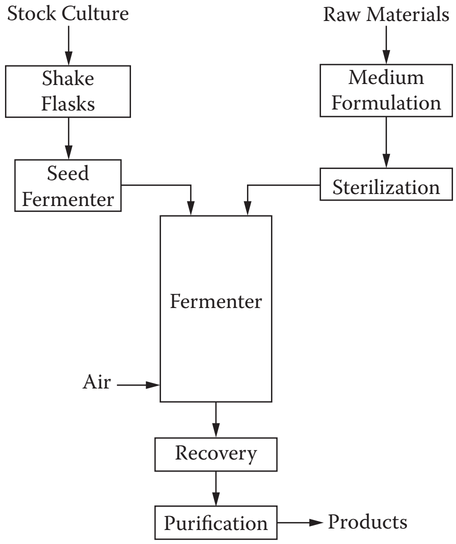

FIGURE 19.1 Typical biological process.

sterilized and introduced to a bioreactor or fermenter, is typically equipped with agitators, baffles, air spargers, and sensing devices for the control of the operating conditions. A pure strain of microorganisms is introduced into the vessel. The number of cells multiplies exponentially after a certain period of lag time and reaches a maximum cell concentration as the medium is depleted. The fermentation is then stopped and the contents are pumped out for the product recovery and purification. This process is operated either by batch or continuous mode.

For large-scale operations, biochemical engineers work with biological scientists to: (1) obtain the best biological catalyst (microorganism, animal cell, plant cell, or enzyme) for a desired process, (2) design and operate the bioreactor in the most efficient way, and (3) separate the desired products from the reaction mixture in the most economical way. Biological processes have advantages and disadvantages as compared with traditional chemical processes (Table 19.2). Bioprocessing is most promising for high-price, low-volume products such as pharmaceuticals, medical enzymes, and analytic reagents (Table 19.1). There are, however, several products produced through bioprocessing that are low-price, high-volume products. Some example of these are high-fructose corn syrup (and

TABLE 19.2
Characteristics of Bioprocessing

Advantages	Disadvantages
The reaction conditions are mild: typically atmospheric conditions.	Complex product mixture and low productivity make the product separation expensive.
Enzyme catalysts are highly specific. A great variety of enzymes exist that can catalyze a very wide range of reactions.	Cells tend to lose desirable characteristics. Enzymes are sensitive and unstable in harsh conditions.
The major raw material for bioprocesses is biomass, which is renewable.	Fermenter and medium have to be sterilized and kept in sterile conditions.

enzymes involved on the process such amylase and glucose isomerase) and laundry additives (protease enzyme).

Lastly, the word *fermentation* needs to be discussed due to the confusion caused by different definitions of the word. Traditionally, fermentation was defined as the process for the production of alcohol or lactic acid from glucose. A broader definition of fermentation, which has been adopted in this handbook, is an enzymatically controlled transformation of an organic compound.

19.2 CELLS AND ENZYMES

19.2.1 Microbial Cells

The three major categories of life are the animal kingdom, the plant kingdom, and the protists (Table 19.3). Protists have a relatively simple biological organization and do not differentiate into separate cell types. The microorganisms classified as the protists are further divided into two categories: eukaryotes and prokaryotes. Prokaryotes are small and simple. It is the unit of structure of bacteria and blue-green algae. The more complex eukaryotic cell has internal unit membrane systems that segregate many of the functional components of the cell. Since eukaryotic cells are also the unit of structure of animals and plants, in modern biology, life is broadly classified into two categories: eukaryotes and prokaryotes (Table 19.3). Among the protists, bacteria and fungi are two most important microorganisms for industrial applications. Table 19.4 gives several examples of microorganisms used industrially.

TABLE 19.3
Major Categories of Life

Type	Haeckel	Modern
Multicellular	Animals	Eukaryotes
	Plants	
Unicellular	Protists	
	Algae

	Fungi	
	Molds	
	Yeasts	
	Bacteria	Prokaryotes
	Blue-green algae	

TABLE 19.4
Industrial Applications of Microorganisms

Microorganism	Industrial Applications
Bacteria	• Production of acetone, butanol, enzymes (such as amylase, protease, invertase, and rennin), lactic acid, sorbose, dextran, and hormones • Bioremediation of hazardous chemicals • Production of mammalian proteins (biopharmaceuticals) from recombinant bacteria
Yeasts	• Production of alcoholic beverages and industrial-grade alcohol • Production of baking goods and food supplements • Production of mammalian proteins (biopharmaceuticals) from genetically modified yeasts
Molds	• Production of penicillin, hormones, and other antibiotics • Production of citric acid, enzymes (such as amylases, invertase, proteases, glucose oxidase, and pectinase), fumaric acid, gluconic acid, and lactic acid

19.2.1.1 Microbial Nomenclature

Microbiologists use the binomial system, in which each organism has two names, for example, *Bacillus subtilis.* Proper names of organisms are always italicized. The first word is the name of the genus and is capitalized. The genus name is usually Latin or Greek; examples are *Bacillus* (a small rod), *Lactobacillus* (a small milk rod), *Micrococcus* (a small grain), and *Clostridium* (a small spindle). The second word in the name of a microorganism is the species name and is not capitalized. There may be several species with the same genus name, for example, *Bacillus subtilis, B. albus,* and *B. coagulans.* When the same genus name is repeated several times, it is often abbreviated.

19.2.1.2 Bacteria

Bacteria are unicellular microscopic organisms; about 1500 known species occur in practically all natural environments. The typical diameter of the cell ranges from 0.5 to 1 μm; the lengths vary greatly. Bacteria occur in a variety of shapes such as *cocci* (spherical or ovoid), *bacilli* (cylindrical or rod shaped), and *spirilla* (helically coiled). Bacteria reproduce predominantly by binary fission: a single cell divides into two after the development of a transverse cell wall to separate the intracellular content.

The nutritional medium to cultivate bacteria provides energy, carbon, nitrogen, sulfur, phosphorus, metallic elements, and vitamins. The physical conditions important for the optimum growth include temperature, the gaseous environment, and pH. The principal gases in the cultivation of bacteria are oxygen and carbon dioxide. Aerobic bacteria grow in the presence of free oxygen. Anaerobic bacteria grow in the absence of free oxygen. Generally, the optimum pH for growth lies between 6.5 and 7.5, while the minimum and maximum limits vary from 4 to 9.

Some bacteria form spores when growth ceases due to starvation or other causes. Spores are more resistant than normal cells to heat, drying, radiation, and chemicals. Spores can remain alive for many years, and can convert back to normal cells at proper conditions. Spore-forming bacteria are found most commonly in the soil.

19.2.1.3 Fungi

Fungi are plants devoid of chlorophyll and are therefore unable to synthesize their own food. They range in size and shape from single-celled yeasts to multicellular mushrooms.

Yeasts are found in fruits, grains, and other foods containing sugar. They are also in or on the soil, the air, the skin, and the intestines of animals. Yeasts are generally unicellular organisms and their shape is spherical to ovoid. Their size is 1 to 5 μm in width and from 5 to 30 μm in length.

TABLE 19.5
Typical Growth Medium for Yeasts

Glucose	100 g
Yeast extract	8.5 g
NH_4Cl	1.32 g
$MgSO_4$	0.11 g
$CaCl_2$	0.06 g
Anti-foam	0.2 mL
Water to make	1 L

The most common growth pattern for yeasts is budding, which is an asexual process. A small bud (or daughter cell) is formed on the surface of a mature cell.

Molds are filamentous fungi. A single reproductive cell or spore is germinated to form a long thread, or hyphae, which branches repeatedly as it elongates to form a vegetative structure called a mycelium. The most important classes of molds industrially are *Aspergillus* and *Penicillium.* Molds can produce antibiotics, industrial chemicals, enzymes, and food additives. The production of penicillin was scaled up between 1941 and 1945 from virtually nothing to more than 650 billion units per month; meanwhile, its cost dropped from $20 to 60¢ per 100,000 units [2]. The dramatic development was due to the improvements in composition of the medium, the development of the submerged culture technique, the production of mutant strains of *Penicillium chrysognum*, and the refinements of downstream separation techniques [3].

19.2.1.4 Culture Media

There are two main types of culture media: natural and synthetic. They vary widely in form and composition, depending on the species of organism to be cultivated and the purpose of the cultivation.

Natural media (or complex media) usually contain peptones, beef extract, or yeast extract. When a solid medium is desired, a solidifying agent such as gelatin or agar may be incorporated into the medium.

Synthetic media (or chemically defined media) consist of dilute solutions of chemically pure compounds. They may be simple such as inorganic ammonium salt plus minerals and a sugar, or complex such as purified casein with added vitamins, minerals, and a sugar. They can be produced with constant compositions year after year. Table 19.5 shows a typical growth medium for the cultivation of yeasts.

The medium must be sterilized to eliminate any living organisms in the vessel, often by moist heat (steam under pressure) in an autoclave. Generally, the autoclave is operated at approximately 15 psig at 121°C. The time of sterilization depends on the nature of the material, the type of container, and the volume; test tubes of liquid media can be sterilized in 15 to 20 minutes at 121°C.

Inoculation is the seeding of a culture vessel with the microbial material (inoculum). The inoculum is introduced with a metal wire or loop that is rapidly sterilized just before its use by heating it in a flame. Transfers of liquid culture are often made by using a sterilized pipette.

19.2.2 Animal Cells

Animal cells are classified as eukaryotic cells, and they can be cultivated in nutritional medium outside the donor's body. Such cultured cells grow in number and size. Tissue culture methodologies are employed to study cancer cells and malignant tumors, to determine tissue compatibility in transplantation, and to study specific cells and their interactions.

The mammalian cell culture technique can be employed to produce human growth hormones, interferon, plasminogen activators, viral vaccines, interleukins, and monoclonal antibodies. Traditionally, these biochemicals had been produced using living animals. However, the quantity obtained from these methods is limited for clinical usage.

Blood and lymph are rather atypical connective tissues with liquid matrices. Cells from blood or lymph fluids are suspension cells, or non-anchorage dependent when grown in culture. Most normal mammalian cells are anchorage dependent, that is, they require a surface for attachment and growth. The most widely used anchorage-dependent cell types are epithelial or fibroblast (broadly classified as connective) cells. Anchorage-dependent cells require a wettable surface such as glass or plastic Petri dishes and roller bottles. Bottles are laid on a slowly rotating roller in an incubator. A 1-liter bottle typically contains 100 mL of medium to facilitate cells both to grow on the wall and to be exposed to medium and gas. However, roller bottles are suitable only for small-scale laboratory use.

The nutritional requirements of mammalian cells are more stringent than those of microorganisms since they do not metabolize inorganic nitrogen. Therefore, many amino acids and vitamins should be provided. Typical medium contains amino acids, vitamins, hormones, growth factors, mineral salts, and glucose. Furthermore, the medium needs to be supplemented with 2% to 20% (by volume) of mammalian blood serum. The serum provides components that have not yet been identified but are necessary for culture viability.

The serum in the medium is not only expensive but also can be the source of virus or mycoplasma contamination. Since the chemical nature of serum is not well defined, its contents may vary batch after batch, which can affect cell growth. Many different proteins in serum often complicate the downstream separation processes. For these reasons, serum-free media have been formulated, which contain purified hormones and growth factors that can substitute for serum supplements [4].

19.2.3 Plant Cells

Plants are a valuable source of chemical compounds such as pharmaceuticals, flavors, pigments, fragrances, and agrochemicals. These products, known as secondary metabolites, are usually produced in trace quantities in plants and have no obvious metabolic function. They serve as a chemical interface between the producing plants and their surrounding environment, such as adaptations to environmental stresses and chemical defenses against microorganisms. Despite substantial advances in synthetic organic chemistry, many secondary metabolic compounds are either too difficult or costly to synthesize (e.g., rose oil). Most plants that produce commercially useful substances are grown in tropical and subtropical regions of the world. As a result, the availability and costs of these materials depend on the political and economic circumstances of the countries involved.

To produce secondary metabolic products from plants, exogenous plant tissue instead of a whole plant may be cultivated as a suspension culture in an aseptic condition. Such cultivation provides several advantages: (1) Plant cells can be cultivated where they are needed regardless of weather and geographical conditions. (2) The product quality and yields can be well controlled by eliminating problems encountered in the processing of botanicals. (3) Some metabolic products can be produced from suspension cultures in higher quantities than those observed in whole plants.

It is a challenge to cultivate plant cells on a large scale and to maximize the production and accumulation of secondary metabolites. This can be accomplished by selecting proper genotypes and high-yielding cell clones, formulating suitable media to cultivate the cells, and designing and operating effective cell culture systems. Plant cells and microbial organisms are, however, so different that the culture conditions and reactor configuration generally need to be modified.

Since plant cells are 10 to 100 times larger than bacterial and fungal cells, the metabolism of plant cells is slower than that of microbial cells by about one order of magnitude. Hence, only high

value-added, low market-volume products are economically feasible to be produced from plant cell culture techniques. Potential products are

1. Food products: color, flavors, oils, sweeteners, and spices
2. Pharmaceuticals: alkaloids, steroids, shikonin, rosmarinic acid
3. Agricultural chemicals

Plant tissue cultures can be divided into two major types: unorganized growth cultures and organized growth cultures.

Unorganized growth cultures lack any recognizable structure of the original plant. Callus cultures are amorphous cell aggregates arising from the unorganized growth of explants on an aseptic solid nutrient medium. *Suspension (or cell) cultures* consist of cells and cell aggregates, growing dispersed in liquid medium. They are usually initiated by placing pieces of a friable callus culture in moving liquid medium. Suspension culture is generally preferred for mass propagation of plant cells because it can be maintained and manipulated similar to submerged microbial fermentation.

Organized growth cultures maintain their original organ structure such as root cultures and embryo cultures. *Root cultures* can be established from root tips taken from many plants. The "hairy root" clones that are produced can be cultivated to produce metabolites. *Embryo cultures* may be established from embryos removed from sterilized seeds, ovules, or fruits. Embryo cultures can be employed for the rapid production of seedlings from seeds that have a protracted dormancy period.

19.2.4 Cell Growth Measurement

Microscopic counts: The number of cells in a culture can be counted under a microscope using a hemocytometer, which has counting chambers etched on the surface of a glass slide. A sample of cell suspension is allowed to flow under the cover slip and to fill the counting chambers. Dense suspensions need to be diluted.

Viable plate count: An aliquot of cell suspension is spread over the agar surface. The plate is then incubated until colonies appear, and the number of colonies is counted. To obtain the appropriate number of cells per unit volume, the sample has to be diluted. For the larger dilution, it is common to use the serial dilution technique. For example, to make $1/10^6$ dilution, three successive 1/100 dilutions or six successive 1/10 dilutions can be made.

Cell dry weight: An aliquot of cell suspension is centrifuged to discard the supernatant. The cells are thoroughly washed with distilled water and recentrifuged to eliminate all soluble matter. The washed cells are dried in an oven and weighed. This is the most direct and probably the most reliable method. However, such determinations are time consuming and relatively insensitive to small changes of cell mass.

Turbidity: The cell mass can be estimated optically by determining the amount of light scattered by suspended cells. A calibration curve is obtained by measuring the absorbency of a sample with a known cell concentration. The measurements are usually made at a wavelength between 600 and 700 nm.

19.2.5 Enzymes

Enzymes are biological catalysts and proteins, which are produced by living organisms. Almost every reaction in a cell requires the presence of a specific enzyme. Their major function is to catalyze the making and breaking of chemical bonds. Therefore, like any other catalysts, they increase the rate of reaction without themselves undergoing permanent chemical changes. An enzyme is highly specific and catalyzes only one or a small number of chemical reactions. The rate of an enzyme-catalyzed reaction is usually much faster than that of the same reaction when

directed by non-biological catalysts. Reaction conditions (such as temperature, pressure, and pH) are mild.

19.2.5.1 Nomenclature of Enzymes

Originally enzymes were given nondescriptive names such as *pepsin* (hydrolyzes proteins) and *lysozymes* (capable of destroying bacterial cell walls). The nomenclature was later improved by adding the suffix *-ase* to the name of the substrate with which the enzyme functions, or to the reaction that is catalyzed. For example

1. Name of substrate
   lactase: splits lactose into glucose and galactose
   lipase: hydrolyzes lipids into glycerol and fatty acids
   maltase: hydrolyzes maltose to glucose
2. Reaction that is catalyzed
   dehydrogenase: removes hydrogen from a substrate
   isomerase: converts one isomer to another
   oxidase: catalyzes oxidation

A systematic scheme of nomenclature for enzymes was proposed by the International Enzyme Commission in 1964. They are now categorized into six major classes depending on the type of chemical reaction that they catalyze.

19.2.5.2 Commercial Applications of Enzymes

Enzymes have been used since early human history without knowledge of what they were or how they worked. They were used for such things as making sweets from starch, clotting milk to make cheese, and brewing alcohol. Enzymes have been utilized commercially since the 1890s, when fungal cell extracts were first used to break down starch into sugars. Fungal amylase takadiastase was employed as a digestive aid by 1894.

Enzymes are usually made by microorganisms grown in a pure culture or obtained directly from plants and animals. The enzymes produced commercially can be classified into three major categories: industrial enzymes, analytical enzymes, and medical enzymes. Industrial enzymes are those that are produced and used in large quantities such as starch conversion enzymes (α-amylase, glucoamylase, and glucose isomerase), which are used to convert starch into high-fructose corn syrup, largely used in soft drinks. Alkaline protease is another example of an industrial enzyme, which is added to laundry detergents as a cleaning aid. Analytical and medical enzymes are produced in the range of milligrams to grams and usually required to be highly purified; hence, their production costs are high.

19.3 KINETICS

19.3.1 Cell Kinetics

Understanding the growth kinetics of microbial, animal, or plant cells is important for the design and operation of the required fermentation systems.

19.3.1.1 Growth Cycle for Batch Cultivation

Four phases are observed during a batch culture: lag, exponential, stationary, and death (Figure 19.2).

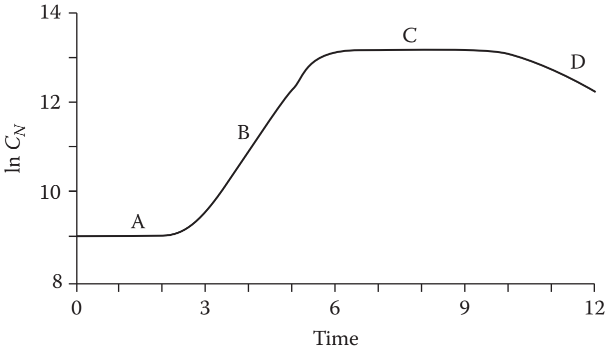

FIGURE 19.2 Typical growth curve of unicellular organisms: (A) lag phase; (B) exponential growth phase; (C) stationary phase; (D) death phase.

The lag phase is the initial period when the change of cell number is negligible; the cells may grow in size, but not in number. The length of the lag period depends on the type and age of the microorganisms, the size of the inoculum, and other culture conditions. The lag usually occurs as the cells adjust to the new medium before growth begins, and as the cells produce the enzymes necessary for the metabolization of the available nutrients.

At the end of the lag phase, growth begins and cell concentration increases exponentially. As the available nutrients are exhausted in the medium, the rate of growth declines and growth eventually stops. The stationary phase is usually followed by a death phase, in which the organisms in the population die due to the depletion of the cellular reserves of energy or due to the accumulation of toxic products.

19.3.1.2 Unstructured Cell Kinetic Models

Cell growth involves numerous complicated networks of biochemical and chemical reactions. A simple unstructured kinetic model was formulated based on the assumptions that

Cells can be represented by a single component, such as cell mass or cell number.
The cell suspension can be regarded as a homogeneous solution.

The rate of the cell growth r_X is proportional to cell concentration C_X as

$$r_X = \frac{dC_X}{dt} = \mu C_X \tag{19.1}$$

where μ is the specific growth rate [hr^{-1}]. Equation (19.1) can be integrated from time t_0 to t to give

$$C_X = C_{X_0} \exp[\mu(t - t_0)] \tag{19.2}$$

where C_{X_0} is the cell concentration at t_0 when the exponential growth starts. Equation (19.2) shows the increase of cells exponentially with respect to time. The cell concentration C_X can be replaced by cell number density C_N.

Actually, M does not remain constant during the exponential period, because it will be affected by the culture condition, such as substrate and production concentrations, which are constantly

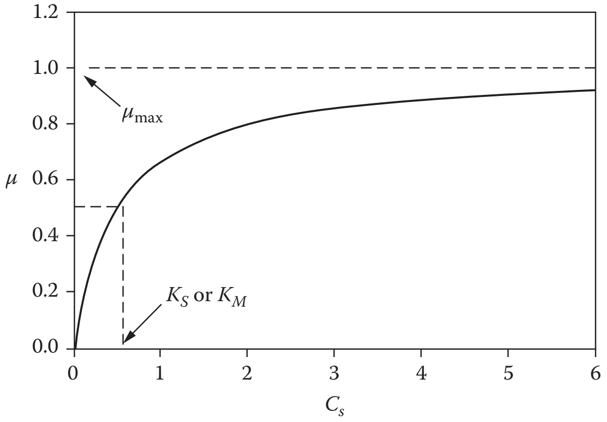

FIGURE 19.3 The effect of substrate concentration on the reaction rate.

TABLE 19.6
Typical Values of Monod's Kinetic Parameters (μ_{max} and K_S) with Glucose as the Limiting Substrate [5]

Organism	Temperature (°C)	μ_{max} (hr^{-1})	K_S (mg/L)
Escherichia coli	37	0.8–1.4	2–4
Saccharomyces cerevisiae	30	0.5–0.6	25
Candida tropicalis	30	0.5	25–75

changing during the period. One of the most widely employed expressions for the effect of substrate concentration on μ is the Monod equation [18]:

$$\mu = \frac{\mu_{max} C_S}{K_S + C_S} \tag{19.3}$$

where C_S is the concentration of the limiting substrate in the medium and K_S is a system coefficient. The value of K_S is equal to the concentration of nutrient when the specific growth rate is half of its maximum value μ_{max}, as shown in Figure 19.3.

While the Monod equation is an oversimplification of the complicated mechanism of cell growth, it often adequately describes fermentation kinetics. The Monod kinetic parameters can be determined by making a series of ideal continuous stirred-tank bioreactors, which will be discussed later. Table 19.6 shows the typical values of the Monod's kinetic parameters when glucose is a limiting substrate.

As cells grow, they produce metabolic by-products that accumulate in the medium. The growth of microorganisms is usually inhibited by these products (C_P), whose effect can be added to the Monod equation as follows:

$$\mu = \mu_{max}\left(\frac{C_S}{K_S + C_S}\right)\left(\frac{K_P}{K_P + C_P}\right) \tag{19.4}$$

or

$$\mu = \mu_{\max}\left(\frac{C_S}{K_S + C_S}\right)\left(1 - \frac{C_P}{C_{Pm}}\right)^n \tag{19.5}$$

19.3.1.3 Structured Models

Unstructured distributed models such as Monod's equation satisfactorily predict the growth behavior in many situations. However, they cannot account for lag phases, sequential uptake of substrates, or changes in mean cell size during the growth cycle of a batch culture. Structured models recognize the multiplicity of cell components and their interactions. Many different models have been proposed based on the assumptions made for cell components and their interactions.

A general structured model equation can be derived by the following assumptions:

1. The system is defined as multiple cells that do not contain any abiotic phase of culture. The mass of the system is m on a dry basis and the specific volume is $\hat{v}$.
2. There are c components in the cell and the mass of the jth component per unit volume of the system is $\hat{C}_{X_j}$.
3. There exist kinetic rate expressions for p reactions occurring in the system and the rate of the jth component formed from the ith reaction per unit volume of the system is $\hat{r}_{X_{i,j}}$.

Then, during batch cultivation, the change of the jth component in the system with respect to time can be expressed as [6]

$$\frac{d(m\hat{v}\hat{C}_{X_j})}{dt} = m\hat{v}\sum_{i=1}^{p}\hat{r}_{X_{i,j}} \tag{19.6}$$

If the specific volume $\hat{v}$ is assumed constant with time, the above equation can be rearranged to

$$\frac{d\hat{C}_{X_j}}{dt} = \sum_{i=1}^{p}\hat{r}_{X_{i,j}} - \frac{\hat{C}_{x_j}}{m}\frac{dm}{dt} \tag{19.7}$$

where the last term represents the dilution of intracellular components by the growth of biomaterial. All variables denoted by circumflexes in the preceding equations are intracellular properties. Since the structural models recognize the multiplicity of cell components and their interactions in the cell, it makes more sense to express the model with intrinsic variables.

The concentration terms in the preceding equations can be expressed as mass per unit culture volume V instead of that per biotic system volume $m\hat{v}$. The two different definitions of concentration are related as

$$\hat{C}_{X_j} = \frac{V}{m\hat{v}}C_{X_j} \tag{19.8}$$

Substituting the above equation into Equation (19.7) and simplifying for the constant V yields

$$\frac{dC_{X_j}}{dt} = \frac{m\hat{v}}{V}\sum_{i=1}^{p}\hat{r}_{X_{i,j}} \tag{19.9}$$

Even though concentration terms are expressed based on the total culture volume, kinetic parameters still remain on a biotic phase basis in the formulation.

One of the simplest structured models is the two-compartment model proposed by Williams [7]. It is based on the assumption that the cell comprises two basic components: a synthetic portion and a structural portion. The synthetic portion is fed by uptake from a substrate and the structural portion is fed from the synthetic portion. The detailed derivation of the model was described by Lee [8].

19.3.2 Simple Enzyme Kinetics

Assume that a substrate (S) is converted to a product (P) by the addition of an enzyme (E) as

$$S \xrightarrow{E} P \tag{19.10}$$

Brown [9] postulated that the enzyme and the substrate form an intermediate complex that enables the substrate to be converted to a product as

$$S + E \underset{k_2}{\overset{k_1}{\rightleftarrows}} ES \tag{19.11}$$

$$ES \xrightarrow{k_3} P + E \tag{19.12}$$

The reaction rate equation can be derived from the preceding mechanism based on the following assumptions:

1. The total enzyme concentration remains constant during the reaction, that is, $C_{E_0} = C_E + C_{ES}$.
2. The amount of enzyme is very small compared to the amount of substrate. Therefore, the enzyme-substrate complex does not deplete the substrate.
3. The product concentration is so low that product inhibition is negligible.

In addition to the preceding assumptions, there are three different approaches to derive the rate equation: Michaelis-Menten approach [10], Briggs-Haldane approach [11], and numerical solution.

19.3.2.1 Michaelis–Menten Approach

In this approach, the product-releasing step, Equation (19.12), is assumed to be much slower than the reversible reaction, Equation (19.11). Since the slower reaction, Equation 19.12, determines the overall rate of reaction, the rate of product formation and substrate consumption is proportional to the concentration of the enzyme-substrate complex C_{ES} as

$$r = \frac{dC_P}{dt} = -\frac{dC_S}{dt} = k_3 C_{ES} \tag{19.13}$$

The concentration is expressed as a molar unit, such as kmol/m^3 or mol/L. The concentration of the enzyme-substrate complex C_{ES} in Equation (19.13), is related to the substrate concentration C_s and the free-enzyme concentration C_E from the assumption that the first reversible reaction Equation (19.11) is in equilibrium as

$$k_1 C_S C_E = k_2 C_{ES} \quad (19.14)$$

Since we assume that the total enzyme contents are conserved, the free-enzyme concentration C_E can be related to the initial enzyme concentration C_{E_0}:

$$C_{E_0} = C_E + C_{ES} \quad (19.15)$$

From the previous three equations, C_E and C_{ES} can be eliminated by substituting Equation (19.14) into Equation (19.15) for C_E and rearranging for C_{ES} as

$$C_{ES} = \frac{C_{E_0} C_S}{\frac{k_2}{k_1} + C_s} \quad (19.16)$$

Substitution of Equation (19.16) into Equation (19.13) results in the Michaelis-Menten equation.

$$r = \frac{dC_P}{dt} = -\frac{dC_S}{dt} = \frac{k_3 C_{E_0} C_S}{\frac{k_2}{k_1} + C_S} = \frac{r_{\max} C_S}{K_M + C_S} \quad (19.17)$$

The Michaelis constant K_M is equal to the dissociation constant K_1 or the reciprocal of equilibrium constant K_{eq} as

$$K_M = \frac{k_2}{k_1} = K_1 = \frac{C_S C_E}{C_{ES}} = \frac{1}{K_{eq}} \quad (19.18)$$

When K_M equals C_S, r is equal to one-half of $r_{\max}$, according to Equation (19.17). The value of K_M equals the substrate concentration when the reaction rate is half of the maximum rate $r_{\max}$, as shown in Figure 19.3. K_M is of importance since it characterizes the interaction of an enzyme with a given substrate.

Another kinetic parameter in Equation (19.17) is the maximum reaction rate $r_{\max}$, which is proportional to the initial enzyme concentration. To express the enzyme concentration in molar units, one needs to know the molecular weight of the enzyme and the exact amount of pure enzyme added.

Enzyme concentration may be expressed in mass units instead of molar units. However, the amount of enzyme is not well quantified in mass units because the actual contents of an enzyme can differ widely depending on its purity. Therefore, enzyme concentration is expressed as an arbitrarily defined unit based on its catalytic ability. For example, one unit of an enzyme, cellobiase, is defined as the amount of enzyme required to hydrolyze cellobiose to produce 1 μmol of glucose per minute. Whatever unit is adopted for C_{E_0}, the unit for $k_3 C_{E_0}$ should be the same as that of r, kmole/m^3/s. Care should be taken for the consistency of units when enzyme concentration is not expressed in molar units.

19.3.2.2 Briggs–Haldane Approach

In this approach, the change of the intermediate concentration is assumed to be negligible. From the mechanism described by Equations (19.11) and (19.12), the rates of product formation and of substrate consumption are

$$\frac{dC_P}{dt} = k_3 C_{ES} \tag{19.19}$$

$$-\frac{dC_S}{dt} = -k_1 C_S C_E - k_2 C_{ES} \tag{19.20}$$

The change of C_{ES} with time, dC_{ES}/dt, is assumed to be negligible as

$$\frac{dC_{ES}}{dt} = k_1 C_S C_E - k_2 C_{ES} - k_3 C_{ES} \cong 0 \tag{19.21}$$

Substituting Equation (19.15) into Equation (19.21) for C_E and rearranging for C_{ES} gives

$$C_{ES} = \frac{C_{E0} C_S}{\dfrac{k_2 + k_3}{k_1} + C_S} \tag{19.22}$$

Substitution of Equation (19.22) into Equation (19.19) results in

$$r = \frac{dC_P}{dt} = -\frac{dC_S}{dt} = \frac{k_3 C_{E0} C_S}{\dfrac{k_2 + k_3}{k_1} + C_S} = \frac{r_{max} C_S}{K_M + C_S} \tag{19.23}$$

which is similar to the Michaelis-Menten equation, Equation (19.17). In the Michaelis-Menten approach, K_M equals the dissociation constant k_2/k_1, while in the Briggs-Haldane approach, it equals $(k_2 + k_3)/k_1$. Equation (19.23) can be simplified to Equation (19.17) if $k_2 >> k_3$, which means that the product-releasing step is much slower than the enzyme-substrate complex dissociation step. Since the formation of the complex involves only weak interactions, the rate of dissociation of the complex is likely rapid.

19.3.2.3 Numerical Solution

From the mechanism described by Equations (19.11) and (19.12), two rate equations are written for C_{ES} and C_S as

$$\frac{dC_{ES}}{dt} = k_1 C_S C_E - k_2 C_{ES} - k_3 C_{ES} \tag{19.24}$$

$$\frac{dC_S}{dt} = k_1 C_S C_E + k_2 C_{ES} \tag{19.25}$$

The rate equation for C_P [Equation (19.19)] and Equations (19.24) and (19.25) with Equation (19.15) can be solved simultaneously. Since the analytical solution of the preceding simultaneous differential equations are not possible, they can be solved numerically using software packages such as Advanced Continuous Simulation Language (ACSL), MathCad (MathSoft, Inc., Cambridge, MA), and Mathematica (Wolfram Research, Inc., Champaign, IL).

This solution procedure requires the knowledge of elementary rate constants, k_1, k_2, and k_3. The elementary rate constants can be measured by experimental techniques, such as pre–steady-state kinetics and relaxation methods [12], which are more complicated compared to the methods to determine K_M and r_{max}. A numerical solution with the elementary rate constants often provides a more precise picture of what is occurring during the enzyme reactions.

19.3.2.4 Evaluation of Michaelis-Menten Parameters

The kinetic parameters can be estimated by making a series of batch runs with different levels of substrate concentration. Then the initial reaction rate is calculated as a function of initial substrate concentration. The results can be plotted graphically so that the validity of the kinetic model can be tested and the values of the kinetic parameters estimated. The most straightforward way is to plot r against C_S as shown in Figure 19.3. The asymptote for r will be r_{max} and K_M *is* equal to C_S when $r = 0.5\ r_{max}$. However, this is an unsatisfactory plot in estimating r_{max} and K_M because it is difficult to estimate asymptotes accurately and also to test the validity of the kinetic model.

Therefore, the Michaelis–Menten equation (Equation (19.17)) is usually rearranged so that the results can be plotted as a straight line. Some of the better known methods are

Langmuir plot [13]:

$$\frac{C_S}{r} = \frac{K_M}{r_{max}} + \frac{C_S}{r_{max}} \tag{19.26}$$

Lineweaver-Burk plot [14]:

$$\frac{1}{r} = \frac{1}{r_{max}} + \frac{K_M}{r_{max}}\frac{1}{C_S} \tag{19.27}$$

Eadie-Hofstee plot [15,16]:

$$r = r_{max} - K_M \frac{r}{C_S} \tag{19.28}$$

If the Michaelis–Menten equation is applicable, the Langmuir plot of Cs/r versus C_S will result in a straight line with slope $1/r_{max}$ and intercept K_M/r_{max}. Similarly, the Lineweaver-Burk plot of $1/r$ versus $1/C_S$ results in a straight line with slope K_M/r_{max} and intercept $1/r_{max}$ The Eadie-Hofstee plot of r versus r/C_S results in a straight line with slope $-K_M$ and intercept r_{max}.

The Lineweaver-Burk plot is the most popular among the three because it shows the relationship between the independent variable C_S and the dependent variable r. However, $1/r$ approaches infinity as C_S decreases, which gives undue weight to inaccurate measurements made at low substrate concentrations. On the other hand, the Eadie-Hofstee plot gives slightly better weighting of the data than the Lineweaver-Burk plot. A disadvantage of this plot is that the rate of reaction r appears in both coordinates while it is usually regarded as a dependent variable. Therefore, the Langmuir plot (C_S/r versus C_S) is the most satisfactory of the three, since the points are equally spaced.

19.3.2.5 Inhibition of Enzyme Reactions

An inhibition (I) decreases enzymes activity, causing the rate of reaction to decrease competitively or noncompetitively (*1*). A competitive inhibitor has a strong structural resemblance to the substrate. Therefore, both the inhibitor and substrate compete for the active site of an enzyme as

$$E + S \underset{k_2}{\overset{k_1}{\rightleftarrows}} ES$$

$$E + I \underset{k_4}{\overset{k_3}{\rightleftarrows}} EI \tag{19.29}$$

$$ES \xrightarrow{k_5} E + P$$

The formation of an enzyme-inhibitor complex reduces the amount of enzyme available for interaction with the substrate and, hence, the rate of reaction decreases. Based on the above mechanism, the rate of product formation can be derived by using the Michaelis-Menten approach to give

$$r_P = \frac{r_{\max} C_S}{C_S - K_{M_1}} \tag{19.30}$$

where

$$K_{M_I} = \frac{k_2}{k_1}\left(1 + \frac{C_I}{k_4 / k_3}\right) = K_M\left(1 + \frac{C_I}{K_I}\right) \tag{19.31}$$

Previous equations show that the maximum reaction rate is not affected by the presence of a competitive inhibitor while the K_{M_I} value is increased.

Noncompetitive inhibitors interact with enzymes in many different ways. They bind to the enzymes reversibly or irreversibly at the active site or at some other region, so the resultant complex is inactive. The mechanism of noncompetitive inhibition is expressed as follows:

$$E + S \underset{k_2}{\overset{k_1}{\rightleftarrows}} ES$$

$$E + I \underset{k_4}{\overset{k_3}{\rightleftarrows}} EI$$

$$EI + S \underset{k_6}{\overset{k_5}{\rightleftarrows}} EIS \tag{19.32}$$

$$ES + I \underset{k_8}{\overset{k_7}{\rightleftarrows}} ESI$$

$$ES \xrightarrow{k_9} E + P$$

Similarly, the rate equation can be derived by employing the Michaelis-Menten approach as follows:

$$r_P = \frac{r_{I\,\max} C_S}{C_S - K_M} \tag{19.33}$$

where

$$K_M = \frac{k_2}{k_1} = \frac{k_6}{k_5}$$

$$r_{I,\max} = \frac{r_{\max}}{1 + \dfrac{C_1}{K_1}} \tag{19.34}$$

$$K_1 = \frac{k_4}{k_3} = \frac{k_8}{k_7}$$

Therefore, the maximum reaction rate will be decreased by the presence of a noncompetitive inhibitor, while the Michaelis constant K_S will not be affected by the inhibitor.

19.4 BIOREACTOR DESIGN

A bioreactor is a reactor in which enzymes or living cells catalyze the biochemical transformations. It is frequently called a fermenter whether the transformation is carried out by living cells or in vivo cellular components (enzymes). Fermentation originally referred to the metabolism of an organic compound under anaerobic conditions. However, modern industrial fermentation includes both aerobic and anaerobic cultures of organisms. Currently, bioreactor and fermenter can be regarded as synonyms.

19.4.1 Bioreactors

19.4.1.1 Stirred-Tank Bioreactor (or Fermenter)

In laboratories, cells are usually cultivated in Erlenmeyer flasks on a shaker. The gentle shaking effectively suspends the cells, enhances the oxygenation through the liquid surface, and aids the transfer of nutrients without damaging the structure of the cells.

For a large-scale operation, the stirred-tank fermenters (STF) are widely used (Figure 19.4). They are employed for both aerobic and anaerobic fermentation of a wide range of cells including microbial, animal, and plant cells. The mixing intensity can be varied widely by choosing suitable impellers and by varying agitating speeds. The mechanical agitation and aeration are effective for the suspension of cells, oxygenation, mixing of the medium, and heat transfer. The STF was one of the first large-scale fermenters developed in the pharmaceutical industries for the production of

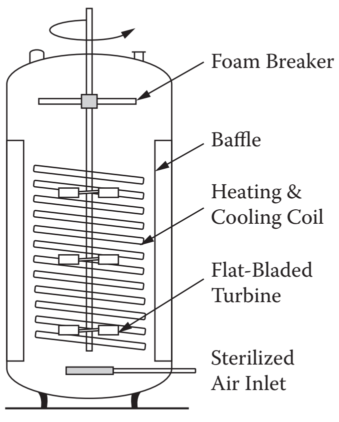

FIGURE 19.4 Schematic diagram of a stirred-tank fermenter.

penicillin. Its performance and characteristics have been extensively studied. Large industrial STFs are usually built with stainless steel, but laboratory-scale fermenters are often made of glass with a stainless steel top plate. Although the agitator is effective in mixing the fermenter content, it can damage a shear-sensitive cell system such as mammalian or plant cells.

The physical configuration of a typical fermenter is as follows: The height of the vessel is two to three times the vessel diameter and a fermenter is usually agitated with two or three turbine impellers. The impeller diameter to tank diameter ratio is generally 0.3 to 0.4. For multiple impeller systems, the distance between impellers is usually 1 to 1.5 impeller diameters. Four equally spaced baffles are usually installed to prevent a vortex formation that reduces the mixing efficiency. For aerobic fermentation, a single orifice sparger or ring sparger is used to aerate the fermenter. The pH in a fermenter can be maintained by employing either a buffer solution or a pH controller. The temperature is often controlled by heat transfer through a heating coil.

19.4.1.2 Alternative Fermenters

Many alternative fermenters have been proposed in order to provide better aeration, heat transfer, and cell retention. They are usually classified based on their vessel type such as tank, column, or loop fermenters [17]. Another way to classify fermenters is based on how the fermenter contents are mixed: by compressed air, by mechanical agitators, or by external liquid pumping. Representative fermenters in each category are listed in Table 19.7, and the advantages and disadvantages of three basic fermenter types are listed in Table 19.8.

The most simple fermenter is the bubble column fermenter (or tower fermenter), which is usually a long cylindrical vessel with a sparging device at the bottom as shown in Figures 19.5a and b. The fermenter contents are mixed by rising air bubbles that also provide the oxygen needs

TABLE 19.7
Classifications of Fermenters

Vessel Type	Primary Source of Mixing		
	Compressed Air	Internal Moving Parts	External Pumping
Tank	—	Stirred tank	—
Column	Bubble column, tapered column	Multistage (or cascade)	Sieve tray packed bed
Loop	Air-lift pressure cycle	Propeller loop	Jet loop

TABLE 19.8
Advantages and Disadvantages of Three Basic Fermenter Configurations

Type	Advantages	Disadvantages
Stirred tank	• Flexible and adaptable	• High power consumption
	• Wide range of mixing intensity	• Damage shear sensitive cells
	• Can handle high viscosity media	• High equipment costs
Bubble column	• Simple, no moving parts	• Poor mixing
	• Low equipment costs	• Excessive foaming
	• High cell concentration	• Limited to low viscosity system
Air-lift	• Simple, no moving parts	• Poor mixing
	• High gas absorption efficiency	• Excessive foaming
	• Good heat transfer	• Limited to low viscosity system

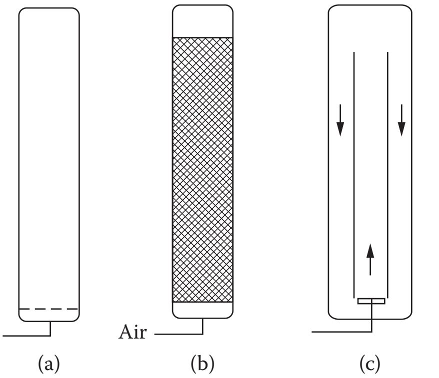

FIGURE 19.5 Alternative fermenters: (a) bubble column; (b) packed column; (c) air lift.

of the cells. Since the fermenter does not have any moving parts, a bubble-column fermenter is energy efficient with respect to the amount of oxygen transfer per unit energy input. As the cells settle, high cell concentrations occur in the lower portion of the column without any separation device. However, bubble-column fermenters are limited to aerobic fermentation. Furthermore, the rising bubbles may not provide adequate mixing for optimal growth. As the cell concentration increases in a fermenter, high airflow rates are required to maintain the cell suspension and mixing. The increased airflow rate can cause excessive foaming and high retention of air bubbles, which decreases the productivity of the fermenter. As bubbles rise in the column, they often coalesce rapidly, leading to a decrease in the oxygen-transfer rate. Therefore, column fermenters tend to be inflexible and limited to a relatively narrow range of operating conditions.

To overcome the weaknesses of the column fermenter, alternatives have been proposed. A tapered column fermenter can maintain a high airflow rate at the lower section of the fermenter where the cell concentration is high. Several sieve plates can be installed in the column for the effective gas–liquid contact and the breakup of the coalesced bubbles. The cylindrical column can be divided into multiple stages with stirrers. This configuration is analogous to stirred-tank fermenters connected in series. To enhance the mixing, the fermentation broth can be recirculated by using a pump.

A loop fermenter is a tank or column fermenter with a liquid circulation loop. Depending on how the liquid circulation is induced, it is often classified into three types: air-lift, stirred loop, and jet loop. The liquid circulation of the air-lift fermenter, Figure 19.5c, is induced by sparged air, which creates a density difference between the bubble-rich liquid in the riser (inner column) and the bubble-depleted liquid in the downcomer (space between the inner and the outer tubes). The liquid circulation and mixing are enhanced by installing a propeller or by circulating liquid externally using a pump. However, the addition of a propeller or pump diminishes the advantages of an air-lift fermenter as being simple and energy efficient.

19.4.2 Mode of Bioreactor Operations

19.4.2.1 Batch or Plug-Flow Bioreactors

An ideal stirred bioreactor is assumed to be well mixed so that the contents are uniform in composition at all times. The plug-flow bioreactor (PFB) is an ideal tubular-flow bioreactor without radial concentration variations. The nutrient concentration of an ideal batch bioreactor after time t will be the same as that of a steady-state PFB at the longitudinal location of the residence time. Therefore, the following analysis applies for both the ideal batch bioreactor and the steady-state PFB.

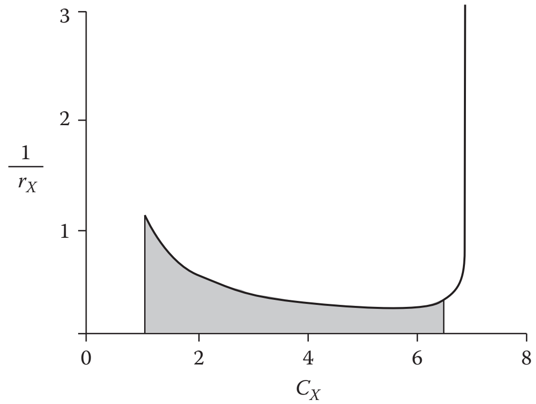

FIGURE 19.6 A graphical representation of the batch growth time $t - t_1$ (*shaded area*). The *solid line* represents the Monod model with $\mu_{max} = 0.935$ hr^{-1}, $K_s = 0.71$ g/L, $Y_{X/S} = 0.6$, $C_{X_0} = 1$ g/L, and $C_{S_0} = 10$ g/L.

19.4.2.1.1 Cell Cultivation

If a batch culture is initiated by the inoculation, cells grow exponentially after the lag phase. The change of the cell concentration is expressed as

$$r_x = \frac{dC_X}{dt} = \mu C_X \tag{19.35}$$

Equation (19.35) can be integrated from time t_0 to t as

$$\int_{C_{X0}}^{C_X} \frac{dC_X}{r_X} = \int_{C_{X0}}^{C_X} \frac{dC_X}{\mu C_X} = \int_{t_0}^{t} dt = t - t_0 \tag{19.36}$$

Equation (19.36) only applies when r_X is larger than zero. Hence, t_0 is the time that the cells start to grow.

According to Equation (19.36), the batch growth time $t - t_0$ is the area under the $1/r_X$ versus C_X curve between C_{X_0} and C_X, as shown in Figure 19.6. Though the batch growth time is rarely estimated by this method, the graphical representation is useful in comparing the performances of various fermenter configurations. The curve is U-shaped, which is characteristic of autocatalytic reactions. The rate is slow at the start because the cell concentration is low. It increases as cells multiply and reaches a maximum rate. As the substrate is depleted and the toxic products accumulate, the rate decreases to a low value.

If Monod kinetics [18] represents the growth rate during the exponential period

$$r_X = \frac{\mu_{max} C_S C_X}{K_S + C_S} \tag{19.37}$$

the substitution of Equation (19.37) to Equation (19.36) results in

$$\int_{C_{X0}}^{C_X} \frac{(K_S + C_S) dC_X}{\mu_{max} C_S C_X} = \int_{t_0}^{t} dt \tag{19.38}$$

The growth yield ($Y_{X/S}$) is defined as the amount of cell produced per substrate consumed as

$$Y_{X/S} = \frac{\Delta C_X}{-\Delta C_S} = \frac{C_X - C_{X_0}}{-(C_S - C_{S_0})} \tag{19.39}$$

Substitution of Equation (19.39) into Equation (19.38) and integration of the resultant equation gives a relationship that shows how the cell concentration changes with respect to time:

$$(t - t_0)\mu_{\max} = \left(\frac{K_S Y_{X/S}}{C_{X_0} + C_{S_0} Y_{X/S}} + 1\right) \ln \frac{C_X}{C_{X_0}} + \frac{K_S Y_{X/S}}{C_{X_0} + C_{S_0} Y_{X/S}} \ln \frac{C_{S_0}}{C_S} \tag{19.40}$$

19.4.2.1.2 Enzyme Reactions

Assume that an enzyme reaction is initiated at $t = 0$ by adding enzyme and the reaction mechanism can be represented by the Michaelis-Menten equation

$$-\frac{dC_S}{dt} = \frac{r_{\max} C_S}{K_M + C_S} \tag{19.41}$$

Equation (19.41) is similar in form to the Monod equation, but is quite different when you compare it with Equation (19.37), which has an extra term, C_X.

An equation expressing the change of the substrate concentration C_S with respect to time can be obtained by integrating Equation (19.41), as follows:

$$\int_{C_{S0}}^{C_S} -\left(\frac{K_M + C_S}{C_S}\right) dC_S = \int_0^t r_{\max} dt \tag{19.42}$$

and

$$K_M \ln \frac{C_{S_0}}{C_S} + (C_{S_0} + C_S) = r_{\max} t \tag{19.43}$$

With known values of $r_{\max}$ and K_M, the change of C_S with time in a batch reactor can be predicted from this equation.

19.4.2.2 Continuous Stirred-Tank Bioreactor

For an ideal continuous stirred-tank bioreactor (CSTB), the concentrations of the various components of the outlet stream are assumed to be the same as the concentrations in the bioreactor. Continuous operation of a bioreactor can increase the productivity of the reactor significantly by eliminating the downtime and the ease of automation.

19.4.2.2.1 Cell Cultivation

Microbial populations can be maintained in a state of exponential growth for extended time by using a system of continuous culture, operated either as chemostat or as a turbidostat. In a chemostat, the flow rate is set at a particular value and the rate of growth of the culture adjusts to this flow rate. In a turbidostat, the turbidity is set at a constant level by adjusting the flow rate. It is easier to operate a chemostat than a turbidostat, because the former is at a constant flow rate, whereas

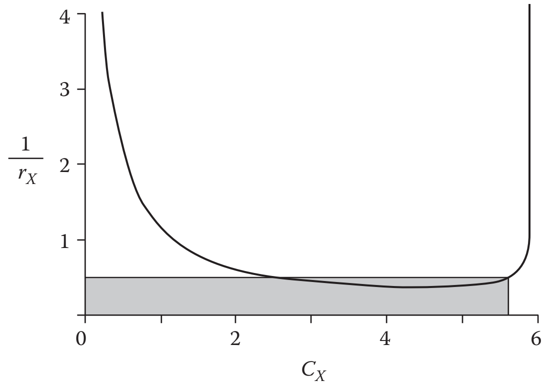

FIGURE 19.7 A graphical representation of the estimation of residence time for the CSTB. The *line* represents the Monod model with $\mu_{max} = 0.935$ hr^{-1}, $K_S = 0.71$ g/L, $Y_{X/S} = 0.6$, $C_{Si} = 10$ g/L, and $C_{X_i} = 0$.

the latter requires an optical sensing device and a controller. However, the turbidostat is recommended when continuous fermentation is performed at high dilution rates near the washout point. Turbidostats prevent washout by regulating the flow rate when cell loss in the output stream exceeds the cell growth in the fermenter.

When a CSTB (volume *V*) is operated with a constant inlet and an outlet flow rate (*F*) with the cell concentration of C_{X_i} and substrate concentration C_{S_i}, the material balance for the microorganisms in a CSTB can be written as

$$FC_{X_i} - FC_X + Vr_X = V\frac{dC_X}{dt} \tag{19.44}$$

where r_X is the rate of cell growth in the CSBR and dC_X/dt represents the change of cell concentration in the bioreactor with time.

For the steady-state operation of a CSTB, the change of cell concentration with time is equal to zero ($dC_X/dt = 0$); the microorganisms in the vessel grow just fast enough to replace those lost through the outlet stream. Therefore, Equation (19.44) becomes

$$\tau_m = \frac{V}{F} = \frac{C_X - C_{X_i}}{r_X} \tag{19.45}$$

which indicates that the required residence time (τ_m) is equal to $(C_X - C_{X_i})$ times $1/r_X$, which is equal to the area of the rectangle of width $C_X - C_{X_i}$ and height $1/r_X$ on the $1/r_X$ versus C_X curve as shown in Figure 19.7 (the shaded rectangular area). This graphical illustration of the residence time aids in comparing the effectiveness of fermenter systems.

If the input stream is sterile $(C_{X_i} = 0)$, and the cells in a CSTB are growing exponentially ($r_X = \mu C_X$), Equation (19.45) becomes

$$\tau_m = \frac{1}{\mu} = \frac{1}{D} \tag{19.46}$$

where *D* is known as the dilution rate and is equal to the reciprocal of the residence time (τ_m). Therefore, for the steady-state CSTB with sterile feed, the specific growth rate equals the dilution

rate. Hence, the specific growth rate of a microorganism is controlled by changing the medium flow rate. If the growth rate is expressed by the Monod equation, then

$$D = \mu = \frac{1}{\tau_m} = \frac{\mu_{max} C_S C_X}{K_S + C_S} \tag{19.47}$$

The equality of the specific growth rate and the dilution rate of the steady-state CSTB is helpful in studying the effects of various components of the medium on the specific growth rate. By measuring the steady-state substrate concentration at various flow rates, kinetic models can be tested and the value of the kinetic parameters can be estimated. By rearranging Equation (19.47), a linear relationship can be obtained as follows:

$$\frac{C_S}{\mu} = \frac{K_S}{\mu_{max}} + \frac{C_S}{\mu_{max}} \tag{19.48}$$

$$\frac{1}{\mu} = \frac{K_S}{\mu_{max}} \frac{1}{C_S} + \frac{1}{\mu_{max}} \tag{19.49}$$

$$\mu = \mu_{max} - K_S \frac{\mu}{C_S} \tag{19.50}$$

These are similar to the equations for the Langmuir, the Lineweaver-Burks, and the Eadie-Hofstee plots that were discussed earlier with the Michaelis-Menten kinetics.

From Equation (19.47), C_S can be calculated with a known residence time and the Monod kinetic parameters as

$$C_S = \frac{K_S}{\tau_m \mu_{max} - 1} \tag{19.51}$$

However, the preceding expression is only valid when $\tau_m \mu_{max} > 1$. If $\tau_m \mu_{max} < 1$, the growth rate of the cells is less than the rate of cells leaving with the outlet stream. Consequently, all of the cells in the fermenter will be washed out.

If the growth yield ($Y_{X/S}$) is constant, then

$$C_X = Y_{X/S}(C_{S_i} - C_S) \tag{19.52}$$

Substituting Equation (19.51) into Equation (19.52) yields the correlation for C_X as

$$C_X = Y_{X/S}\left(C_{S_i} - \frac{K_S}{\tau_m \mu_{max} - 1} \right) \tag{19.53}$$

Similarly, one can derive a relationship for the product concentration C_P as

$$C_P = C_{P_i} + Y_{X/S}\left(C_{S_i} - \frac{K_S}{\tau_m \mu_{max} - 1} \right) \tag{19.54}$$

19.4.2.2.2 Enzyme Reaction

The substrate balance of a CSTB can be set up as follows:

$$FC_{S_i} - FC_S + r_S V = V\frac{dC_S}{dt} \tag{19.55}$$

where r_S is the rate of substrate consumption for the enzymatic reaction, while dC_S/dt is the change of the substrate concentration in the bioreactor. As shown in Equation (19.55), r_S is equal to dC_S/dt only when F is zero, which is the case in batch operation.

For the steady-state CSTB, the substrate concentration of the reactor should be constant. Therefore, dC_S/dt is equal to zero. If the Michaelis-Menten equation can be used for the rate of substrate consumption (r_S), Equation (19.55) can be rearranged as

$$\frac{F}{V} = D = \frac{1}{\tau_m} = \frac{r_{\max} C_s}{(C_{S_i} - C_S)(K_M + C_S)} \tag{19.56}$$

Equation (19.56) can be rearranged to give the linear relationship

$$C_S = -K_M + \frac{r_{\max} C_S \tau_m}{C_{S_i} - C_S} \tag{19.57}$$

Michaelis-Menten kinetic parameters can also be estimated with a series of steady-state CSTB runs with various flow rates and plotting C_S versus $(C_S\tau_m)/(C_{S_i} - C_S)$. However, the initial rate approach in a batch mode already discussed is a better way to estimate the kinetic parameters than this method because steady-state CSTB runs are more difficult to make than batch runs.

19.5 AGITATION AND AERATION

19.5.1 Introduction

A key factor in designing a fermenter is to provide adequate mixing of its contents. Mixing in fermentation disperses the air bubbles, suspends the microorganisms (or animal and plant cells), and enhances both heat and mass transfer in the medium. Because most nutrients are highly soluble in water, little mixing is required during fermentation to transfer nutrients to the surfaces of living cells from the bulk solution. However, dissolved oxygen in the medium is an exception because its solubility of oxygen is very low, while its demand for the growth of aerobic microorganisms is high.

For example, the typical maximum concentration of oxygen in an aqueous solution in equilibrium with air is often 6 to 8 mg/L. The oxygen requirement is on the order of 10 mg/L/min. Therefore, the saturated dissolved oxygen will be consumed in less than 1 minute if not replenished continuously. Adequate continuous oxygen supply to cells is often critical in aerobic fermentation.

Mixing by a laboratory shaker is adequate to cultivate microorganisms in flasks or test tubes. Rotary or reciprocating action of a shaker is effective to provide gentle mixing and surface aeration. For bench-, pilot-, and production-scale fermenters, the mixing is usually provided by mechanical agitation.

Correlations are next reported for gas-liquid mass transfer, interfacial area, bubble size, gas hold-up, agitation power consumption, and volumetric mass-transfer coefficients, which are vital tools for the design and operation of fermenter systems.

19.5.2 Determination of Oxygen-Absorption Rate

The oxygen absorption rate per unit volume q_a/v can be estimated by

$$\frac{q_a}{v} = K_L a(C_L^* - C_L) = k_L a(C_L^* - C_L) \tag{19.58}$$

where a is the interfacial area per unit volume and C_L^* is the liquid-side oxygen concentration in equilibrium with the gas-phase oxygen. Because the oxygen is a sparingly soluble gas, the overall mass-transfer coefficient K_L is approximately equal to the individual mass-transfer coefficient k_L. An objective in fermenter design is to minimize power consumption and airflow rate. To increase the oxygen absorption rate, larger k_L, a, and, $C_L^* - C_L$ are needed. Since the concentration difference is limited because the value of C_L^* is low, the main parameters of interest are the mass-transfer coefficient and the interfacial area.

19.5.2.1 Estimation of Equilibrium Oxygen Concentration C_L^*

Table 19.9 lists the dissolved concentration of oxygen in water that is in equilibrium with pure oxygen at atmosphere pressure at various temperatures. Since air supplies the oxygen to a bioreactor, the maximum concentration of oxygen is about one-fifth of the solubility listed, according to Henry's law:

$$C_L^* = \frac{P_{O_2}}{H_{O_2}(T)} \tag{19.59}$$

where P_{O_2} is the partial pressure of oxygen and $H_{O_2}(T)$ is Henry's law constant of oxygen at a temperature, T. The value of Henry's law constant can be obtained from the solubility listed in Table 19.9.

19.5.2.2 Sodium Sulfite Oxidation Method

One of the simplest techniques to determine $k_L a$ is the sodium sulfite oxidation method [19], which is based on the oxidation of sodium sulfite to sodium sulfate in the presence of a catalyst (Cu^{++} or Co^{++}) as

$$\mathrm{Na_2SO_3 + \frac{1}{2}O_2 \xrightarrow{Cu^{++}\ or\ Co^{++}} Na_2SO_4} \tag{19.60}$$

The rate of this reaction is independent of the concentration of sodium sulfite (within the range of 0.04 to 1 N) and is also much faster than the oxygen transfer rate. Therefore, the rate of oxidation is controlled by the rate of mass transfer alone. The sodium sulfite solution, however, has quite different physical and chemical properties. This technique is helpful though in comparing the performance of bioreactors and studying the effect of scale-up.

19.5.2.3 Dynamic Technique

By using the dynamic technique [20], the k_La value for the oxygen transfer during a fermentation process can be estimated. This technique is based on the oxygen material balance in an aerated batch bioreactor while microorganisms are actively growing as

$$\frac{dC_L}{dt} = k_La(C_L^* - C_L) - r_{O_2}C_X \tag{19.61}$$

where r_{O_2} is the cell respiration rate [g O_2/g cell/h].

While the dissolved oxygen level of the bioreactor is steady, if the air supply is suddenly stopped, the oxygen concentration will be decreased (Figure 19.8) as follows:

$$\frac{dC_L}{dt} = r_{O_2}C_X \tag{19.62}$$

Therefore, by measuring the slope of the C_L versus t curve, we can estimate $r_{O_2}C_X$. If the air flow is restarted, the dissolved oxygen concentration will increase according to Equation (19.61), which can be rearranged to result in a linear relationship as

$$C_L = C_L^* - \frac{1}{k_La}\left(\frac{dC_L}{dt} + r_{O_2}C_X\right) \tag{19.63}$$

The plot of C_L versus $dC_L/dt + r_{O_2}C_X$ results in a straight line that has a slope of $-1/(k_La)$ and a intercept of C_L^*.

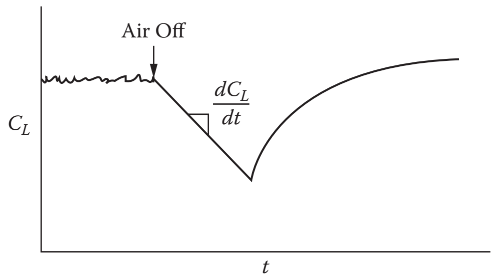

FIGURE 19.8 Dynamic technique for the determination of k_La.

19.5.3 Correlation for k_La

19.5.3.1 Bubble Column

Akita and Yoshida [21] correlated the volumetric mass-transfer coefficient k_La [s^{-1}] for the absorption of oxygen in various aqueous solutions in bubble columns, as follows:

$$k_La = 0.6 D_{AB}{}^{0.5} v_c{}^{-0.12} \left(\frac{\sigma}{\rho_c} \right)^{-0.62} D_T^{0.17} g^{0.93} H^{1.1} \tag{19.64}$$

where

D_{AB} = diffusivity of A through B [m^2/s]
v_c = kinematic viscosity [m^2/s]
σ = interfacial tension [kg/s^2]
ρ_c = the density of liquid [kg/m^3]
D_T = tank diameter [m]
g = gravity constant [m/s^2]
H = the height of the liquid level in a tank [m]

19.5.3.2 Mechanically Agitated Vessel

For aerated mixing vessels in an aqueous solution, the mass-transfer coefficient is proportional to the power consumption. Van't Riet [22] correlated the data of several investigators as follows:

1. For "coalescing" air-water dispersion,

$$k_La = 0.026 \left(\frac{P}{v} \right)^{0.4} V_S^{0.5} \tag{19.65}$$

2. For "noncoalescing" air-electrolyte solution dispersions,

$$k_La = 0.002 \left(\frac{P}{v} \right)^{0.7} V_S^{0.2} \tag{19.66}$$

where

P = power dissipated by impeller during agitation [W]
v = volume of the liquid [m^3]
V_S = superficial gas velocity [m/s]

These correlations are applicable for volumes up to about 2.6 m^3.

19.5.4 Power Consumption

Power consumption by agitation is a function of physical properties, operating conditions, and vessel and impeller geometry. For fully baffled agitated vessels,

$$\frac{P}{\rho N^3 D_I^5} = \alpha \left(\frac{\rho N D_I^2}{\mu} \right)^\beta \tag{19.67}$$

The dimensionless group in the left-hand side of Equation (19.67) is the power number N_P and that in the right-hand side is the impeller Reynolds number N_{Re_i}. D_I and N are the diameter and the speed of an impeller, respectively.

The power number decreases with an increase of the Reynolds number and reaches a constant value (6 for a flat six-bladed turbine) when the Reynolds number is greater than 10,000. At this point, the power number is independent of the Reynolds number. For the normal operating conditions of gas-liquid contact, the Reynolds number is usually greater than 10,000. For example, for a 3-inch impeller with an agitation speed of 150 rpm, the impeller Reynolds number is 16,225 when the liquid is water. Therefore, for a six flat-bladed turbine, the power number is

$$\frac{P}{\rho N^3 D_I^5} = 6 \quad \text{when } N_{Re_i} > 10{,}000 \tag{19.68}$$

19.5.5 Scale-Up

For the optimum design of a production-scale fermentation system (prototype), we must translate the data on a small scale (model) to the large scale. The fundamental requirement for scale-up is that the model and prototype should be similar. To ensure similarity, two conditions must be satisfied: (1) geometric similarity of the physical boundaries and (2) dynamic similarity of the flow fields. The first requirement is obvious and easy to accomplish. The second is achieved when the values of the nondimensional parameters (such as Reynolds number and power number) are the same. However, it is difficult, if not impossible, to satisfy the dynamic similarity when more than one dimensionless group is involved in a system, which creates the need for scale-up criteria.

No one scale-up rule applies to different mixing operations. However, some principles for the scale-up are as follows [23]:

1. The system can be scaled up so that one of the important properties (such as pumping capacity, oxygen transfer coefficient, and shear rate) can be maintained.
2. The big tank has a longer blend time, a higher maximum impeller shear rate, and a lower average impeller shear rate.
3. The power per volume can be used as a scale-up criterion.

20.1 INTRODUCTION

To measure physical properties reliably, the following must occur: The measuring instruments must be carefully selected and the instrument must be properly installed and operated. Factors to be considered in the selection process include the range of property to be measured, accuracy and reproducibility of the readings desired, ease of installation and servicing, and both capital and expected maintenance costs.

Advice is offered here on selecting instruments or techniques to measure temperature, pressure, flow rates, etc. More details are in references [1, 2]. In general, a relatively large number of instruments are candidates for any specific application.

20.2 TEMPERATURE-MEASURING DEVICES

Numerous types of sensors are employed in industrial plants, pilot plants, and laboratory units. Often, several are considered before the final selection is made for a specific application. The method of installing and operating the sensor is also most important. Attempts are often needed to minimize the temperature difference between the sensor and the process stream (or unit) to be measured, as discussed later.

The most commonly used thermometers (or temperature-measuring devices) in chemical or related processes are as follows: thermocouples employed in the range of about –260°C to 2500°C; resistant measuring instruments from –250°C to 650°C; radiation and infra-red pyrometers from 0°C to 4000°C, plus an assortment of bi-metallic and liquid-filled thermometers, color indicators, pneumatic cones, etc. These thermometers are often calibrated using the following materials: liquid hydrogen at its triple point of –259.34°C, gold at its freezing point of 1064.33°C, plus freezing

and boiling points, respectively, of water at 0°C and 100°C (depending on barometric pressure). The current discussion will be limited to the most popular thermometers. More advice and information on various sensors relative to their installation and operation are in the literature.

20.2.1 Thermcouples

Two dissimilar wires are connected in two places to form a loop. The first connection is positioned where the temperature is to be measured; the second connection is positioned where the temperature is known. This temperature difference causes a potential (or voltage) difference in the wires. Tables are available for predicting the temperature changes of several combinations of two dissimilar wires [3]. Temperature ranges for common thermocouples are as follows:

Chromel/alumel	–180°C to 1370°C
Iron/constantan	–180°C to 760°C
Copper/constantan	–180°C to 400°C
Platinum 10% rhodium/platinum	0°C to 1760°C
Tungsten/tungsten 26% rhenium	0°C to 2850°C
Tungsten 5% rhenium/tungsten 26% rhenium	0°C to 2850°C

Thermocouples unfortunately develop only relatively small voltage (electromotive force, or emf) changes for a temperature difference of 1°C. Hence errors of predicted temperatures are often relatively large. The first three thermocouples often have errors of 2°C to 3°C or 0.5% to 0.75%. The latter three (and more expensive) thermocouples typically have smaller errors. With specially constructed thermocouples having purer metals, better connections, etc., errors are reduced by perhaps 50% as compared with the values reported above.

Thermocouples tend to be relatively inexpensive, but the instruments to measure voltages and to record the temperatures are generally more expensive. To obtain reliable temperature measurements, the following factors are important relative to the installation of the thermocouple plus other types of thermometers:

1. The tip of the thermocouple (or other thermometer) often cannot be inserted directly in the liquid, gas, slurry, etc., due to chemical attack or erosion of the thermocouple. Obtaining a leak-proof system is frequently a problem.
2. A thermowell is often employed for the temperature probe in order to protect it against direct contact with the material being investigated. A gas such as air is often in the thermowell in direct contact with the thermocouple. As a result, the thermocouple may become oxidized or corroded, causing the calibration to change. Thermocouples for ethylene furnaces operated at about 800°C to 1000°C often need to be replaced after several months of operation.
3. Sometimes appreciable heat transfer may occur in both the thermocouple and the thermowell, e.g., in ethylene furnaces. In these furnaces, there are large temperature gradients along the length of the thermocouple.
4. Frequently, thermocouples are provided with protective sheaths, and their purchasing price is considerably higher.

A well-designed system, including thermocouple, thermowell, and often protective sheath, generally provides more reliable measurements.

20.2.2 Resistance Thermometers and Thermistors

For these thermometers, the electrical resistance of a metal or metal oxide changes with temperature. This resistance change can be measured by three-wire or four-wire null bridges (or Wheatstone

bridges) in order to predict temperature. The following metals, and their range of temperature, are all used commercially:

Platinum (wound and thin film)	–259°C to 482°C
Nickel	–195°C to 426°C
70% nickel/30% iron (Balco)	–195°C to 260°C

Platinum resistance thermometers that are carefully constructed and also carefully operated have been used as international standards from –259°C up to 1095°C. In general, resistance thermometers predict considerably more accurate temperatures than thermocouples. Resistance thermometers are often accurate to <0.01°C; they tend to retain their accuracy after extended use. In general, they are more expensive, more fragile, and larger than thermocouples.

For platinum resistance thermometers, the platinum is often wrapped around a ceramic or glass core; the above is often encapsulated in a ceramic or glass capsule. An alternative design is a deposit of platinum film on a substrate; next, the film is encapsulated. Sometimes highly inert Teflon is used as the outer encapsulating layer. With Teflon, the thermometer can often be immersed in highly corrosive liquids. On occasion, the resistance thermometer is attached (or “cemented”) by using a suitable adhesive to solid surfaces to measure temperatures from about –200°C to 260°C. Thermowells are also frequently employed. Resistance thermometers are available in a wide variety of sizes (diameters, lengths, etc.), designs, and protective or encapsulating materials. Numerous companies sell the instruments to measure the electrical resistance and to record the predicted temperature [1].

Another type of resistance thermometer uses metal oxides, instead of metals; it is frequently referred to as a thermistor. Electrical resistance of these metal oxides changes rapidly with even rather small temperature changes. Hence, thermistors are often emplyed to measure small temperature changes such as 1°C to 5 °C. The thermistor proper tends to have low purchase prices. Metal oxides, which are semiconductors, include mixtures of the following oxides: nickel, manganese, copper, cobalt, tin, germanium, etc. [1].

20.2.3 Radiation and Infrared Pyrometers

Pyrometers predict temperatures for the following:

- Interior of high-temperature furnaces; pyrolysis operations; production of steels, alloys, etc.
- Moving materials on conveyor belts, rollers, etc.
- Highly corrosive materials or materials that are easily contaminated
- Distant surfaces in a plant or those not easily accessible

Prediction of the temperature based on radiation considerations is based on the Stefan-Boltzmann law, which states the amount of radiation depends on the absolute temperature raised to the fourth power. To obtain accurate temperature predictions of a solid, liquid, or gas requires consideration of several factors:

1. Absorbance and emissivity of the material being investigated; they are defined as the ratio of that property as compared with that of a blackbody. Hence, both have values between 0.0 and 1.0
2. Reflectivity of the material; once again, it is defined as the ratio compared with that of a blackbody that absorbs all the radiation to which it is exposed, i.e., there is no reflection with a blackbody.
3. Geometry of the system.

4. Gas or suspended solids or liquids in the space between the material being measured and the radiation detector measuring the radiation.
5. Wavelengths of the radiation being recorded by the measuring device. Wavelengths being emitted from the object being investigated vary significantly with its temperature often in range of 0.3 to 100 microns. At ambient temperatures, wavelengths in the visible range predominate, but at about 1000°C, infrared wavelengths of about 2 to 20 microns predominate. At still higher temperatures, even shorter wavelengths result, i.e., near infrared, ultraviolet, etc. Modern pyrometers often record the emissions of two or more wavelengths.
6. Most desired instrument for recording the radiation of the object being investigated.
7. Method of collecting radiation from the object being investigated. The size of the aperture or opening to view the object plus area being sited is important.

Several temperature readings sometimes need to be recorded. In an ethylene furnace, for example, a hydrocarbon feedstock is pyrolyzed to produce an ethylene-rich stream. At the inlet to the coil reactor, much lower temperatures occur as compared with the outlet. In addition, the ceramic wall of the furnace is often relatively close to that of the hot combustion gases. These gas temperatures are much higher than those of the metal walls. Normally, the measuring detector collects information at different locations inside the furnace through a small aperture on the wall of the furnace. De Witt and Albright [4] report the results of a test of a furnace for distilling crude oil in a refinery about 20 years ago. In this test, flat targets were employed in which calibrated thermocouples were embedded. One target was essentially at the temperature of the combustion gas (and hence was considerably hotter) while another target was cooled to a much lower temperature. The pyrometers of those tests resulted in temperature measurements that were too low for the low-temperature target. Newer instruments and improved methods of predicting the temperatures have since significantly improved the accuracy of measurements.

Emissivities of different metals vary greatly. Liptak et al. [1] report values for common metals including 0.03 for gold and 0.94 for dull oxidized wrought iron. Calibrations based on emissivities correct to a high degree predicted values. Part of the radiant energy is adsorbed by intervening smoke, carbon dioxide, etc. Narrow-band pyrometers use only a narrow band of the spectrum, often in the red zone. By proper selecting of the band, the desired temperature of the solid, gas, or glass can be predicted. They recommended the wavelength in microns for vacuum depositions (0.2 to 0.3); furnaces, refractory metals, etc. (0.653); metal processing (0.6 to1.0); textiles, plastics, food products (2.0 to 2.6); thin film polymers (3.43 ± 0.14); and carbon dioxide gas (4.8 to 5.6).

20.2.4 Filled-Bulb and Glass-Stem Thermometers

These thermometers contain either mercury, alcohol, etc., as liquids. The thermal expansion of these liquids is greater than the glass, so the height of liquid in the glass capillary rises as the temperature increases. A major problem is that the glass can be easily broken. Furthermore, mercury causes toxicity problems if the thermometer breaks. Visual observations are usually required to read the thermometers. Often these instruments are restricted to temperatures from about –40°C to 400°C. Their advantages are low costs, long life if properly protected, and reasonable accuracy. They still are widely used in experimental setups and for various home uses.

Some filled-bulb thermometers take account of the pressure increase in the capillary stream. This increase is due to the vapor-pressure rise of the liquid phase plus the rise due to the compression of the gas. A relatively high pressure may hence occur. Bending the capillary tube is sometimes used, and the tube straightens to a degree as the pressure rises. The amount of straightening can be calibrated with a pointer on a dial to measure the temperature.

20.2.5 Bi-Metallic Thermometers

Bi-metallic thermometers are based on the principle that different metals expand at different rates as the temperature increases. Two strips of the dissimilar metals are connected in the form of a spiral or helix. A pointer connected to these assemblies indicates the temperature on a dial. Such thermometers are widely used to measure temperatures of homes or buildings. They are often used over a temperature span of about 80°C.

20.2.6 Pyrometric Cones

These cones change shape over a rather wide range of temperatures. They have found use in the ceramic industries and in applications to determine the approximate final temperatures in materials such as films, throw-away items, and onetime applications.

20.3 FLOWMETERS

Numerous flowmeters are often available for a specific application. Factors of importance in making a choice include the following:

1. Character of fluid (gas, liquid, slurry or dispersion, etc.). What are the physical properties of the fluid including viscosity, density, surface tension, etc.?
2. Number of phases flowing. If multiple phases, what are the degree of dispersion, ratio of phases, continuous phase, etc.?
3. Cleanness and/or impurities in the fluid.
4. Corrosiveness of fluid must be known when choosing the materials of construction of the flowmeter.
5. Flowrates expected for fluids and Reynolds number of fluids. Hence, the expected diameter of the tubing to and from the flowmeter must be chosen. Are flows steady or pulsating?
6. Pressures range to be monitored. Pressures may vary greatly. A pressure drop is often experienced in the flowmeter, but pressure increases occur if metering pumps are employed.
7. Expected maintenance costs. Corrosion, deposition of solids, etc., add significantly to costs, changes in calibration of flowmeter, etc.
8. Reproductibility, accuracy, and calibration. Some applications require high accuracy.
9. Both the initial capital costs and expected maintenance costs are obviously important factors.
10. Devices to transmit the signals from the flowmeter to the recorders are often required. The costs of such devices are often relatively large.
11. Possible problems in startup and shutdown of the units need to be considered.

20.3.1 Several Popular Types of Flowmeters

Flowmeters can often be divided into the following categories:

1. Meters that measure differential pressures over the flowmeter and such pressure changes that can be interpreted as flowrates. Such flowmeters with a large number of designs include orifices, venturi tubes, pitot tubes, elbow taps, etc. Fluids that result in changes of the cross-sectional area due to erosion, corrosion, or deposition of solids obviously change the calibrations. These meters tend to be relatively cheap but are often not very accurate.
2. Several flowmeters are based on electromagnetic properties of the fluid. Often electrical conducive fluids are required. Coriolis mass flowmeters are widely used; an angular

momentum is imparted to flowing fluid by providing harmonic vibrations. Sometimes a U-bend is provided, and in other designs, two tubes are operated in parallel. Costs of these units tend to be high, but the electromagnetic detectors often provide highly reliable flowrate predictions. Reigner [6], however, indicates they are not reliable for two-phase flows such as aerated liquids. Omega Engineering [7] also provides important recommendations.
3. Displacement flowmeters for both liquids and gases. In some cases, positive displacement pumps are employed for liquids.
4. Rotameters can often be used for liquids and gases, but safety issues such as loss of toxic materials if the tube breaks are concerns.
5. Weirs and flumes are sometimes employed.
6. Flowmeters are available for granular solids.

20.4 PRESSURE MEASUREMENTS

Measuring pressure is obviously of great importance in chemical processes, and numerous instruments and techniques are available. Key considerations in selecting the best instrument for a specific application include the following:

1. Range of pressures to be measured may vary from high vacuums to several thousand atmospheres.
2. Short-time pulsations of pressure. For example, some pumps cause rapid pulsations.
3. Desired accuracy and precision of pressure reading.
4. Temperature range of materials being measured.
5. Character or nature of materials including corrosiveness, freezing point, viscosity, etc. Sometimes special precautions are needed in transferring pressure from process stream to pressure measuring device. For common Bourdon tubes, fluids such as silicone oils, light hydrocarbon oils, glycerine, etc., are employed for such transfers.
6. The required or preferred method of reading or recording the pressure. Pressures, for example, can be read usually from a gauge or a recorder.

Methods and instruments for measuring pressure are available for $100 or less up to several thousand dollars. It should be emphasized that many pressure devices read pressure differences between the process stream and atmospheric pressure.

1. Pressure gauges containing Bourdon tubes are widely used for either pressures from atmospheric to high pressures, such as over 700 bars, or from atmospheric to high vacuums. With pressure changes, the tube changes shape causing a needle to change direction so the pressure can be read. Gauges calibrated by the manufacturer often have inaccuracies up to ±2.0% over at least a portion of their range. Better accuracy can be obtained with more carefully manufactured and hence more expensive gauges.
2. Pressure gauges involving spring and bellows, bell-cased mounting, diaphragms, and other devices have also been developed.
3. Strain-gauge transducers are also employed for pressure measurements; mechanical strain caused by pressure changes causes the electrical resistance of the transducer to change. Semiconductors such as geranium or silicon are often employed. Thermal errors are minor at near-ambient temperatures. A wide range of prices occurs for such transducers.
4. Manometers are employed for relatively small pressure changes. Often costs are low.
5. Dead-weight piston gauges are employed to calibrate pressures up to large pressures. Well-designed gauges of this type are relatively expensive.

20.5 LEVEL MEASUREMENTS

A variety of methods are available to measure liquid or solid particle levels in storage tanks, reactors, etc. Methods vary from cheap, such as measuring pressure changes as gas is bubbled upward through liquid, to considerably more expensive using capacitane and radio frequency, conductivity, lasers, microwaves, radar, etc. In storage tanks with relatively large diameters and cross-sectional areas, a large amount of material is stored in a volume only 1 to 2 mm thick, so relatively accurate level control is sometimes needed.

Variables of importance in selecting instruments for level control include:

- Liquid, slurry, or solid
- Temperature range
- Pressure range
- Viscosity and physical properties of liquids
- Character of solid particles
- Capital and expected maintenance costs
- Expected precision and accuracy of readings
- Possible foam, boiling, and agitation

20.6 OTHER MEASUREMENTS

Other instruments are needed in many plants, including electrical ones, viscometers, densities, etc. Often more than one instrument can be chosen for a specific application, so the engineer must choose with consideration to operating, economics, and safety concerns.

21.1 AN OVERVIEW OF THE MATERIALS SELECTION PROCESS

In selecting metals and alloys as materials of construction, one must have knowledge of how materials fail, for example is, how they corrode, become brittle with low-temperature operation, or degrade as a result of operating at high temperatures. Corrosion, embrittlement, and other degradation mechanisms such as creep will be described in terms of their threshold values. Transient or upset operating conditions are common causes of failure. Examples include start-ups and shut-downs, loss of coolant, the formation of dew point water, and hot spots due to the formation of scale deposits on heat transfer surfaces. Identification and documentation of all anticipated upset and transient conditions are required.

Corrosion debris is a related problem. In some applications, materials with nominally low corrosion rates produce considerable corrosion debris. Such problems are always associated with units that contain large surface areas exposed to the corroding fluid. Examples include heat

exchanger surfaces and packed beds. The materials selection process must document and organize such information.

This section will discuss problems that can complicate the selection procedure. Such problems include the variability of materials selection criteria, conflicting project objectives such as minimizing capital cost, and mandatory criteria such as those in governing engineering codes. Other topics discussed include organization of the information needed for the materials selection process, a procedure for materials selection, and the use of a materials selection diagram.

21.1.1 Materials Selection Criteria

Many engineers associate materials selection only with the design and construction of new facilities, plant additions, or plant renovations. However, it is also part of a plant's routine maintenance activities, being a subject of discussion between operations, planning, and maintenance personnel. Such discussions usually illustrate the need for both short-term and long-term solutions.

For simple jobs such as replacements in-kind or for jobs with which the responsible engineer has prior experience, materials selection is usually a straightforward task. However, some jobs involve complex combinations of requirements, which may include (1) demanding mechanical requirements such as thermal cycling, (2) conservative design requirements such as "leak-before-break", (3) stringent process-related requirements such as avoiding process contamination, (4) special fabrication requirements such as postweld heat treatment (PWHT), (5) aggressive corrodents or crack-inducing agents, (6) upset or transient operating conditions (i.e., nonstandard operating conditions), (7) limited capital budgets, and (8) aggressive project schedules.

21.1.2 Mandatory Requirements

Most localities mandate compliance with national engineering codes such as the ASME (American Society of Mechanical Engineers) Boiler & Pressure Vessel Code [1]. These codes govern mechanical design and provide the maximum allowable stresses and required low-temperature toughness, as a function of temperature, for approved materials. The codes also define requirements for fabrication procedures such as PWHT. All codes contain rules that ensure the selected material of construction will not be susceptible to brittle fracture at the minimum design temperature. Users of the codes must develop a familiarity with these rules. For example, code rules help avoid specifying materials at temperatures for which they are not permitted.

The codes do not normally include guidelines on materials selection. However, they often provide information about degradation mechanisms. Most designers use this information as if it were mandatory. For the same reason, nonmandatory recommended practices, such as NACE (National Association of Corrosion Engineers) MR0175 [2] and API (American Petroleum Institute) Publication No. 941 [3], are often customarily used as mandatory documents. Because of safety concerns and potential liabilities related to process guarantees such as yield or purity, materials selection guides provided by process licensors are usually regarded as mandatory. The materials recommended by process licensors are conservative. All engineering codes used for mechanical design contain tables defining allowable stresses for each material, usually as a function of temperature. Most, if not all, codes restrict materials selection to the listed materials only. Thus the design engineer must know the materials permitted.

21.1.3 Governing Criteria

All design data such as pressures and temperatures are regarded as mandatory conditions that must be satisfied. Upset and transient operating conditions are sometimes governing. For example, the maximum design pressure and coincident temperature will determine the wall thickness of a carbon steel process vessel containing dry H_2S. However, even traces of liquid water in the presence of H_2S can initiate sulfide stress corrosion cracking in carbon steel. This should add the requirement of PWHT.

Operating Temperature (Minimum/Maximum): ______________________________

Corrodents: ______________________________

Crack-Inducing Agents: ______________________________

Metallurgy: ______________________________

PWHT(Y/N): ______________ **Valve Trim*:** ______________ **Corrosion Allowance:** ______________

Notes: ______________________________

* For most services, valve trim will be 13Cr stainless steel. Use full hard facing for temperatures >600°F (315°C).

FIGURE 21.1 A simplified materials selection template. (Copyright Marcel Dekker, Inc.; reprinted with permission [5].)

21.1.4 Special Requirements

The required design life will generally affect materials selection and/or the determination of the recommended corrosion allowance. Normally, the user or process licensor will define design life requirements. It is helpful to define the design life requirements in the "Notes" addendum of the template.

Materials selection for some projects is affected by special objectives such as minimal capital cost, minimal maintenance, short project schedule, extended design life, concerns about product purity, or the consequences of a leak or rupture. If such objectives are governing, they should be included in the materials selection design basis in the "Notes" addendum of the template. Occasionally, objectives may be in conflict, such as minimal capital cost vs. short schedule. When this occurs, compromises are made. Or a superior material may not be selected if its delivery would delay start-up. Safety and environmental concerns must always be considered.

21.1.5 Materials Selection Template

A materials selection template, containing critical design and operating conditions for each piece of equipment and piping run, is used as part of a structured method to select suitable materials of construction. It is usually prepared by a plant or project process engineer, and is customized for the plant or project (see Figure 21.1 for an example of a simple template).

The template serves two major purposes: (1) it organizes all the technical information needed for materials selection; and (2) on a large job or project, the template is a convenient means to transmit process and materials selection information to design engineers.

21.2 BASIC METALLURGY

Metallurgical descriptions often contain jargon and arcane words, as explained below.

21.2.1 Heat Treatments

21.2.1.1 Annealing

For carbon and low-alloy steels, full annealing requires heating to a temperature of 1350°F to 1750°F (730°C to 955°C). The steel is held at this temperature long enough to ensure through-

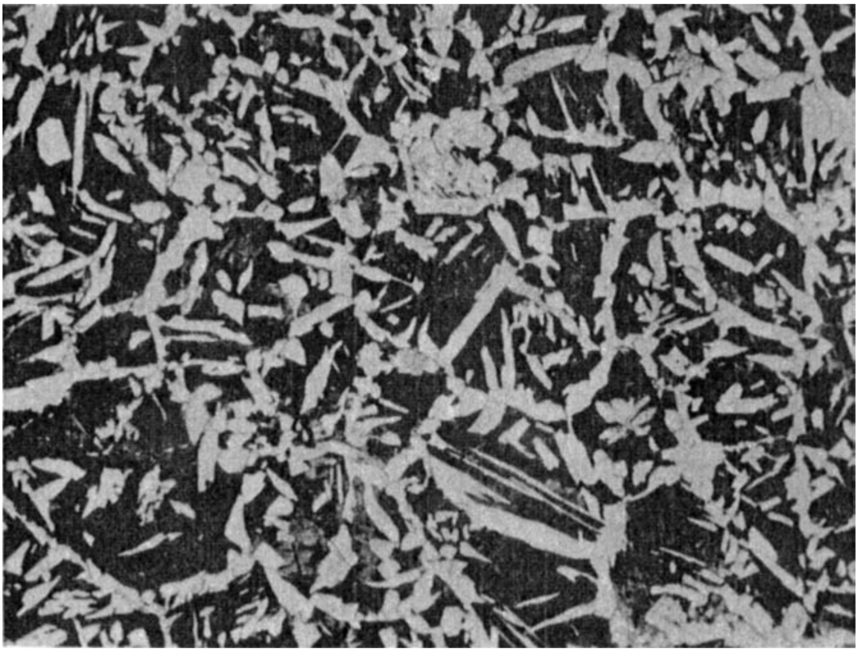

FIGURE 21.2 Carbon steel that has been furnace annealed. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5]. (Courtesy of Dr. E.V. Bravenec, Anderson & Assoc.)

thickness heating; then the material is furnace cooled, producing a "dead soft" carbon steel (Figure 21.2). This condition is usually unacceptable, because carbon and low-alloy steels can be very brittle in the fully annealed condition. Such steels are usually subsequently normalized. Figure 21.3 shows the microstructural effects due to normalizing.

For austenitic stainless steels, annealing is usually at about 2000°F (1095°C), followed by either a water quench or rapid cooling in air. This procedure is more properly called a "solution anneal," since the objective is to redissolve any chromium carbides formed during prior processing. Rapid cooling minimizes formation of carbides during the cooling period. The minimum temperature for solution annealing depends on the composition of the alloy.

Chemically stabilized alloys such as Type 321 SS are available in a heat-treated condition known as "stabilization annealed." In this condition, such alloys have maximum resistance to sensitization and its effects. Sensitization is discussed in Section 21.4.

21.2.1.2 Normalizing

In this process, a carbon or low-alloy steel is heated to about 1650°F (900°C) and is then air-cooled. The process partially relieves stresses from prior processing and "refines" the material. "Refining" reduces the grain size and the grain structure becomes more homogeneous, thereby producing a tougher, more ductile product. Figures 21.2 and 21.3 illustrate the microstructural benefits of normalizing.

21.2.1.3 Preheat

Many steels are susceptible to cracking during or after welding. Examples include high-strength carbon steels and low-alloy steels such as the air-hardenable Cr-Mo steels. Preheating the base metal or substrate reduces the risks. Engineering codes [4] usually contain preheat temperatures and procedures.

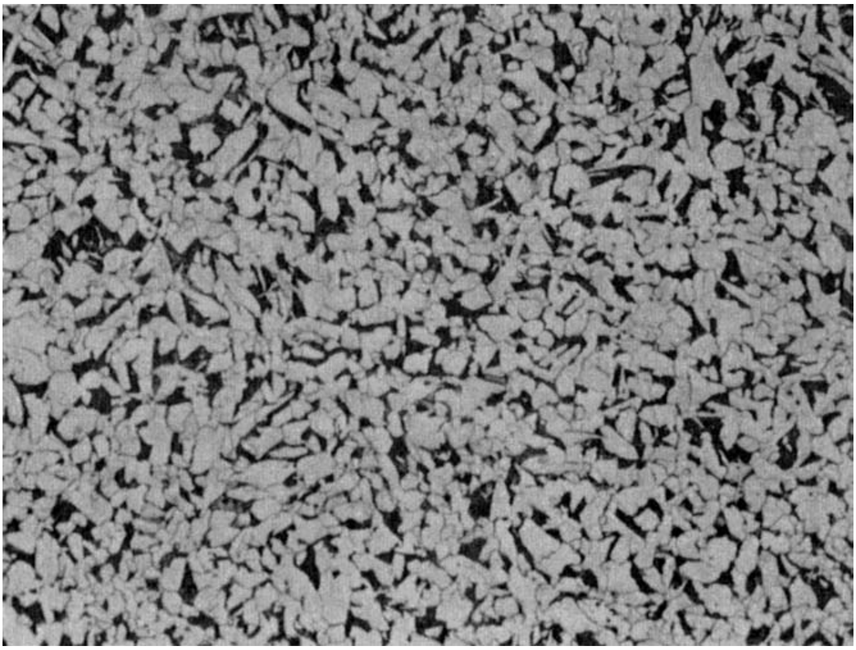

FIGURE 21.3 Carbon steel that has been normalized. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

21.2.1.4 Stress Relief/Postweld Heat Treatment

Residual stresses can be introduced into a metal by fabrication processes such as forging or rolling, by uneven heating or cooling, or by welding. The magnitude of such stresses is usually on the order of the yield strength, but sometimes approaches the tensile strength.

To stress relieve or postweld heat treat carbon and low-alloy steels, they are typically heated to 1100°F to 1350°F (595°C to 730°C) for extended time, followed by air cooling. The minimum time is specified by the relevant engineering code, and the temperature must be less than the lower transformation temperature of the steel, which is the lowest temperature at which austenite starts to form, for example, 1333°F (720°C) for plain carbon steels. In order to avoid degrading the required mechanical properties of a heat treated alloy, subsequent fabrication heat treatment temperatures, such as those for stress relief and PWHT, must not exceed the tempering temperature (discussed in the next section).

The yield strengths of metals and alloys decrease with increasing operating temperature. Residual stresses in excess of the reduced yield strength are eliminated via plastic deformation. Upon cooling, the maximum residual stress possible is the yield strength at the holding temperature. For carbon steels, heat treatment will reduce residual stress by about two-thirds. When done for the purpose of removing residual stresses caused by cold work, the process is termed stress relief.

As the liquid metal in a weld solidifies, it becomes at least partially constrained by the surrounding parent metal. When the weld metal cools to ambient temperature, the resulting residual stress in the weld is approximately equal to the ambient temperature yield strength of the parent metal. Stress relief heat treatment for welds is called postweld heat treatment. An additional benefit of such treatment is a reduction of the hardnesses of the weld metal and heat-affected zone (HAZ), thus reducing the risk of stress corrosion cracking.

Stress corrosion cracking in heat treated weldments indicates that postweld heat treatments are sometimes ineffective. Sometimes this result can be attributed to microalloying. (Microalloying is discussed later.) In some cases, subsequent stress corrosion cracking can be traced to an improperly

executed PWHT, for example, where the PWHT temperature was too low. In other cases, it has been speculated that even the lowered level of residual stress was sufficient for the initiation of stress corrosion cracking. When experience indicates that PWHT may be ineffective, a stress corrosion cracking mitigation measure (such as a cracking-resistant weld overlay) or a change in the process or the material of construction is indicated.

Some engineering codes allow low-temperature PWHTs if the weldment is held at the lower temperature for an extended time. Such PWHTs should not be permitted to avoid or minimize the risk of stress corrosion cracking.

Austenitic stainless steels are not usually stress relieved or postweld heat treated. When they are heat treated, they are held at 1600°F to 1650°F (870°C to 900°C), followed by rapid cooling. Such cooling avoids sensitization. (Sensitization involves thermally-induced precipitation of carbides in microstructural grain boundaries). Stress relief or postweld heat treatments of ordinary austenitic stainless steels at less than 1600°F (870°C) may sensitize the alloy. For this reason, local stress relief of unstabilized austenitic stainless steel is usually impractical, since the "runout" areas immediately adjacent to the region being heat treated will be grossly sensitized. An exception is stress relief of low-carbon grades of thin-section products such as tubing. These can be stress relieved fast enough to avoid gross sensitization. Stabilized grades of austenitic stainless steels such as Type 321 SS are much less susceptible to sensitization if they have been stabilization annealed (see Section 21.4 for a discussion of sensitization and stabilization annealing). Stabilized grades are usually selected if local stress relief or PWHT is required.

21.2.1.5 Quench and Temper

This procedure produces materials with improved strength and/or toughness. It is usually restricted to alloys whose microstructures are transformed upon cooling. In this procedure, a ferritic steel is first heated to a temperature of about 1650°F (900°C) or higher, then quickly cooled (i.e., quenched) in air, water, water spray, oil, or salt bath. The required conditions depend on alloy chemistry, section thickness, and desired mechanical properties.

Quenching produces a hard, strong—but brittle—phase called martensite. Tempering is usually performed at 1100°F to 1300°F (595°C to 705°C). The tempering procedure is very similar to that used for stress relief or PWHT. Tempering promotes the diffusion of some carbon from the martensite, thereby greatly improving the ductility and toughness of the quenched steel.

Occasionally, satisfying the simultaneous requirements for an ASTM product form heat treatment and for its construction code postweld heat treatment can be a problem. For example, the minimum tempering temperature for ASTM A335 1-1/4Cr-1/2Mo pipe is 1200°F (650°C). The ASME B31.3 piping code postweld heat treatment minimum temperature for this material is 1300°F (705°C). Thus, it can happen that 1-1/4Cr-1/2Mo pipe ordered to ASTM A335 will be subsequently postweld heat treated at a temperature exceeding the tempering temperature. If this happens, the minimum mechanical properties indicated by the ASTM specification may deteriorate, thus threatening the integrity of the design. This situation can be avoided by modifying the purchase order in either of two ways: (1) Establish a minimum ASTM tempering temperature that exceeds the subsequent PWHT temperature. To ensure that this strategy is followed, it will be necessary to instruct the fabricator regarding the maximum permitted PWHT temperature. In this manner, the minimum requirements of both the ASTM specification and the construction code are satisfied. (2) Require that coupons, exposed to the same heat treatments to be used for actual fabrication, be tested to demonstrate that the proposed heat treatments do not degrade the minimum required mechanical properties.

Thick sections of many ferritic steels cannot be cooled quickly enough in air to obtain the desired normalized microstructure. In such cases, quenching is often used to hasten the cooling rate. The objective is to produce the same microstructure as obtained from normalizing a thinner section of the same material. In thick sections of such materials, even quenching does not ordinarily

generate the cooling rates necessary to develop martensite. Hence, tempering is primarily for stress relief rather than for softening martensite. Many codes, such as the ASME Boiler & Pressure Vessel Code, Section VIII [1] and materials specifications such as ASTM A516, permit such thick sections, properly quenched and tempered, to be equivalent to normalized material. Tempering is also sometimes done in conjunction with other heat treatments such as normalizing in order to soften and/or toughen the steel. In some cases, stress relief may be a secondary or even a primary objective.

Fabricators occasionally propose multiple heat treatments or heat treatments having unusually long holding times or unusually high holding temperatures. The user should be wary of such proposals. Some multiple heat treatments may cause degradation of carbon and low-alloy steels with loss of strength and/or loss of toughness. The fabricator should be required to demonstrate, by testing, that the proposed procedure will not result in material degradation.

21.2.2 Microstructural Terms

21.2.2.1 Austenite

Austenite is a high-temperature form of carbon steel, having a face-centered cubic crystal structure. The lowest temperature at which ordinary carbon steel can be fully austenitic is 1333°F (720°C). During normalizing heat treatments, the holding temperature and time are specified so that the alloy becomes fully austenitic. For the common carbon steels, the austenitizing temperature is typically specified as 1650°F (900°C).

Austenite has a much higher solubility for carbon than other forms of steel. Heating the steel to an austenitizing temperature causes any carbides present to dissolve. Alloys capable of forming austenite at high temperatures, but that transform to other crystal structures at lower temperatures, are said to be hardenable by heat treatment. Martensitic steels are an example. Most carbon and low-alloy steels are hardenable by heat treatment.

When alloying elements such as nickel or manganese are added to carbon steel, the austenitic microstructure becomes stable at low temperatures. For example, most austenitic stainless steel and high-nickel alloys exhibit stable austenitic microstructures at temperatures approaching absolute zero. These alloys have excellent low-temperature fracture toughness and are resistant to hydrogen embrittlement from causes other than cathodic charging. Most austenitic alloys are not hardenable by heat treatment, the major exception being a few precipitation hardenable types.

21.2.2.2 Ferrite

Ferrite is essentially pure iron with a body-centered cubic crystal structure. Ferrite forms from austenite at about 1675°F (915°C), as the austenite cools from a normalizing heat treatment. Because ferrite does not contain enough carbon to permit the formation of martensite, it is not hardenable by heat treatment. The most common truly ferritic steel is Type 405 SS, a ferritic stainless steel. The generic term "ferritic steel" often refers to carbon or low-alloy steels that contain other phases in addition to ferrite. Such steels are usually hardenable by heat treatment. Ferritic steels become brittle at low temperatures. This phenomenon is reversible, that is, the steels regain their former toughness after being warmed up. Ferritic steels are also susceptible to hydrogen embrittlement.

21.2.2.3 Martensite

Martensite is formed from high-temperature austenite, in heat-treatable alloys, by cooling the austenite fast enough to prevent the formation of ferrite. For some heat-treatable alloys, quenching in water or some other liquid such as oil or a molten salt is often required. Some steels have sufficient alloying additions that quenching is not necessary. Air cooling produces the martensitic microstructure in Type 410 SS and other martensitic stainless steels. Since martensite is usually brittle, it is normally subsequently tempered. The tempering temperature is less than the austenite

transformation temperature. Tempering permits some carbon to diffuse from the martensite. Tempered martensite is significantly stronger and tougher than the parent ferritic alloy. It should never be stress relieved or postweld heat treated at a temperature exceeding the final tempering temperature, since its mechanical properties can be seriously degraded.

Although heat-treated martensitic steels have superior fracture toughness, they do tend to be brittle at low temperatures. Most martensitic steels are sensitive to hydrogen embrittlement. Martensitic alloys are widely used as high-strength bolting such as ASTM A193 Type B7, high-strength quenched and tempered plates such as ASTM A543, and martensitic stainless steels such as Type 410 SS.

21.2.2.4 Pearlite

Pearlite can form in most carbon and low-alloy steels with enough carbon to be hardenable by heat treatment. However, carbon steels usually are not intended to be hardened by heat treatment. Instead, they are normally produced with a more ductile, lower strength microstructure that forms during slow cooling from austenitic temperatures. This microstructure is a mixture of ferrite and pearlite. During cooling, ferrite starts to form from austenite. The ferrite contains essentially no carbon. As the ferrite forms, it leaves behind an increasing concentration of carbon in the remaining austenite. The excess carbon is eventually ejected from austenite. Normally, the excess carbon combines with iron to form iron carbide (Fe_3C), called "cementite." If the austenite cools relatively slowly, as in air cooling, pearlite forms. Pearlite is laminar, consisting of very fine alternating layers of ferrite and cementite. Such a microstructure is often found in normal carbon steels, as shown in Figure 21.3.

21.2.3 Metallurgical Terms

The terms defined in this section are frequently used in purchasing specifications. Other, less frequently used terms are defined as necessary in the text. For more complete definitions, see reference [6].

Base metal is used interchangeably with the term parent metal; it refers to the material of the components in a weldment, to differentiate such material from the weld metal and the HAZ of the base metal.

Carbon equivalent (CE) is used in evaluating the weldability of a carbon steel. Many different formulas are used to calculate the *CE* value, the most common being

$$CE = \mathrm{C} + \mathrm{Mn}/6 + (\mathrm{Cr} + \mathrm{Mo} + \mathrm{V})/5 + (\mathrm{Ni} + \mathrm{Cu})/15 \tag{21.1}$$

where the concentration of each element is expressed in weight percent (wt%).

The *CE* value is used to evaluate the risk of developing hard HAZs and the susceptibility of the weldment to delayed hydrogen cracking. Table 21.1 shows typical limits for carbon steels. When the maximum allowed *CE* value is exceeded, additional fabrication measures such as preheat, PWHT, and/or inspection for the effects of delayed hydrogen cracking are usually necessary.

Cold working is when a metal is stressed above its yield strength and plastic deformation occurs. Such deformation raises the internal energy of the material. The mechanism of energy storage creates distortions in the crystal structure of the material, i.e., an increase in unit entropy. Cold work involves plastic deformation at temperatures up to several hundred degrees. Deformation is irreversible, unless the material is subsequently heat treated, such as normalizing or solution annealing. Cold-worked materials sometimes have increased yield strengths and reduced ductilities; such materials are sometimes said to have been strain hardened.

Plastic deformation is caused by a stress that exceeds the yield strength of the material. Deformation at stresses less than the yield strength is elastic deformation. It is reversible, i.e., the

TABLE 21.1
Typical Carbon Equivalent (CE) Limits for Carbon Steels

Wall Thickness	1/2" (12.7 mm)	5/8" (15.9 mm)	3/4" (19 mm)	7/8" (22 mm)	1.0" (35.4 mm)
Max. CE Value	0.4	0.39	0.37	0.35	0.34

deformation disappears with the removal of the stress. Plastic deformation (sometimes called permanent strain) is permanent, i.e., plastic deformation remains after removal of the stress that caused it.

Galling is related to adhesive wear. When two metals of similar chemistry and hardness are in moving contact and under pressure, in the absence of lubrication, surface asperities (high points) tend to momentarily weld together. Continued movement ruptures these very local welds, resulting in metallic particles being torn from one or both surfaces. These particles result in rapidly increasing friction. Galling is an extreme form of adhesive wear, causing gross surface damage. Austenitic stainless steels are the most common susceptible materials. Examples include threaded fasteners (galling occurs in the threaded region) and valve closures.

Hardenable describes alloys that can be hardened and strengthened by cold working, for example, strain-hardened bolting. Hardenability describes the ability of an alloy to be hardened and strengthened, usually by heat treatments such as quenching and tempering.

Heat-affected zone (HAZ) is the volume of parent metal in which the mechanical properties and/or the microstructure have been changed by the heat of welding or thermal cutting. For most welds in carbon and low-alloy steels, the HAZ is a band, usually about 1/8 in. (3 mm) wide, adjacent to the fusion line of the weld. In austenitic stainless steels, a narrow, secondary HAZ may be generated some distance from the fusion line as illustrated in Figure 21.4.

Hot working causes plastic deformation to occur at a temperature high enough to prevent the material from becoming strain hardened. Instead, it spontaneously "recovers" plastic deformation. Hot-worked materials therefore do not have the internal energy characteristic of cold-worked materials. In practice, hot-work threshold temperatures are dictated by factors such as tool life. These temperatures range from as low as 350°F (175°C) for aluminum alloys to as high as 2300°F (1260°C) for steels and nickel alloys.

Oxide stabilized refers to materials, such as aluminum and the stainless steels, whose corrosion resistance depends on the formation and stability of a very thin surface oxide layer that is inert, easily "healed" if damaged, and tenacious. When the oxide layer has been disrupted and not healed, the material usually has little corrosion resistance. Both active and passive states sometimes exist adjacent to each other on the surface, resulting in rapid local corrosion. Crevice corrosion in stainless

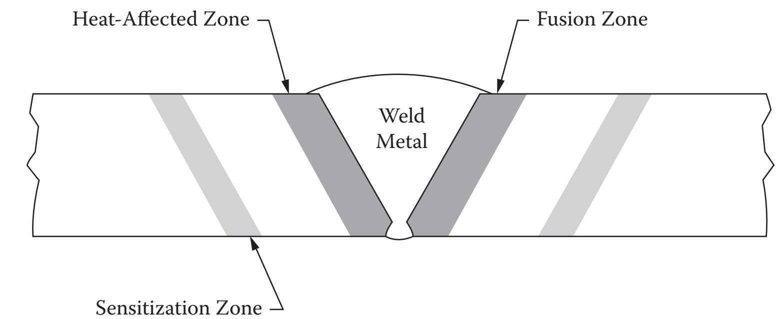

FIGURE 21.4 The typical features of a weld. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

steel socket welds is a good example of rapid local corrosion. The potential difference between the anodic and the cathodic states drives the corrosion cells (this is an example of galvanic corrosion). Corrosion due to adjacent active-passive sites can be particularly rapid if the corrosion cell has an unfavorable anode/cathode area ratio.

Product forms include plate, strip, sheet, wire, pipe, tubing, bolting, bars, forgings, extrusions, and castings.

Toughness describes the ability of a material to deform plastically and absorb energy before fracturing. Fracture toughness is the energy per unit area necessary to create a fracture surface. Brittle materials fracture easily, requiring relatively little energy to crack. Fracture-tough materials, such as the ordinary austenitic stainless steels, require much more energy. Toughness is usually measured by the energy absorbed during an impact test. The most common example of such a test is the Charpy V-notch impact test (see ASTM A370).

Weldment is an assembly whose parts are joined by welding.

21.2.4 Alloy Designations

Alloys are usually designated by the Unified Numbering System (UNS) [7, 8], which incorporates earlier identification systems developed for particular alloy families such as aluminum and copper alloys. The UNS system is particularly useful when designating proprietary alloys such as the nickel-based alloys. Ordinary alloy designations that are nonproprietary, such as those of the 300-series stainless steels, are commonly used instead of the UNS number.

21.2.5 Manufacturing of Metals and Alloys

Metals and alloys are available as *wrought* and *cast*. Products created by other methods such as powder metallurgy are uncommon and not discussed here. Wrought products are formed from solid metal, usually hot. Wrought processes generally employ compressive forces, which may be either continuous or cyclic, with or without dyes. Examples of wrought processes include rolling, forging, extrusion, and drawing, to produce plate, pipe, tubing, sheet, wire, forgings, extrusions, and bars. Wrought products are sometimes heat treated during the manufacturing process. The terms "hot finished" and "hot rolled" are usually not regarded as substitutes for heat treatment. If the materials selection process indicates a heat treatment requirement, check the purchasing specification to see if the product is in the heat-treated condition or if heat treatment is still needed.

Castings are products formed in a mold by solidification of a liquid. (Welds are a type of casting.) Virtually all wrought products begin as castings, such as ingots or continuously cast strands. Castings dominate pump cases, where geometry favors the simplicity of castings. Almost all castings are heat treated (the primary exceptions being some high alloys). Occasionally, a casting requires repair welding, as part of either a fabrication or maintenance procedure. Postweld heat treatment (or solution annealing in the case of austenitic stainless steels) may be indicated. Heat treatments can, however, warp previously machined surfaces. Special welding procedures, hardness controls, shot peening, etc., can avoid heat treatment. To avoid or minimize warping, special fabrication measures use strong-backs or bracing.

The chemical compositions of cast materials are usually different from those of their wrought equivalents. Castings usually contain more silicon than the wrought equivalent. (Silicon improves the "pourability" or fluidity of the liquid alloy.) Some alloys are available only in cast form, as they are too unstable or brittle to be formed by wrought methods. A few alloys are provided only in wrought form. Typically, an alloy in cast form usually has a different name than its wrought counterpart. For example, Grade CF-8 is the cast version of Type 304 SS. See reference [9] for a compilation of specifications, compositions, names, and typical mechanical properties of many casting materials.

Wrought products are usually preferred to castings. The hot-forming procedures employed break up and weld shut defects in the ingot or strand, while such defects remain present in

castings. Wrought products tend to have a uniform, fine, partially isotropic grain structure. However, they are normally more expensive, reflecting the fabrication costs of hot working, machining, welding, etc.

Castings typically have lower strength, lower toughness, higher defect concentrations, and coarse anisotropic grain structures. Depending on the casting process, the surface may be less corrosion resistant than the bulk material. Because of this, corrosion tests should represent the expected surface condition of the casting. The advantages of castings include relatively low cost, ease of obtaining complex shapes, and minimal machining. In some alloys, the silicon addition and/or cast grain structure produces exceptional corrosion resistance. For example, austenitic stainless steel castings are more resistant to chloride stress corrosion cracking than are their wrought equivalents. In addition, castings are often less weldable, usually because of their greater silicon and/or carbon contents. Thus, repairability may be an issue and may be enhanced by specifying tighter compositions. A common example is the use of Grade CA-6NM (12Cr-4Ni-Mo) (UNS J91540) instead of Grade CA-15 (13Cr) (UNS J91150) for 12Cr castings. (The CA-6NM alloy has a much lower carbon allowable than the CA-15 alloy.) When choosing between wrought and cast components, the lower flaw density and/or better repairability of the wrought product or the lower cost or a unique property of the cast product should be considered.

Welding results in a metallurgical discontinuity* with different microstructures than the parent metal. Mechanical properties of the weld metal usually differ. Even with PWHT, weldments retain a residual stress field. Heat affected zones often contain a coarsened grain structure and/or "hard spots." Corrosion testing of the welds may be a critical part of the testing program.

As discussed earlier, cold work can change the mechanical properties of a material, including adversely affecting the fracture toughness. For applications such as bolting that will not be exposed to crack-inducing agents, cold working is deliberately used to increase yield strengths. However, cold-worked areas are typical sites for the development of strain aging (see Section 21.4). In addition, cold-worked areas can be susceptible to corrosion pitting, stress corrosion cracking, hydrogen embrittlement, and other damaging phenomena. For applications in which excessive cold working may be harmful, it is normal practice to stress relieve materials that have received more than 5% permanent outer fiber strain.

21.2.6 Metals and Alloys

21.2.6.1 Cast Iron

Cast irons typically contain at least 2 wt% carbon; the cast carbon steels used for plant construction rarely contain more than 0.35%. The high carbon content of cast iron makes it difficult to weld. Two types of cast iron are commonly used:

1. *Gray cast iron* such as ASTM A48 material is plain cast iron, composed of ferrite containing graphite stringers. Figure 21.5 shows the microstructure. It is relatively brittle and is used for applications in which toughness is not a concern, including utility services, as pump cases, and valve bodies.
2. *Ductile cast iron* (also known as *nodular* or *spheroidal iron*) contains a small amount of magnesium, which greatly improves ductility and toughness; an example is ASTM A536. Figure 21.6 shows the microstructure. Nodular cast iron is occasionally used in valve bodies, in pumps in various utility services, and in large reciprocating compressors. Malleable cast iron such as ASTM A47 material is a related alloy that is relatively expensive. Mildly acidic water can graphitize both gray and ductile cast iron as the iron

* A metallurgical discontinuity is an interruption in the normal physical structure of a metal. Examples include welds, cracks, laps, seams, bolted closures, inclusions, and porosity. A metallurgical discontinuity may or may not be a defect, that is, a discontinuity that is regarded as harmful.

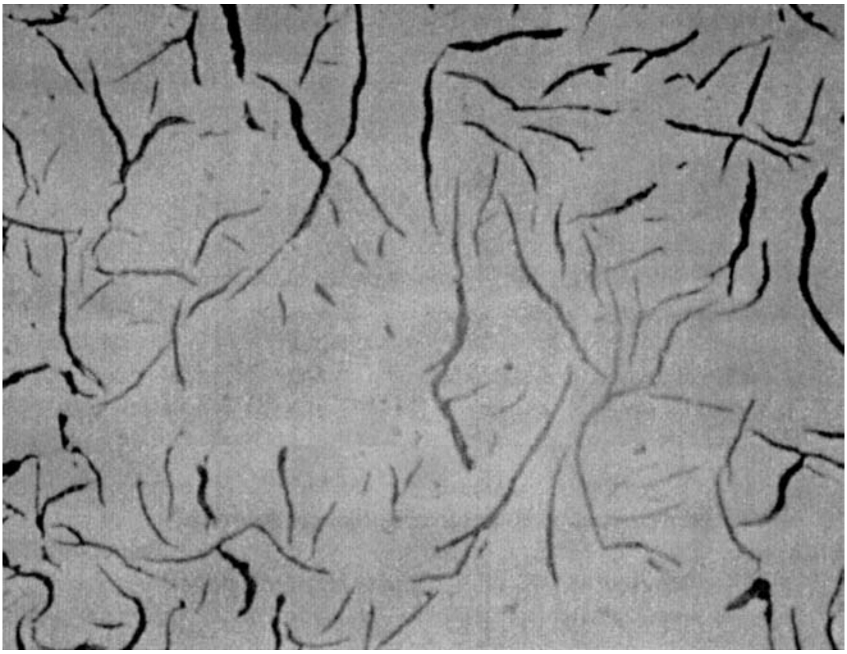

FIGURE 21.5 Gray cast iron. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

is slowly leached from the casting forming a network of graphite (Figure 21.7), resulting in low mechanical strength.

Three specialty cast irons are occasionally employed. Corrosion and erosion resistant *silicon cast irons* such as those of ASTM A518 find use in acid and abrasive services. They are relatively brittle and difficult to machine, limiting their usefulness. *White cast irons* such as ASTM A532, containing up to 25% chromium, are used in highly abrasive services such as pumping abrasive slurries; they are also relatively brittle. Nickel-rich cast irons, known as *Ni-resist cast irons* (such as those of ASTM A436), find use in both low- and high-temperature applications that require resistance to wear, and as seawater alloys. Because of its brittleness, cast iron is normally not permitted for hydrocarbon streams.

21.2.6.2 Carbon Steel

Carbon steels are the most widely used materials of construction. Unalloyed carbon steels typically contain nominal amounts of manganese, silicon, phosphorus, and sulfur. They are normally supplied with a pearlitic-ferritic microstructure (see Figure 21.3) produced by air cooling a hot-formed product (e.g., hot-rolled plate) or by a normalizing heat treatment. They are available as either killed carbon steel or plain carbon steel.

21.2.6.2.1 Killed Carbon Steel

Raw liquid steel is saturated with gaseous oxygen. By adding an oxygen scavenger such as silicon to the liquid steel before it is poured, the oxygen is removed as slag. The resulting "killed" steels are cleaner and contain fewer defects than "unkilled" (sometimes called "wild" steels) or partially deoxidized steels. ASTM A106 pipe, A105 forgings, and A516 plate are examples. Cast carbon steel products are also killed, even though typical ASTM specifications do not mention this requirement. Vacuum degassing is less commonly used to remove nitrogen, oxygen, hydrogen, and carbon dioxide.

Steels killed with silicon, such as ASTM A515 plates, tend to have a coarse grain structure usually with a silicon content of 0.15 to 0.30 wt%. They characteristically have relatively high brittle-ductile transition temperatures, making them unsuitable for applications requiring low-

temperature toughness. However, these coarse grained steels are more resistant to creep, graphitization, and some forms of corrosion. Steels killed with both silicon and aluminum or aluminum alone have a fine austenitic grain size. They have good low-temperature toughness; ASTM A516 (plate) is an example. Such steels are usually described in ASTM specifications as being made to "fine grain practice."

21.2.6.2.2 Plain Carbon Steel

The terms "semikilled," "rimmed," and "capped" refer to many carbon steels that have been partially deoxidized or not deoxidized at all. Examples include ASTM A53 and API 5L [10] for pipe and ASTM A36, a structural steel specification. (While these specifications do no require a killing practice, some, such as API 5L, are normally supplied in the killed condition). Although plain carbon steels are often permitted in benign services such as chemically treated utility water or air lines, killed carbon steels are generally used for at least three reasons: (1) There is virtually no cost difference between the two steels. The killed carbon steel is usually preferred because of its lower defect density and higher maximum code-allowable stress at higher service temperatures. (2) Common specifications such as ASTM A53 permit killed steel. (3) Because silicon killed and unkilled steels have different fracture toughness and also different design strengths, unintentional mix ups could cause fabrication, commissioning and/or operating problems.

21.2.6.3 Alloy Steel

Microalloyed steels (sometimes called high-strength, low-alloy steels, or HSLA steels) are intermediate between carbon steels and low-alloy steels. They are killed steels with small amounts of elements such as vanadium, titanium, and niobium; the combined total is usually about 0.1 wt% or less. These elements modify the microstructure, forming a small and uniform grain size that improves toughness and strength (typical specified minimum yield strengths are 60 ksi (410 MPa), or higher). These steels are usually used when section thickness or gross weight (and cost) is a concern, for example, large-diameter long pipelines. Such steels are also sometimes selected for improved toughness for piping and vessels. Microalloyed steels require care in selecting weld joint geometries and welding procedures.

Microalloyed steels can produce hard HAZs, increasing their risk of being susceptible to hydrogen stress cracking. Double-sided welds such as those preferred for vessels are much more likely to produce hard HAZs than single-sided welds normally used in piping and pipelines.

The common carbon steels are permitted by ASTM specifications to contain unreported microalloying elements capable of producing excessively hard HAZs. Occasionally, a weldment of a conventional carbon steel contains small regions in the HAZs having excessive hardness ("hard spots"). Current hardness testing is incapable of detecting hard spots in the HAZs.

Some users either prohibit the use of microalloyed carbon steels or place limits on both the carbon equivalent and the microalloying content. The microalloying limits vary from user to user, but usually fall in the range of 0.03 to 0.10 wt% for the sum of Ti, V, and Cb.*

Low-alloy steels are iron-based alloys containing less than a total of 12 wt% intentional alloying elements. They are all killed. Alloying enhances mechanical properties and/or improves corrosion resistance.

Alloying for improved mechanical properties can improve strength, toughness, and fatigue resistance. Such steels are normally heat treated to enhance their properties. Welding these alloys can degrade them.

Low-alloy Cr-Mo steels such as 1Cr-1/2Mo and 1-1/4Cr-1/2Mo steels are often used at temperatures above 800°F (425°C). Carbon steels become susceptible to creep at temperatures above about 750°F (400°C). In addition, carbon steels are weakened by carbide spheroidization and/or graphitization if exposed to sustained temperatures above 850°F (455°C).

* The element niobium is often called columbium (Cb) in engineering applications.

The mechanical properties of several Cr-Mo low-alloy steels are improved by adding vanadium. Examples include vanadium-enhanced 1Cr-1Mo for turbine rotors and vanadium-enhanced 1Cr-1/2Mo bolts, widely used for temperatures up to 1100°F (595°C). Vanadium-enhanced versions of the 2-1/4Cr-1Mo and 3Cr-1Mo plate and forging alloys are employed in heavy-wall vessel construction. These alloys can permit substantially reduced wall thicknesses. Alloys such as AISI 4140 steel (1Cr-0.2Mo, with carbon between 0.37 and 0.49%) (UNS G41400) are used as rotating equipment shafts, bolts, high-strength forgings, etc.

Ni-Mn (with either 3-1/2 or 9Ni) alloys are used for moderately low-temperature services, in the range of –50°F to –320°F (–46°C to –195°C). They are commonly used in liquified petroleum gas and liquified natural gas plants. (See ASTM A203, A333, A334, A350, A352, and A420 for various product forms of these materials.) Type 304L SS, while more costly, may result in a lower fabricated cost by avoiding welding problems.

Various enhanced strength plate steels are used in pressure vessels for high-pressure applications. Conventional carbon steels would require excessive wall thickness. Most enhanced steels also have increased low-temperature toughness. Postweld heat treatment is usually mandatory for these materials. Plate materials of this class include A302 (Mn-Mo and Mn-Mo-Ni steels), A517 (high-strength, low-alloy steels, quenched and tempered), A537 (Mn-Si steels; depending on section thickness, some grades can be qualified by impact testing at temperatures of –90°F (–68°C) or colder), A542 (micro-alloyed Cr-Mo steels, quenched and tempered), and A543 (Cr-Ni-Mo steels, quenched and tempered).

Alloying steels for improved corrosion resistance in chemical and hydrocarbon plants is based on chromium and molybdenum additions. The lowest of these alloys, 1Cr-1/2Mo and 1-1/4Cr-1/2Mo, are often used above 800°F (425°C). Low-alloy Cr-Mo steels (with 5% or greater Cr) are resistant to high-temperature sulfidic corrosion. However, the Cr-Mo alloys find their most critical use in high-temperature, high-pressure hydrogen service. The most commonly used alloys are the 1-1/4Cr-1/2Mo, 2-1/4Cr-1Mo, and 3Cr-1Mo steels. 9Cr-1Mo is available as piping, but is not commonly used in pressure vessel construction. A vanadium-enhanced version of 9Cr-1Mo is used in heavy wall vessels intended for high-pressure, high-temperature hydrogen service. All Cr-Mo alloys are air-hardenable and usually require PWHT. (See ASTM A182, A199, A217, A335, A336, A387, A541, and A739).

Weathering steels, many often classified as HSLA steels, are a common class of low-alloy steels employed for corrosion resistance. They commonly have small chromium and copper additions to form a stable patina-type rust in mildly corrosive atmospheres. These steels are used primarily in structural applications. (See ASTM A242, A588, and A618 for various product forms.)

21.2.6.4 Stainless Steel

21.2.6.4.1 Straight Chromium Stainless Steels

The 12Cr stainless steels are the least expensive and most commonly used alloys in this class. They are available in both ferritic and martensitic microstructures. Type 405 SS and Type 410S (ferritic) and Type 410 SS (martensitic) are corrosion resistance, particularly in wet CO_2 and in hot (T > 500°F [260°C]) services containing organic sulfur compounds or hydrogen sulfide. Type 410 SS, because it is martensitic, is used only when welding is not required. For welding, either Type 405 SS or Type 410S SS is specified. All 400-series stainless steels often grain coarsen in welds, causing relatively high brittle-ductile transition temperatures. Martensitic grades, being air-hardenable, often produce very brittle HAZs. Consequently, straight chromium stainless steels are usually not recommended for pressure containment utilizing welded construction. Their major use is in heat exchanger tubing, valve and pump internals, vessel internals, and as clad or weld overlayed linings in pressure vessels and heat exchangers.

Four hundred-series alloys are resistant to chloride stress corrosion cracking, but not chloride pitting. Accordingly, they are rarely used in aqueous chloride services. However, "superferritic"

stainless steels, containing up to 29% chromium and 4% molybdenum, are now available. Some contain up to about 4% nickel without affecting their ferritic microstructure. One example is 25Cr-4Ni-4Mo (UNS S44635). They have satisfactory resistance to chloride pitting and chloride stress corrosion cracking except for the most severe services. Utilization of the superferritic alloys is restricted because they form embrittling phases while being cooled after annealing. This tendency limits useful thickness to about 0.2 in. (5 mm). Stabilized superferritic alloys, resistant to sensitization, are also available, for example, 26Cr-3Ni-3Mo, stabilized with niobium and titanium (UNS S44660).

The higher chromium grades such as Type 430 SS are susceptible to "885°F (475°C) embrittlement" at temperatures above ~750°F (400°C). Such embrittlement is usually mild in the straight 12Cr grades but may be severe in grades with 15% or more chromium. Straight chromium stainless steels are usually avoided for pressure containment above 650°F (345°C). The higher chromium grades should not be used above 650°F (345°C) unless subsequent embrittlement is of no concern. In addition, all ferritic and martensitic stainless steels are susceptible to hydrogen stress cracking phenomena, hydrogen embrittlement, and low-temperature embrittlement. If sensitized, these steels are susceptible to intergranular corrosion.

21.2.6.4.2 Austenitic Stainless Steel

Austenitic stainless steels including the 200-series austenitic Cr-Mn-Ni stainless steels (exemplified by Types 201, 202, and 216) are generally as corrosion resistant and stronger than their 300-series Cr-Ni cousins. These alloys are uncommon in chemical or hydrocarbon plants. As a consequence, the term "austenitic stainless steel" has come to mean the 300-series Cr-Ni alloys such as Type 304 SS. Sometimes called the "18-8s" (representing a nominal 18Cr-8Ni composition), the 300-series austenitic stainless steels are the workhorses for corrosion resistance in industry. Figure 21.8 shows a typical austenitic stainless steel microstructure. The 300-series finds extensive use as internals, cladding, and overlays in vessels exposed to corrosive services. They are also widely used in pumps, valves, and piping. Most are available in both wrought and cast forms.

FIGURE 21.8 Solution annealed austenitic stainless steel. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

The austenitic stainless steels do not require PWHT as a hardness control measure. They are sometimes stress relieved or postweld heat treated to reduce residual stresses, thereby improving their resistance to stress corrosion cracking. The austenitic stainless steels are sometimes chosen in preference to the Cr-Mo low-alloy steels because PWHT can be avoided (the fusion zones of welds of the Cr-Mo low-alloy steels may be air hardenable).

The workhorse alloy of the 300-series is Type 304 SS, while the workhorse casting alloy is CF-8M. The low-carbon grades (Type 304L for the wrought alloy, CF-3M for the cast alloy) are preferred for welded construction. The low-carbon grades (as well as the stabilized grades such as Types 321 SS and 347 SS) are also preferred if sensitization is a problem. Type 316 SS (its small molybdenum addition differentiates it from Type 304 SS) is specified when chloride pitting or crevice corrosion is a problem. Type 316 SS also has a higher maximum allowable stress. The high-carbon H grades such as Type 304H SS are specified for high-temperature use (T > 1000°F [540°C]), since they have an allowable stress advantage over the conventional grades. The H grades should be used with caution if service-induced carburization may be a problem.

Higher chromium-nickel austenitic alloys are used extensively in high-temperature applications such as heaters, in both cast and wrought form. Examples include Type 310 stainless steel (25Cr-20Ni), a cast analogue called HK-40 (25Cr-20Ni) (UNS J94204), the Alloy 800-series (20Cr-32Ni, with Ti and Al) (UNS N08800, N08810, and N08811), and proprietary alloys such as the "HP-Mod" materials. These alloys can have problems such as weldment cracking, embrittlement, carburization, nitriding, oxidation, and metal dusting. (These phenomena are discussed in Section 21.4.) Industry experience or consultation with alloy specialists is recommended before material selection.

Galling is sometimes a problem with austenitic stainless steels; lubricants such as molybdenum bisulfide and graphite, and coatings are sometimes employed. The problem is also avoided by using two mating surfaces with a hardness difference of at least 50 BHN. With components such as valve closures, the hardness differential is usually obtained by using a hard face weld overlay or electroless nickel plating on one of the two components. In threaded connectors, the differential is usually obtained from cold working one of the components. Sometimes the hardness differential is obtained by specifying two materials having appropriately different hardnesses. Some users have employed electroplated or vapor-diffused aluminum on fasteners (preferably on the male component). Galling may also be mitigated by specifying one component to be a free machining grade such as Type 303 SS. Free machining materials are, however, sensitive to stress cracking problems. For example, NACE MR0175 [2] does not allow free machining grades in wet sour service.

Wrought austenitic stainless steels are more susceptible to chloride stress corrosion cracking than are the cast austenitic alloys. Accordingly, cast austenitic stainless steel valve bodies and pump casings are often useful in services in which higher alloys are necessary for the wrought components (pipe, tubing, fittings, plate, etc.). Ferritic stainless steels such as Type 410 SS are also subject to chloride pitting. Superferritic grades are an alternative to the plain ferritic grades if the component can be fabricated in thin sections, such as for heat exchanger tubing; for neutral or near-neutral pH applications, high-nickel stainless steels such as Alloy 20 Cb-3 (20Cr-35Ni-2.5Mo-Cb) (UNS N08020) have elevated chloride stress corrosion cracking threshold temperatures.

Alloys resistant to chloride stress corrosion cracking include: (1) "superaustenitic" alloys with high chromium and nickel content, as well as 2% to 6% molybdenum; Alloy AL-6XN (21Cr-25Ni-6.5Mo-N) (UNS N08367) is an example of a superaustenitic stainless steel; (2) nickel-chromium alloys such as Alloy 825 (22Cr-42Ni-3Mo, Ti stabilized) (UNS N08825), with nickel contents of approximately 40% or more; (3) duplex austenitic-ferritic alloys such as Alloy 2205 (22Cr-5Ni-3Mo-N) (UNS S31803); and (4) Ni-Cu alloys such as Alloy 400 (67Ni-30Cu) (UNS N04400).

Unless heavily cold worked, the austenitic stainless steels are resistant to hydrogen stress cracking such as that caused by hydrogen sulfide. They are also resistant to hydrogen embrittlement caused by phenomena other than cathodic charging. If sensitized, austenitic stainless steels can also be susceptible to intergranular corrosion.

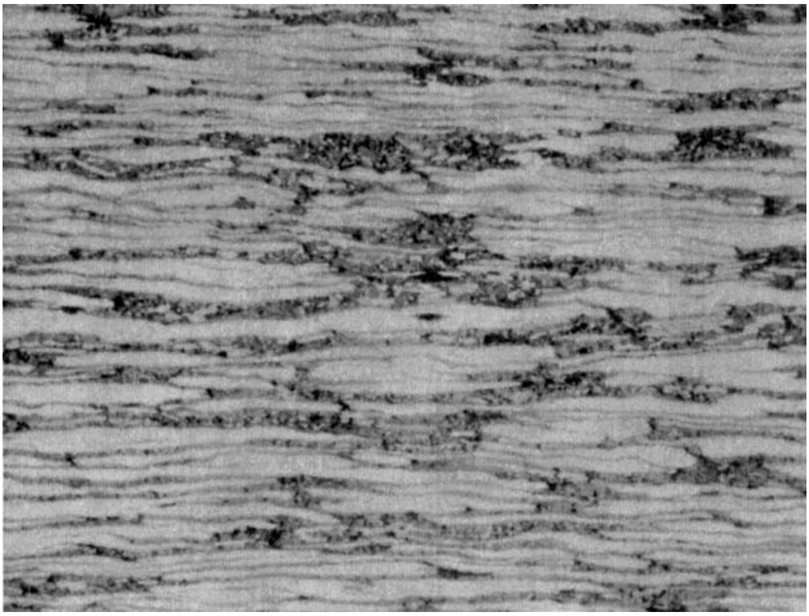

FIGURE 21.9 Duplex stainless steel (plate). © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

Cast austenitic alloys are usually more resistant to high-temperature corrosion than are their wrought equivalents. The cast alloys usually have a small, but significant, ferrite content, and they differ from their wrought equivalents as follows: (1) they are more susceptible to corrosion in acidic services; (2) they are more susceptible to sigma phase embrittlement; and (3) they are usually slightly magnetic, while the wrought alloys are nonmagnetic unless severely cold worked.

21.2.6.4.3 Duplex Stainless Steel

Duplex stainless steels contain both ferrite and austenite in approximately equal amounts; Alloy 2205 is an example. Figure 21.9 illustrates the microstructure of a duplex stainless steel microstructure in plate material. Typically, the duplex stainless steels contain 17 wt% or more chromium and <7% nickel. The more corrosion-resistant types contain at least *2%* molybdenum. They are much stronger than the austenitic stainless steels, permitting a thinner section thickness. Thus, while they may cost more per pound, they may cost less per piece.

With the desired microstructure, these alloys are resistant to hydrogen stress cracking and much more resistant to chloride stress corrosion cracking than are the austenitic stainless steels. (The threshold temperature for chloride stress corrosion cracking of duplex alloys in neutral pH aqueous chlorides is about 300°F [150°C].) The chloride stress corrosion cracking resistance of the duplex alloys is similar to that of superaustenitic alloys such as Alloy AL-6XN. Because they contain about 50% ferrite, the duplex stainless steels are more susceptible to hydrogen embrittlement.

Welds of duplex stainless steels can become susceptible to chloride stress corrosion cracking and/or to hydrogen stress cracking. Welding and manufacturing of duplex stainless steel are usually more costly than those with conventional austenitic stainless steels. Because the duplex stainless steels can be embrittled by high temperature service, they are not recommended for operating temperatures greater than 650°F (345°C). The national engineering codes do not provide for design temperatures exceeding 600°F (315°C).

21.2.6.4.4 Precipitation Hardening Stainless Steel

Precipitation hardening stainless steels are those alloys ending with the suffix "PH" (i.e., precipitation hardening), for example, 17-4 PH (17Cr-4Ni-4Cu) (UNS S17400). They are hardenable by heat treatment. They are most often used for springs, valve stems, the internals of rotating equipment,

and other applications where both high strength and superior corrosion resistance are desirable. Their corrosion resistance is superior to the 12Cr stainless steels but is somewhat inferior to Type 304 SS. They can be susceptible to both chloride stress corrosion cracking and hydrogen stress cracking.

Further information on stainless steels is available from the trade organization:

21.2.6.5.2 Copper Alloys

Copper alloys, including brasses and bronzes, find extensive use in heat transfer systems exposed to corrosive waters (primarily brackish or saline waters). Naval brasses such as UNS C46400, usually as a cladding on carbon steel, are used for tubesheets and plate components. Inhibited admiralty alloys such as UNS C44300 and the 70/30 (UNS C71500) and 90/10 (UNS C70600) Cu/Ni alloys are often used for piping and heat exchanger tubes. The Cu/Ni alloys are usually preferred, as they have better impingement resistance and can tolerate higher velocities. Aluminum bronzes such as UNS C60800 are relatively high-strength alloys used for pump and valve components. The upper temperature permitted by most engineering codes for copper alloys 400°F (205°C). A few alloys with higher allowable temperatures include aluminum bronzes and Cu/Ni alloys.

Most copper alloys are unsuitable with ammonia, sometimes in even trace amounts and for wet sour services. Most are corroded by caustics. Some brass alloys contain zinc in excess of 15%. Unless properly "inhibited" by arsenic, antimony, or phosphorus, such alloys can "dezincify" in brackish or saline waters. To evaluate copper alloys, contact an alloy specialist or the copper alloy trade organization:

Copper Development Association

21.2.6.5.3 Cobalt Alloys

Cobalt alloys are used for hardfacing to improve the resistance to abrasion, galling, and/or impact; Stellite 6* (60Co-29Cr-5W) (UNS R30006) is an example. Most alloys are in closure

* Registered trademark of Deloro Stellite Group, Goshen, Indiana.

applications such as valve seats, where both galling resistance and leak tightness are required, and in abrasive services such as mixers and nozzles. Grinding, which requires wear resistance, is also a common use. Cobalt hardface alloys are typically as corrosion resistant as the 300-series stainless steels and contain 30 to 60 wt% cobalt, typically with additions of carbon, nickel, chromium, tungsten, and/or molybdenum. They are applied, usually in one or two layers, by welding or thermal spray processes. The harder, more wear resistant alloys are difficult to apply and often develop cracks (called "crazing" or "check" cracks) in the overlay. Applied hardnesses are typically in the range of 20 to 50 HRC. Some alloys can be further hardened by cold work. Hardface alloys can be applied to almost any metallic substrate, with thicknesses of 1/16 to 1/4 in. (1.5 to 6.4 mm).

Cobalt-based alloys, in both wrought and cast forms, have also been developed for high-temperature applications such as gas turbine components, furnaces, and kilns. Alloy 25 (55Co-20Cr-10Ni-15W) (UNS R30605) is an example. Manufacturers are usually consulted in selecting these alloys.

21.2.6.5.4 Reactive and Refractory Metals

Reactive and refractory metals plus their derivative alloys are oxide-stabilized and can become reactive if the oxide layer is disrupted. These metals and their alloys often display both active and passive behavior. The definition of a refractory metal is somewhat arbitrary, and refractory metals are defined here as having melting points greater than that of iron (2795°F [1535°C]). Those of most interest (titanium, zirconium, and tantalum) are all sensitive to hydriding. Galvanic cells that promote hydriding can be particularly damaging. Zirconium and tantalum find applications in severe services such as hot concentrated inorganic acid processes. Most of these metals are relatively resistant to corrosion attack in aqueous oxidizing environments. However, each is subject to attack by specific corrodents and/or crack-inducing agents. All are, however, subject to catastrophic oxidation in certain environments. Selection should be on the basis of successful prior experience or a testing program.

21.2.6.5.5 Aluminum

Aluminum is a reactive (but not a refractory) metal having a melting point of 1221°F (660°C). Aluminum alloys are available in many variations, emphasizing properties such as strength, fatigue resistance, toughness, and enhanced corrosion resistance. Some aluminum alloys are hardenable (i.e., strengthened) by heat treatment. The mechanical properties and, to a large extent, the corrosion resistance are determined by their heat treatment. Aluminum and most of its alloys have excellent low-temperature toughness, permitting cryogenic applications such as liquified natural gas and liquified air. However, they lose strength rapidly with increasing temperature. The upper temperature limit is 400°F (205°C).

Many low- to moderate-strength aluminum alloys (primarily in the 1000-, 3000-, 5000- and 6000-series) have useful corrosion resistance. They are used in mildly corrosive atmospheres (such as those offshore or at seacoasts and for cable trays and fins on air cooler tubes). Several 5000-series alloys are moderately resistant to chloride pitting and find applications in clean seawater and other aqueous chloride services. They are very resistant to corrosion by wet CO_2 and are compatible with organics such as acetic acid.

Aluminum and alloys are not suitable for (1) alkalis, (2) acids at pH 4.5, and (3) mercury, which can be a significant risk in some liquified natural gas operations. The heat treatable, high-strength aluminum alloys of the 2000- and 7000-series are rarely used because of environmental cracking susceptibility. Aluminum and its alloys are susceptible to chloride pitting and to concentration cell problems such as crevice corrosion and under-deposit corrosion.

Due to its galvanic activity (aluminum is anodic to most common metals), aluminum is often used as a sacrificial anode and hence it corrodes preferentially to protect less active metals such as carbon steels. For evaluating aluminum alloys, contact:

www.aluminum.org

21.2.6.5.6 Chromium

Chromium is a refractory metal having a melting point of 3375°F (1857°C). Neither chromium metal nor chromium-based alloys are widely in the hydrocarbon or chemical industries. Chromium plating is useful for aesthetic purposes, and "hard" chromium plating finds some use in hardface applications. It is extensively used as an alloy addition to low-alloy steels (usually for the purpose of stabilizing carbides) and in cast irons (to produce wear-resistant products) and nickel alloys (for increased corrosion resistance). Chromium is the main alloying addition in the 400-series stainless steels and is used extensively in the 200- and 300-series stainless steels.

21.2.6.5.7 Titanium

Titanium is a reactive refractory metal with a melting point of 3034°F (1668°C). It and its alloys find heat transfer applications in hydrocarbon and chemical process industries. It is resistant to both organic and inorganic corrodents; it is employed in heat exchanger tubing for corrosive processes on one side and corrosive cooling water such as seawater on the other side; it finds use for wet chlorine and for concentrated hot caustic solutions. It can be useful in mildly reducing applications, such as wet alkaline sour overhead condensing systems. However, titanium (and the other reactive and refractory metals) are generally unstable in strongly reducing environments. It can also become unstable in the presence of powerful oxidizers including dry chlorine, red fuming nitric acid, and liquid oxygen. Titanium is embrittled by the formation of hydrides.

Only three titanium alloys are commonly used in the chemical industries, grades 2, 7, and 12. Grade 2 is pure titanium, while grade 7 has a small Pd (palladium) addition. Grade 12 has small molybdenum and nickel additions and has a corrosion resistance between that of grades 2 and 7. Grade 7 alloy is intended for most severe services, and is especially useful in hot, low pH, chlorine-saturated brines. Grade 12 is useful to about 500°F (260°C) for pH <4, and grade 7 is resistant to such corrosion at temperatures of at least 500°F (260°C). Titanium alloys lose strength rapidly with increasing temperature. The upper temperature limit permitted by the common engineering codes 600°F (315°C). Titanium alloys are available in most, if not all, product forms.

21.2.6.5.8 Zirconium

Zirconium, having a melting point of 3365°F (1852°C), is a reactive refractory metal, but it and its alloys are relatively difficult to fabricate. Welded construction should be heat treated at 1425°F (775°C) and cooled rapidly to achieve the best corrosion resistance. These materials, although expensive, can be very useful in severe applications, such as hot concentrated alkalies and inorganic acids. They are favored in high-temperature processes for the production of urea, hydrogen peroxide, many organic acids, including formic and acetic acids, etc., and for high-temperature organic processes utilizing hydrogen chloride. It is one of the better metals for hydrochloric acid and sulfuric acid, being resistant up to 70% at the boiling point and up to 75% at 265°F (130°C). Stress corrosion cracking sometimes occurs in 64% to 69% sulfuric acid at elevated temperatures. An advantage of zirconium over nickel alloys is that it can handle these acids when oxygen or other oxidants are present. It is not suitable, however, for hydrofluoric acid. Corrosion of zirconium sometimes produces compounds that are pyrophoric; the corrosive products can ignite when equipment is taken out of service. Zirconium is resistant to oxidizing acids such as nitric acid. Its corrosion rate is less than 5 mpy* (0.1 mm/yr) in zero to 70% acid at temperatures up to 500°F (260°C). However, it is susceptible to stress corrosion cracking in concentrations exceeding 70%.

* mpy = mils per year, where a mil is 0.001.

Zirconium has greater resistance to caustics than tantalum. Because of its expense, zirconium is used only if no other metals or alloys are suitable. Utilization of zirconium and its alloys is generally confined to clad plate and to thin-wall applications, such as heat exchanger tubing or sheets used for "strip lining" or "wall papering." Zirconium alloys lose strength rapidly with increasing temperature. The upper temperature limit is 700°F (370°C).

21.2.6.5.9 Tantulum

Tantulum is the most expensive refractory metal used for corrosion resistance; it has a melting point of 5425°F (2996°C). Its resistance is often compared to that of glass, except that it tolerates higher temperatures. It is however attacked by hydrofluoric acid, caustics, oleum, sulfur trioxide, and chlorosulfonic acid. Tantalum is susceptible to catastrophic oxidation by air, dry oxygen, or chlorine gases. Because it is expensive, tantalum is used mainly in thin-section applications such as bayonet heaters, heating coils, plate heaters, or sheets used for strip lining or wall papering. Typical applications include heaters and condensers for organic acid recovery, ammonium chloride concentrators, hydrochloric acid absorbers, bromine condensers, and ferric chloride heaters.

21.3 CORROSION

Corrosion causes many plant problems. An understanding of electro-chemical principles is necessary in order to choose the best mitigation measures such as barrier coatings, inhibitors, and cathodic protection. Reference [11] provides further information.

21.3.1 Corrosion Basics

The three simultaneously necessary conditions for electrolytic corrosion to occur are (1) an electrolyte, which is usually water containing dissolved salts; (2) a corrosion cell is composed of an *anode,* the area being corroded (i.e., oxidized), and a *cathode,* the area where electrons enter the electrolyte; and (3) the anode and cathode are connected by an electronically conductive (i.e., metallic) path. Figure 21.10 illustrates corrosion of iron exposed to wet CO_2 (carbonic acid).

Electrons provided by the iron at the anode flow through the metal to the cathode. Simultaneously, protons (hydrogen ions, H^+) generated at the anode diffuse through the electrolyte to the cathode. At the cathode, the protons combine with electrons flowing from the anode to generate hydrogen gas. The anode is an *electron donor* while the cathode is an *electron acceptor.* The two sites differ (e.g., grain orientation, degree of cold work, state of stress, composition, etc.). The differences can be transient, leading to situations in which a site alternates between being an anode and a cathode. (Cyclic stresses can cause this behavior.)

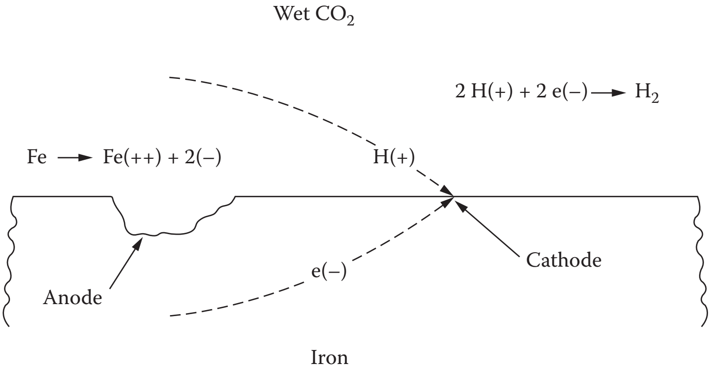

FIGURE 21.10 The essential features of an electrolytic corrosion cell. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

Thermodynamically, an anode has a higher Gibbs free energy. For example, both cold work and residual tensile stresses increase the local free energy in metals and alloys. For two dissimilar metals, the different inherent corrosion resistances of the two metals translate into one having a greater Gibbs free energy. Because of the induced current and in accordance with Ohm's law,* corrosion rates become a function of current flow and electrical resistance.

21.3.1.1 Cathodes

In hot-formed carbon steel, the cathode is often the area covered by mill scale (Fe_3O_4), while the anode sites are cracks in the mill scale.

The cathode area is sometimes the noncold-worked area in a component that has been partially cold worked, for example, the straight-run tubing in a U-bend heat exchanger bundle.

In heat exchangers, pumps, and vessels, the internals are often the more corrosion-resistant alloys as compared with the material of the pressure retaining component. Thus, the internals are cathodic with respect to the pressure retaining component and the pressure retaining component is in effect a galvanic anode.

21.3.1.2 Anodes

The anode area may be the metal under a deposit on an otherwise clean surface.

For crevices such as in those in socket welds, the metal in the crevice is likely to be anodic. Crevice corrosion and under-deposit corrosion can be serious problems in oxide-stabilized materials such as aluminum and the stainless steels. Crevices and deposits can also accelerate corrosion in metals (such as carbon steel) that do not exhibit both active and passive states. However, the rate of corrosion is much slower in such materials because they lack the galvanic driving force of the active-passive states characteristic of the oxide-stabilized metals and alloys. The anode areas in crevices and under deposits are typically smaller than the cathode areas. This difference accelerates the corrosion rate.

The welding-induced sensitized area in a stainless steel is usually anodic.

21.3.2 Corrosion Control

The rate of corrosion at the anode is directly proportional to the anode current density (expressed as amps per unit area). This knowledge aids in developing methods to control or eliminate corrosion.

21.3.2.1 Barrier Coatings

Barrier coatings prevent or reduce current flow between the corrodent and the metal surface.

21.3.2.1.1 Inhibitors

Inhibitors act to control corrosion, particularly in piping systems. They form a very thin (perhaps monomolecular) adsorbed layer that acts as a barrier. Film-forming amines are a common example. Because inhibitors may locally de-adsorb, they are usually continuously injected. For large-diameter pipelines, batch inhibition may be necessary. Inhibition is usually not permitted in processes for high-purity products.

Chemical inhibition is usually not effective in applications involving turbulent flow (such as pumps and control valves) or in systems having deposits that prevent the inhibitor from contacting the metal surface to be protected. In most pipeline systems using inhibitors, regular cleaning by "pigging" is used. It is performed using pipeline pressure to push a mechanical cleaning device through the pipeline.

* $V = IR$, where V is the electrical potential (in volts), I is the current (in amperes), and R is the resistance (in ohms).

21.3.2.1.2 Coatings and Linings

Coatings and linings that are dielectric are electrical insulators. In immersion services, large anode current densities can occur if the coating has "holidays."* Holidays act as very small anode areas. With thick linings, pinholing is not regarded as a problem since most are usually quickly plugged with corrosion products. The subsequent slow corrosion rate is controlled by diffusion and polarization. However, thin-film coatings, such as most paints, do have a fairly high risk of either initial or age-induced holidays resulting in locally high corrosion rates. Thin-film coatings should not be used in most immersion services without a cathodic protection system. In such situations, coating the anode without controlling the cathode can lead to unfavorable anode/cathode area ratios, e.g., coating the carbon steel channel/channel cover in a seawater heat exchanger having a more noble aluminum bronze tubesheet. In such a case, any holiday in the anode coating could result in an enormous anode current density. Two good mitigation responses for this example are as follows: (1) Coat the tubesheet as well as the channel/channel cover, using sacrificial anodes to handle holiday problems. (2) Coat only the tubesheet (cathode), without requiring the use of supplemental cathodic protection.

Galvanically noble metal coatings such as electroless nickel or chromium plating are often used as barrier coats on carbon steel. The coatings are cathodic, making any pinhole an anode, with a very large cathode/anode area ratio. The current densities at such anodes can be enormous: rapid pitting results. Such coatings, being galvanically noble, generate a large electrical potential between the anode and the cathode. For high-conductivity fluids such as seawater, resistivity is small. Ohm's law indicates why such couples have increased current densities.

The galvanic series in seawater is often used to estimate the risk of galvanic corrosion in other media, for which the series may not be available. The risk of galvanic corrosion depends as much on the corrosivity and conductivity of the medium as on the separation of the two metals in the galvanic series. Fresh waters generally have neither the corrosivity nor the conductivity to support galvanic activity.

In rare cases, a relatively small area near the weld will be an anode to the relatively large cathodic surface area of the parent metal. In moderately corrosive media, this zone may corrode much faster than either the weld metal or the parent metal. Postweld heat treatment is usually helpful. In some instances, normalizing (or even solution annealing in the case of an austenitic stainless steel) the weldment is necessary, a measure that can cause significant distortion problems. In most cases, the weld metal, HAZ, and parent metal do not have significant galvanic differences.

21.3.2.1.3 Cathodic Protection

Cathodic protection converts the surface to be protected into a cathode in one of the following two ways: (1) It is electronically and electrolytically connected to an inert material such as graphite or silicon iron. A power supply imposes a voltage that makes the inert material an anode, i.e., an electron donor. Such an *impressed current* cathodic protection system is frequently used for buried pipelines and submerged structures, and in plants to provide external cathodic protection to tank bottoms, buried piping runs, etc. (2) It is electronically and electrolytically connected to a more reactive material. For example, iron can be protected by connecting it to a less noble material (for example, zinc or aluminum) that acts as a *sacrificial anode.* Galvanized carbon steel is a common example of this application. Sacrificial anodes provide cathodic protection to offshore structures and pipelines. In plants, they are used for short, buried piping runs and for internal cathodic protection of tanks and vessels.

21.3.2.1.4 Anodic Protection

Anodic protection uses an impressed current to protect oxide stabilized metals and alloys, such as stainless steel or titanium, that can exist in both active and passive states. A power supply, an inert

* In the paints and coatings industry, "holidays" is the name sometimes used for pinholes.

impressed current electrode, and a potentiostat provide a potential that keeps the material in the passive state. The most common application is for stainless steel tanks in strong mineral acids and for coolers in sulfuric acid plants. The technique should only be used with expert advice. A similar application, without an impressed current system, involves spreading the cathode current over a large anode area. This minimizes the cathode area and thus minimizes the total cathode current available for corrosion on a carbon steel tank. It has been shown that turning the entire tank bottom (uncoated) into an anode, by abrasive blasting, reduces local pitting rates.

21.3.2.1.5 Passivation

Passivation consists of exposing a clean metal surface to an oxidizing environment to form an oxide film. This surface is much more corrosion resistant than it would be in an unpassivated state. In materials such as carbon steel, which form weak oxides, passivation can be destroyed rather easily. In oxide-stabilized alloys such as the stainless steels, this corrosion resistance is not easily destroyed.

Passivation is usually part of a chemical cleaning process using a sodium nitrite solution. (Chromates, once used extensively, are now considered to be too toxic.) Austenitic stainless steels are usually passivated in air after pickling and neutralization. *Pickling* is a chemical process to descale or clean new stainless steel. (See ASTM A380 for recommended procedures.) For heavily oxidized materials, the pickling process removes the chromium-depleted surface beneath the layer of scale. The acid solutions used contain sufficient nitric acid (a good oxidizer) so that a subsequent passivation step is unnecessary.

21.3.2.1.6 Polarization

Polarization occurs because of ion concentration buildup near the anode and/or cathode. Once the ion concentration reaches saturation, corrosion essentially stops. Polarization can occur when: (1) Hydrogen ions concentrate at an active cathode in the absence of a cathodic depolarizer. Dissolved oxygen acts as a cathodic depolarizer. (2) Metal ions saturate the electrolyte around an anode. (Soluble Fe^{++} may saturate the anode, perhaps as the result of the precipitation of an insoluble iron salt, inhibiting the diffusion of Fe^{++}. For example, insoluble surface compounds such as carbonate scales in a fresh water often occur on carbon steel.)

Examples of polarization are: (1) In deaerated, but otherwise corrosive, water, hydrogen polarization all but shuts down the corrosion mechanism. For example, seawater deaerated to less than about 10 ppbw is noncorrosive to carbon steel. (2) Many waters form insoluble dense scales on the corroded surface. The scale acts as a barrier to the diffusion of new corrodent and dissolved oxygen to the substrate surface. Scaling tendencies and corrosivities of waters can be estimated by analysis [12]. Polarization is prevented by: (1) Ions such as sulfides and cyanides that are "cathode poisons." Instead of the hydrogen ions forming hydrogen gas, which acts to polarize the cathode, cathode/poisons promote the formation of nascent hydrogen atoms. This hydrogen then diffuses into the substrate material. In ferritic steels, the following may result: hydrogen embrittlement, hydrogen stress cracking, and various forms of hydrogen induced cracking, including blistering. (2) By fluid flow phenomena such as turbulent flow or particulate erosion. (3) Cathodic depolarizers; the most common is dissolved oxygen.

The selection of materials must also consider oxidation/reduction processes that occur in the absence of an aqueous electrolyte. Examples include sulfidation, destructive oxidation of alloys in air or steam at high temperatures, carburization, nitriding, fuel ash corrosion, and high-temperature hydrogen attack.

21.3.3 Stress Corrosion Cracking

Failures due to stress corrosion cracking, while not common, may occur without warning, with catastrophic consequences. This cracking occurs only if both of the following conditions occur simultaneously: (1) a susceptible material and (2) an appropriate combination of stress (*tensile stress is required*), temperature, crack-inducing agent, pH, aeration, etc. For example, chloride

stress corrosion cracking of austenitic stainless steels can be dependent on the presence of dissolved oxygen. Sometimes, stress corrosion cracking can be avoided by applying practical knowledge of the mechanism, for instance, keeping the temperature <140°F (60°C) for saline water in contact with an austenitic stainless steel.

There are at least three types of stress corrosion cracking: (1) hydrogen stress cracking (e.g., sulfide stress cracking); (2) anodic stress-cracking phenomena, such as alkaline stress cracking of carbon steels and chloride stress cracking of austenitic stainless steels; and (3) intergranular stress cracking (e.g., polythionic acid stress corrosion cracking). Cracking is usually associated with the residual stress fields of welds, although cracking can occur in cold-worked parent metal or metal subject to applied tensile stresses. Stress corrosion cracking depends on an electrolyte, usually liquid water containing the crack-inducing agent. Special metallurgical and fabrication requirements are customarily specified to prevent such cracking.

Hardness controls reduce the risk of *crack initiation. Crack propagation* risks are reduced by either increasing the fracture toughness of the material (usually by heat treatment) or by reducing stresses. The objective is to eliminate crack propagation or to ensure that it is slow and stable in order to obtain "leak-before-break" (i.e., failure is not catastrophic).

The following measures are recommended for hardness controls: (1) NACE RP0472 ("Methods and Controls to Prevent In-Service Cracking of Carbon Steel Welds in P-1 Materials in Corrosive Petroleum Refining Environments" [13]) limits the hardness of carbon steel weld metal to 200 BHN. Weld testing ensures that HAZ hardnesses do not exceed 248 VHN. Industry practice limits the hardness of weld metals for air-hardening Cr-Mo low-alloy steels as follows: for $1 < Cr < 3$, 225 BHN and for $3 < Cr < 9$, 241 BHN. Potential problems in welds may involve dissimilar metals and unusually different thicknesses at the weld joint. Tube-to-tubesheet welds and thin fillet welds used to attach tray support rings are examples. (2) Materials subject to hydrogen stress cracking mechanisms should also be required to meet the limitations of NACE MR0175 ("Sulfide Stress Cracking Resistant Metallic Materials for Oilfield Equipment" [2]).

Normalizing, sometimes in conjunction with tempering, increases the fracture toughness of carbon and some low-alloy steels. Other heat treatment methods such as quench and tempering may be used, e.g., for some Cr-Mo steels. NACE MR0175 [2] requires that most carbon and low-alloy steels in wet H_2S service have a toughness-enhancing heat treatment. Hot rolling is acceptable for carbon steel in wet H_2S service. Most carbon steel pipe is exempt from this requirement.

Postweld heat treatment (PWHT) is a stress reduction technique. It is widely used to avoid alkaline stress corrosion cracking in carbon steels and for enhancing fracture toughness in carbon and low-alloy steels. PWHT can also soften hard welds and HAZs, making them more resistant to crack initiation in services subject to hydrogen stress cracking. PWHT is often required based on some domestic recommended practices and foreign engineering codes for services known to be subject to stress corrosions.

Stress relief also reduces stress cracking in materials that have been cold worked. Common applications are for spun or pressed heads and for the U-bends in heat exchanger bundles.

Hardness control, normalizing, and PWHT and stress relief may be unnecessary if the combined stress in tension (applied) is less than the "10% rule." Examples of such applications are small tanks, atmospheric and low-pressure vessels, equipment and piping, and drains. Under such conditions, the residual stresses and/or untempered hardnesses of welds and/or HAZs may indeed initiate cracking and may even eventually produce through-thickness cracks. However, the combined stresses are too low to generate catastrophic cracking. Through-thickness cracks usually occur only after many years; risk-limiting measures are often not cost effective for such low-stress situations. If minimum capital cost is a project objective, the 10% rule may justify avoiding expenses such as those of hardness controls, PWHT and stress relief, and normalizing.

Four exceptions where risk-limiting measures may be justified include: (1) For new equipment subject to local laws that mandate conformance to an engineering recommended practice. (2) When through-thickness cracks, even though stable, would release a lethal, flammable, or corrosive

substance. (3) For thin-ligament pressure-containing components where leaks could develop quickly and would require unscheduled maintenance (e.g., tube-to-tubesheet welds). (4) In new equipment or piping where subsequent inspection and/or repairs after long-term service would be excessively expensive. For example, sites where congestion may make it difficult to mobilize the necessary repair equipment (e.g., cranes).

Shot peening, in which hard shot is impinged on a surface, produces surfaces that are in residual compression, thus making them resistant to stress corrosion cracking.

Cladding or *overlays* are sometimes applied to carbon and low-alloy steel to avoid stress corrosion cracking problems. For example, carbon steel clad with Type 304L SS is often used in severe amine services.

Paint coatings are occasionally used to minimize stress corrosion cracking. They are often provided for external stainless steel surfaces exposed to wet chlorides, marine atmospheres, or in services under wet insulation. For under-insulation surfaces, some users coat only the welded areas where chloride stress corrosion cracking usually occurs. Paint coatings are also sometimes used to minimize stress corrosion cracking in old equipment that may be exposed to a crack-inducing agent. Internal coatings in vessels and tanks are occasionally employed.

Crack-inducing agents generally require the presence of an electrolyte in order to be active. For example, H_2S cracks carbon steel only in the presence of water or other electrolytes. The most common electrolytic crack-inducing agents for carbon and low-alloy steels are aqueous solutions of amines, caustics such as caustic soda (NaOH), hydrogen sulfide, dilute sulfuric acid, hydrofluoric acid, and mixtures of carbon monoxide and carbon dioxide. The austenitic stainless steels are sensitive to chloride stress corrosion cracking, caustic stress corrosion cracking, and, at high temperatures, to intergranular stress cracking by liquid zinc. When sensitized, these materials often experience intergranular stress corrosion cracking by weak oxidizing acids such as polythionic acid. High-strength aluminum alloys can be susceptible to chloride stress corrosion cracking. Most copper alloys are rapidly cracked by liquid mercury.

A few crack-inducing agents do not require an electrolyte, e.g., the attack of copper alloys by ammonia. Accordingly, the template should include the information necessary to determine if a crack-inducing agent is either active or can become active.

21.3.4 Microbiologically Influenced Corrosion (MIC)

This corrosion is defined as the corrosion of materials caused by microorganisms. The combination of unexpected attack and rapid failure is sometimes a concern. Generally it occurs in stagnant water systems or the water legs of mixed-phase, quiescent process streams at ambient temperatures (but may occur at temperatures up to 200°F [93°C]). Most materials of construction are susceptible. A typical MIC problem is the pitting corrosion in the bottom of a pipeline, before commissioning, due to microbial activity in residual hydrotest water. Systems subject to stagnant operation, shut-downs, or velocities less than 2 ft/sec (0.6 m/sec) are at risk. In some media, such as seawater, colonization by microorganisms may occur at velocities up to about 5 ft/sec (1.5 m/sec). For stagnant water or quiescent water-wet systems, exposures exceeding 30 days often lead to severe MIC.

The microorganisms responsible for MIC are primarily bacteria and fungi. They may be anaerobes (which do not function in the presence of oxygen), or aerobes (which require oxygen), or a mixture of several microorganisms living in colonies. While strictly anaerobic environments are not common in nature, anaerobes can develop in even highly aerated systems. For example, anaerobic conditions can be established under the slime film formed by some aerobic microbes. Common organisms include sulfate-reducing bacteria, sulfur/sulfide-oxidizing bacteria, iron/manganese-oxidizing bacteria, aerobic slime formers, methane producers, and acid-producing bacteria and fungi. They usually form discrete biodeposits, either nodules or flat shiny deposits. An exception is when they exist in high concentrations in anaerobic soil environments, where they do not need to form either a film or a deposit to become active. Under such conditions, these organisms often cause corrosion.

There are four prerequisites for MIC: (1) The material of construction must be susceptible to MIC. (2) Microbes must be present in the environment. (3) The service temperature range must support microbial metabolism. It is often in a narrow temperature range (10°F to 20°F [5°C to 11°C]). However, different organisms can be active from below freezing to above 200°F (93°C). (4) The environment must supply the appropriate nutrients and provide the aerobic or anaerobic conditions required.

21.3.4.1 Effect on Materials of Construction

Carbon and low-alloy steels and *stainless steels* are the most commonly affected materials. The morphologies created by MIC attack seem to be related to the organisms involved. Pinhole openings under nodules, accompanied by extensive tunneling, may be typical of Gallionella bacteria on stainless steels, while shallow surface attack beneath nodules or open pits may be typical of sulfate-reducing bacteria on stainless and carbon steels.

Aluminum alloys can also be attacked by microorganisms. For example, there have been MIC problems with aluminum fuel tanks and transfer lines. In this case, microorganisms grow in the water layer under the fuel to produce volcano-shaped tubercles, frequently evolving gas. Pitting occurs under the tubercles. MIC attack on *copper alloys* is usually insignificant. However, corrosion of copper condenser tubes by microbially produced ammonia has been reported. In addition, sulfuric acid has been produced by microbial activity by corrosion of underground copper pipes.

21.3.4.2 Mitigation Methods

To prevent microbiological activity, avoid the development of stagnant or quiescent water legs. Use of barrier materials, biocide treatments, or using materials resistant to damage by MIC is also often effective. Once a MIC problem develops, cleaning and chemical treatment are necessary. Cleaning disrupts the colonies protected by their biofilms or by occlusion due to corrosion products such as tubercles. Mechanical cleaning employs brushes, pigs, sponge balls, water, or gas jets. Backwashing or flow jogging is also used. Acid cleaning, sometimes incorporating surfactants and/or dispersants, is usually an effective cleaning method (and can be an effective biocide treatment as well). Other chemical treatment options include biocides and biostatic inhibitors.

21.4 FAILURE MODES

Materials degradation, including electrolytic corrosion, high-temperature corrosion, and stress corrosion cracking, must be considered when selecting materials of construction in order to achieve the desired design. In addition, embrittlement by high- and low-temperature phenomena, as well as by various chemicals, must be properly addressed. Engineering codes often provide little guidance. In this section, the most common degradation phenomena and methods of mitigation are discussed.

21.4.1 Embrittlement Phenomena

The following terms are employed relative to embrittlement.

Brittleness is the opposite of toughness. A "brittle" crack propagates with little or no macroscopic plastic deformation. Crack propagation requires very little energy and is rapid, usually resulting in rupture. Engineering codes contain rules to avoid brittle fractures.

Ductile crack propagation is accompanied by gross plastic deformation. Such propagation absorbs significant energy and is typically very slow. Fast ductile fractures do occur, in a ductile material, when the remaining ligament is too small to support the gross load; they usually exhibit gross tearing. Brittle fractures can be virtually eliminated by materials that are qualified in accordance with construction code requirements and by avoiding or accommodating service-induced

embrittlement. In practice, most fractures involve ductile crack propagation due to plastic instability occurring in pressure-containing components that have been thinned by corrosion or erosion.

Risk of fracture differs from brittleness. A brittle material will not fracture as long as the applied stress is below the crack propagation threshold. In practice, brittle materials such as gray cast iron and glass can be used safely if the applied stresses are kept small so that inherent flaws in the material do not propagate into unstable cracks (i.e., brittle fracture). In ductile materials, the risk of fracture usually depends on the thickness in a locally thinned area. Evaluating the risk of fracture involves employing *fitness-for-service* or *remaining life assessment* techniques. In some localities, such analysis is a regulatory requirement. A conservative rule-of-thumb is to require further evaluation only if the corrosion allowance has been consumed. A less conservative criterion is to evaluate if the remaining minimum thickness is insufficient to limit the pressure hoop stress* to the specified minimum yield strength of the pressure-containing material. For simple cylindrical geometries such as vessel shells and piping, the pressure hoop stress can be adequately estimated by the "Barlow formula":

$$\text{Stress (sigma)} = \frac{(P)(r)}{t} \tag{21.2.}$$

where P is pressure, r is the internal radius, and t is the remaining thickness.

Fracture-safe design is when there is little likelihood of a serious accident even if a through-thickness crack occurs. For each metal and alloy, there is a combination of critical crack size, stress intensity, and thickness above which cracks will no longer propagate in a ductile manner. Brittle fractures of this type are rarely encountered in low- to medium-strength carbon and low-alloy steels; they typically have tensile strengths of 70 ksi (480 MPa). As a result, fracture mechanics is not commonly used in most plant designs, except in the chemical and hydrocarbon industries for high-pressure processes in which relatively high-strength materials of construction are employed. The ASME Boiler and Pressure Vessel Code, Section VIII, Div. 3 [1], is used in such cases.

Leak-before-break is a common application of fracture-safe design, used to ensure that a pressure-retaining system will leak before breaking. This design procedure utilizes fracture mechanics to ensure that the applied stress is insufficient to cause a through-thickness crack to propagate in a brittle manner. Propagation of a through-thickness crack will be ductile. The crack will start leaking before there is a break. The 10% rule is one application of leak-before-break; it involves piping and equipment in relatively low-pressure services. For carbon and low- to medium-strength low-alloy steels, brittle fracture will not occur if the combined stress in tension is less than about 10% of the material's tensile strength. (This will hereafter be referred to as the "10% rule"). For carbon and low-alloy steel equipment, in compliance with the 10% rule, leak-before-break will prevail. This principle has been incorporated into many engineering codes. While low-stress conditions do not permit brittle fracture, stable crack propagation by other mechanisms such as stress corrosion cracking can still be active.

Embrittlement refers to a loss of ductility and fracture toughness. Embrittlement causes crack growth to change from ductile to brittle. In most cases, brittle or embrittled materials have a threshold temperature range above which they respond to crack propagation stresses in a ductile manner. Cracking below the threshold temperature is at least partially brittle. Such cracking is often catastrophic. Cracking above the threshold temperature is by a ductile mechanism. Embrittlement examples include: (1) The term "embrittlement" is applied to the ambient temperature brittleness of an alloy that has become embrittled by high-temperature service. (2) Process fluids can embrittle an otherwise ductile material. Hydrogen embrittlement is an example of this effect. (3) In carbon

* Pressure hoop stress is the circumferential tangential (tensile) stress on a cylinder as a result of internal pressure.

and low-alloy steels and in ferritic and martensitic stainless steels, the term sometimes refers to the brittleness that develops at temperatures below the brittle-ductile transition range.

21.4.2 Carbon and Low-Alloy Steel

Temper embrittlement occurs in 2-1/4Cr-1Mo and 3Cr-1Mo steels, often used for the pressure shells of heavy-walled reactors such as hydrotreaters. Temper embrittlement occurs at 700°F to 1100°F (370°C to 595°C); it is reversible by exposure to higher temperatures. In the 700°F to 1100°F (370°C to 595°C) range, elements such as tin, phosphorus, and arsenic segregate at the grain boundaries. Silicon and manganese also contribute to grain boundary embrittlement. While these (tramp) elements cannot be completely eliminated from the alloy, modern steel mills can control them, so that temper embrittlement of these alloys should not be a concern. Temper embrittlement does not affect high-temperature ductility at >250°F (120°C). Accordingly, components suspected to be temper embrittled can be safety operated if they are not pressurized at temperatures <250°F (120°C).

Creep embrittlement is a misnomer. It causes a loss of strength due mostly to a decrease in load-bearing capacity as gross cracks form. It can occur in 1Cr-1/2Mo and 1-1/4Cr-1/2Mo steels exposed to temperatures exceeding 850°F (455°C), usually within 8 to 15 years. The mechanism is unpredictable, since cracking occurs mainly in the HAZs of welds, usually at nozzles having sharp changes in cross section. This embrittlement is irreversible, and there is no consensus on how to prevent or control it. In low-stress applications, leak-before-break will govern. For higher stress applications, there are two choices: (1) Select the less expensive 1Cr-1/2Mo or 1-1/4Cr-1/2Mo material, with the risk of replacement or repair; the anticipated life is probably 15 to 20 years minimum. (2) Select 2-1/4Cr-1Mo, a more expensive alloy; however, this alloy is susceptible to temper embrittlement, as discussed above.

Strain aging occurs in many carbon and low-alloy steels. A cold-worked material ages at ambient or relatively low temperatures, developing anomalously high strength and hardness, but with reduced ductility. The rate of aging depends on the temperature. At ambient temperature, the effect may not be apparent for months, but when exceeding 400°F (205°C), aging may occur in minutes. Aluminum killed steels are quite resistant to strain aging. Such embrittlement is relatively rare, since materials that are deliberately cold-worked are usually stress relieved before being placed in service. Also, most modern carbon and low-alloy steels are aluminum killed. Typically, a limit of 5% cold work (defined in terms of outer fiber strain) is permitted without subsequent heat treatment. Because cold work is sometimes used to straighten or repair dented or bent structurals or equipment, there is a risk of such embrittlement.

Strain aging can also occur in susceptible steels by welding near a crack, causing embrittlement (called *dynamic strain aging*). For this and other reasons, many users require that plate material intended for pressure-containing components be scanned by ultrasonic inspection equipment for cracks and flaws near edges to be welded.

Hydrogen embrittlement can occur in carbon and low-alloy steels, in ferritic and martensitic stainless steels, and in duplex stainless steels. It is normally not a problem in either the austenitic stainless steels or nickel-based high alloys. Hydrogen can dissolve in a steel as a result of a number of phenomena: (1) Corrosion creates nascent hydrogen, usually in the presence of a cathodic poison. (2) High-temperature, high-pressure hydrogen. (3) Excessive cathodic protection or cathodic charging saturates a steel with nascent hydrogen. The most common example is due to an electroplating procedure in bolting. (4) Welding with moist consumables may also cause embrittlement in carbon and low-alloy steels.

At less than about 250°F (120°C), dissolved hydrogen sometimes results in a loss of ductility. Hydrogen embrittlement is reversible; dissolved hydrogen is driven from the material by a "bakeout" at high temperature, e.g., 600°F (315°C) for 4 hours. Bakeout is unnecessary if the component is allowed to "outgas" for a minimum of 7 days at ambient temperature. It is also temperature dependent, occurring from subambient to ~250°F (120°C). The maximum effect is in the range of

0 to 100°F (–18°C to 38°C). The risk rapidly diminishes >175°F (80°C). Hence, low-alloy steels such as the Cr-Mo steels are usually not pressurized, if in gaseous hydrogen service, until the operating temperature is brought up to 250°F (120°C). Ordinary low- to medium-strength steels (with tensile strengths of up to 70 ksi [480 MPa]) are moderately susceptible to this embrittlement. Between 70 and 90 ksi (480 and 620 MPa) tensile strength, steels are susceptible to it. Higher-strength steels (with tensile strengths in excess of about 90 ksi [620 MPa]) can be severely embrittled. Bolting is the most common product form in which hydrogen embrittlement is observed in plants, since they are often electroplated without a subsequent hydrogen bakeout (the electroplated material does not allow trapped dissolved hydrogen to escape by diffusing to a free surface).

For carbon and low-alloy steels, the relationship between susceptibility to hydrogen embrittlement and strength is very similar to that between susceptibility to hydrogen stress cracking and strength. This embrittlement often occurs in carbon steels, low-alloy steels, and ferritic or martensitic stainless steels subject to hydrogen stress cracking environments. The measures to minimize embrittlement are essentially the same as those to minimize the risk of stress corrosion cracking (hardness controls, control of microalloying additions, PWHT, etc.)

Hydrogen embrittlement is normally not a problem in most chemical plants, because the material strengths are too low to propagate cracks. Four situations should, however, be given special attention: (1) The rate and extent of hydrogen embrittlement are affected by the amount of residual cold work; hence, stress relieve components that have been cold worked. Five percent cold work is often used as the threshold. Designs should avoid sharp notches, as these can subsequently become cold worked. (2) Metals for high-temperature, high-pressure hydrogen service are often at risk, especially upon cooldown. Such components (usually Cr-Mo low-alloy steels) may be subject to brittle fracture if exposed to tensile or bending stresses during maintenance, revamp fabrication, etc. (3) Hard HAZs may be susceptible to both hydrogen embrittlement and hydrogen stress cracking. Welding and joint configurations are generally not susceptible to these phenomena. However, if a carbon steel parent metal has excessive microalloying, or if the weld cools too rapidly, excessive HAZ hardness can be created when a thin section is welded to a thick section, as in tube-to-tubesheet welds. Heat-affected zone hardnesses of 200 BHN or less are not likely to be affected by dissolved hydrogen. Similarly, hard spots susceptible to cracking can form at the fusion zone in dissimilar metal welds involving relatively high-carbon plain or low-alloy steels to stainless steels or Cr-Ni alloys. (4) *Delayed hydrogen cracking* (also called *underbead cracking* or *cold cracking*) is sometimes associated with hydrogen embrittlement; it is a form of hydrogen stress cracking. The problem occurs in freshly made welds, usually because of hydrogen generated during welding if a moist welding flux is used. However, such cracking can occur in repair welds because of hydrogen dissolved in the steel while in service. Cracking in repair welds is prevented by a bakeout. The delayed hydrogen cracking mechanism requires an incubation period before cracking occurs. Such cracking may not be visible if the weld is inspected immediately after it is completed. Inspection should be delayed 2 or 3 days after welding. The primary mitigation measures are (a) bakeout, if necessary; (b) preheat; and (c) control of welding flux to avoid moisture absorption.

Caustic embrittlement is a misnomer. The loss of ductility causes a reduction in load-carrying capability because of the formation of cracks due to caustic stress corrosion cracking.

Low-temperature embrittlement occurs in carbon and low-alloy steels at temperatures below their brittle-ductile transition temperature range. The effect is reversible: when the alloy is heated above the transition range, ductility is restored. This embrittlement is avoided by following the Charpy impact test requirements of the relevant engineering codes. The need to test depends primarily on the material, its thickness and the minimum design temperature.

Aluminum, copper, and other face-centered cubic metals and alloys (such as the austenitic stainless steels and nickel-base alloys) do not become brittle at low temperatures, except if heavily cold worked. Most such alloys are exempt from impact testing for design temperatures down to –320°F (–195°C). Some types, such as Type 304, are exempt down to –425°F (–255°C). The exemption temperatures for weld metals and HAZs are usually higher than those for the parent metal.

21.4.2.1 Stainless Steel

Ferritic stainless steels, such as straight chromium stainless steels containing 12% chromium, may be embrittled at 750°F to 975°F (425°C to 525°C). Embrittlement is not evident at high temperatures, but lack of ductility can occur at ambient temperatures; it is called *885°F* (475°C) *embrittlement* (or "blue embrittlement"). This embrittlement is reversible at higher temperatures. Alloys that embrittle, if used in pressure-containing services, should not be exposed to temperatures >650°F (345°C). However, some common domestic codes allow design stresses up to 1200°F (650°C). In most cases, these codes caution that these materials may embrittle.

Ferritic stainless steels are sometimes used for their corrosion resistance above the 885°F embrittlement threshold. Such applications usually involve vessel trays and internal cladding. Embrittlement 885°F (475°C) is not normally a problem in the 12Cr alloys such as Type 410S stainless steel. Type 405 stainless steel, with its slightly higher chromium content and small aluminum addition, and Type 409, containing a titanium addition, are more susceptible. For ferritic stainless steels containing 15% or more chromium, embrittlement can become severe. One should not accept "upgrades" of straight chromium stainless steels without first checking on their thermal history and the intended operating temperatures. Table UHA-109 in ASME Section VIII, Div. 1 [1] provides guidance on the risk of 885°F embrittlement of high-chromium stainless steels.

The higher chromium grades of the ferritic stainless steels such as Type 446 become susceptible to embrittlement, caused by the formation of intermetallic phases such as sigma or chi phases, at temperatures ~1050°F (565°C). Most straight chromium grades are also susceptible to sensitization-induced corrosion problems. These alloys should be avoided for high pressures when the operating temperature exceeds 650°F (345°C). Such alloys should be confined to nonpressure components such as valve trim, vessel internals, and pressure boundary liners such as weld overlays. These applications occur for high-temperature sulfur-containing streams such as refinery coke drums and crude units processing sour crudes. Ferritic stainless steels are also susceptible to low-temperature embrittlement. The engineering codes typically require such steels to be impact tested.

Martensitic stainless steels are susceptible to low-temperature embrittlement and engineering codes typically require they be qualified for low-temperature service by impact testing. As discussed earlier, the martensitic stainless steels can grain coarsen in the HAZs of welds. Grain coarsening causes relatively high brittle-ductile transition temperatures. Martensitic grades, being air hardenable, can also produce brittle HAZs. Consequently, martensitic stainless steels are not usually recommended for pressure vessels containing welds. However, some codes provide allowable design stresses for a few martensitic stainlesses up to 1200°F (650°C).

Austenitic stainless steels are often susceptible to *sigma-phase embrittlement* after extended exposure at 1050°F to 1700°F (565°C to 925°C). Occurrence depends primarily on the temperature and the presence of ferrite. While Type 304 SS can develop sigma-phase embrittlement, it is more common in austenitic products that contain small amounts of ferrite. Examples include austenitic weld metal and castings.

The upper temperature limit for sigma-phase formation varies from about 1600°F to 1800°F (870°C to 980°C), depending primarily on alloy composition. Embrittlement occurs slowly. Type 304 SS will usually show only 2% to 3% sigma phase in its microstructure after 10 years at 1200°F (650°C). At temperatures near the upper limit of the embrittlement range, embrittlement may develop in a few weeks. The rate of embrittlement is increased by cold work prior to exposure to embrittling temperatures. The nonstabilized alloys such as Type 304 SS embrittle more rapidly than do the stabilized alloys, typically represented by Types 321 and 347 SS. This embrittlement is reversible by solution annealing. The effect of sigma-phase embrittlement on toughness depends somewhat on both temperature and alloy composition. For nonstabilized austenitic stainless steels, a sigmatized alloy can be brittle up to 1400°F (760°C). Above this temperature, sigma phase has little effect. The behavior of the stabilized grades is less clear, but they recover some ductility at increasing temperature.

Duplex stainless steels are susceptible to 885°F (475°C) embrittlement and to sigma-phase formation, and they are usually not selected for temperatures above 650°F (345°C). Because of their ferrite content, they are susceptible to low-temperature embrittlement. However, the duplex stainless steels tend to have relatively low brittle-ductile transition temperatures. The engineering codes typically require the duplex stainless steels to be qualified for low-temperature service by impact testing. They can be susceptible to hydrogen embrittlement, but are less susceptible than are the ferritic and martensitic stainless steels.

21.4.3 High Alloys

High alloys with little exception suffer some embrittlement if exposed to sustained high-temperature service due to the formation of intermetallic compounds. Conditions and rates of embrittlement vary with the alloy. Check with alloy manufacturers for specific information. High alloys containing enough nickel to ensure an austenitic microstructure are, like austenitic stainless steels, unaffected by low-temperature embrittlement.

21.4.4 Hydriding

Hydriding is a common problem for all refractory metals, including titanium, zirconium, columbium, and tantalum. Galvanic cells that promote hydriding can be particularly damaging. Instances of iron sacrificial anodes causing hydriding in titanium heat exchanger components have been reported. Hydriding is related to hydrogen embrittlement. Hydrides are brittle, thermodynamically stable compounds. Re-refining the metal is required to destroy the hydrides.

Titanium is the most common material of construction that can be hydrided; it has a threshold temperature of ~175°F (80°C). Hydriding can be caused by: (1) Titanium can absorb hydrogen directly from anhydrous process streams containing hydrogen gas. Because only a small amount of moisture is necessary to inhibit such embrittlement, it is relatively uncommon. (2) Nascent hydrogen generated by a corrosion reaction involving cathodic poisons (such as sulfides, cyanides, and arsenic or antimony compounds) diffuses into titanium to form hydrides. (3) Cathodic protection of titanium charges the metal with hydrogen (most often the cathodic protection is inadvertent, being caused by a materials mismatch, such as titanium tubes rolled into a nontitanium tubesheet).

21.4.5 High-Temperature Effects

21.4.5.1 Mechanical Effects

More expensive materials of construction are often needed at high temperatures. Whenever possible, determine if the maximum design temperature can be reduced.

Creep frequently occurs. Most metals and alloys exhibit a temperature above which the grain boundaries become weaker than the grains themselves. Fabricated equipment such as furnaces, heaters, and combustion gas turbines often experience creep. Creep begins for carbon steel at ~750°F (400°C), for Cr-Mo steels at ~900°F (480°C) and higher, and for conventional austenitic stainless steels at 1050°F to 1100°F (565°C to 595°C). A safe estimate for the creep threshold temperature of a material is the upper temperature limit permitted by ASME Section VIII, Div. 2 [1]. Engineering codes such as ASME B31.3 [4] for piping and ASME Section VIII, Div. 1 [1] for vessels contain provisions for creep design. If creep is a concern, coarse grained materials are favored. Carbon steels killed with silicon are usually recommended when creep is a concern, e.g., ASTM A106 for pipe and ASTM A515 for plate.

Stress rupture can occur as a result of sustained operation in the creep range. Stress rupture design keeps allowable stresses much lower than for noncreep designs. The stress rupture design life is the expected period of *secondary* creep, during which cracking damage slowly accumulates, often over several years. During this period, component dimensions such as heater tube diameter

and length increase. In wrought materials such as Alloy 800, secondary creep strains of 10% to 20% are common before failure. In high temperature cast materials such as HK-40 (25Cr-20Ni) (UNS J94204), total secondary creep strains, at failure, are usually 1% to 3%.

When operating in the creep range, temperature excursions are far more damaging as compared with pressure excursions. A 50°F (28°C) excursion may reduce the equipment life by 50% or more. If operating temperatures are high enough to permit creep, thermal fatigue can produce fractures that are virtually identical with those of creep failures. (Thermal fatigue is caused by thermal stresses, generated by thermal cycling. For heaters and furnaces, the most severe cause of thermal fatigue damage is due to operating "trips.") Some codes permit high-temperature maximum allowable stresses high enough to generate thermal fatigue. Accordingly, if thermal cycles are a feature of equipment design (such as for coke drums), thermal fatigue analysis is usually required.

21.4.5.2 Metallurgical Effects

Sensitization of conventional stainless steels, both the austenitic 300-series alloys and the straight chromium grades such as Types 405 and 410 SS, are subject to intergranular corrosion or cracking as a result of *sensitization* in both wrought and cast alloys. Chromium carbides precipitate in the grain boundaries of the alloy at 800°F to 1600°F (425° to 870°C). As the chromium carbides develop, the nearby metal is depleted in chromium, creating a local zone of corrosion-susceptible iron-nickel alloy. For straight chromium grades, this composition may approach that of plain carbon steel. A chromium-depleted zone can also interact galvanically with nearby nondepleted grains to accelerate intergranular corrosion rates.

The rate of sensitization depends strongly on temperature. For conventional austenitic stainless steels, sensitization at about >850°F (455°C) requires extremely long exposure times. The high-carbon H grades have both lower threshold temperatures and faster sensitization rates than do the regular and low-carbon grades. Cold-worked austenitic stainless steels sensitize as low as 700°F (370°C). Sensitization occurs most rapidly above 1500°F (815°C). For example, welding can sensitize the HAZs in stainless steels that have conventional carbon content. Sensitization is often caused by cooling too slowly following solution annealing or stress relief treatment.

Weld rusting occurs when mildly acidic liquids cause the locally chromium-depleted iron-nickel alloy to slowly rust. An example is HAZ rusting of stainless steel by dew (containing CO_2 dissolved from the air) condensing on the outside of a pipe. While normally this is only an aesthetic problem, in some contamination-sensitive processes, such rusting is unacceptable. If chlorides are involved, such corrosion may become aggressive as ferric chloride forms.

Intergranular corrosion results when some fluids, such as oxidizing acids, cause intergranular corrosion in the chromium-depleted grain boundaries. It is sometimes called "weld decay." In some cases, intergranular attack is stress-related and is more properly referred to as *intergranular stress corrosion cracking.* Such corrosion in hydrocarbon plants is usually caused by *polythionic acid*,* in the process-exposed side of a pipe, vessel shell, exchanger bundle, heater tube, etc. The phenomenon usually starts when the steel surface forms a thin iron sulfide film, after exposure to small amounts of sulfur, usually from hydrogen sulfide. During a shut-down, air and liquid water (often dew point water) convert the sulfides to polythionic acid. The polythionic acid then corrodes the chromium-depleted grain boundaries of the sensitized alloy. Because stainless steels are usually supplied to fabricators in the solution annealed condition, sensitization is usually confined to the HAZs of welds. Upon subsequent start-up, leaks may develop after two or more shut-downs. In some cases, the problem becomes obvious during a shut-down while repair welding. A massive growth of a crack network sometimes occurs.

Process controls often protect against such polythionic attack: (1) *Prevent air ingress* by monitoring a positive pressure to ensure that any leaks that do occur are from the inside to the

* $H_2S_nO_6$, where *n* may vary from 2 to 5.

outside. (2) *Prevent the formation or ingress of water.* Purge with a dry inert gas such as nitrogen and then maintain a slightly positive pressure. (3) *Use a neutralizing wash.* Both ammonia and soda ash solutions are used to maintain a basic pH. Refer to NACE RP0170: "Protection of Austenitic Stainless Steel from Polythionic Acid Stress Corrosion Cracking During Shutdown of Refinery Equipment" [14] for recommended practices.

External polythionic acid attack may occur in plants having atmospheric sulfide pollution including gas applications with water condensation. However, the problem does not usually occur on external surfaces in fired equipment because excess air causes sulfates to form, instead of sulfides. Wet sour systems containing carbon steel heat transfer surfaces may generate substantial iron sulfide. Such systems should not be flushed or drained into stainless steel piping or equipment prior to a shut-down unless appropriate precautions are taken. Several metallurgical methods address intergranular corrosion caused by sensitization.

21.4.6 Low-Carbon Stainless Steel

The "L" grades such as Type 304L SS with a low carbon content, limit the level of sensitization. However, they have lower allowable stresses than either the conventional grades or the stabilized grades. The low-carbon grades are typically chosen for services in which welded fabrication is required but the operating temperatures will be less than the sensitization threshold, about 800°F (425°C). With a low-carbon content, the rate of sensitization is low, and the postweld cooling rate in the HAZ is fast enough to avoid significant sensitization. 29Cr-4Mo (UNS S44700) is an example of a low-carbon ferritic stainless steel.

21.4.6.1 Chemically Stabilized Stainless Steel

Types 321, 347, and 348 SS and their H grades, and Types 316Ti and 316Cb SS are resistant to sensitization. They contain carbon scavengers (titanium in Type 321 and Type 316Ti and niobium in Type 347, Type 348, and Type 316Cb) that inhibit chromium depletion. These materials are referred to as *stabilized alloys.*

ASTM specifications for austenitic stainless steels, including the stabilized grades, are usually provided in the solution annealed condition, in which these alloys are not resistant to sensitization caused by long-term, high-temperature service. ASTM specifications warn the user that solution annealing the stabilized grades may result in inferior resistance to intergranular corrosion. With these specifications, the mill solution annealing heat treatment should be followed by a *stabilization anneal.* A widely used practice is to hold the alloy at about 1650°F (900°C) for 2 to 4 hours followed by air cooling to promote stable carbides, formed from either titanium for Types 321 and 316Ti SS or from niobium for Types 347, 348 SS, and 316Cb, without chromium depletion. The purchaser should specify stabilization annealing.

Special alloy composition requirements may be necessary to assure proper stabilization annealing [15]. These requirements limit the ratios of Ti/C in Type 321 stainless steel and of Cb/C in Type 347. The protection provided by a stabilization anneal can be partially destroyed by welding, since some chromium carbides may form. For full protection, welds made after the stabilization anneal should be restabilized. Type 321 SS is more susceptible to this welding effect than is Type 347.

Several stabilized nickel-based high alloys (such as Alloy 825 (22Cr-42Ni-3Mo, Ti stabilized) (UNS N08825) are resistant to sensitization. They are usually furnished in the stabilization annealed condition but may be made susceptible to sensitization by subsequent PWHTs. The alloy manufacturer should be consulted before undertaking stress relief or PWHTs.

Hot bending may cause cracking in stabilized stainless steel pipe, and should be avoided. Virtually all nonstabilized Cr-Ni and nickel-based high alloys are susceptible to sensitization and intergranular corrosion. If fabrication involves aggressive pickling, or if the alloy is to be exposed to polythionic acid or other oxidizing acids, sensitization and resistance to intergranular corrosion should be considered. Check the technical literature or consult with the alloy manufacturer.

Sensitization requires the following considerations: (1) Alloys susceptible to sensitization are acceptable if not welded and if the maximum design temperature does not exceed 800°F (425°C). For cold working of these alloys, the maximum design temperature should be <700°F (370°C). (2) The low-carbon "L" grades are acceptable in weldments for which the maximum design temperature does not exceed 800°F (425°C); in a cold-worked condition, <700°F (370°C). (3) Stabilized alloys are selected for up to 800°F (425°C). Types 316Ti and 321 SS are acceptable in weldments and in processes for temperatures <900°F (480°C). Types 347, 348, and 316Cb SS are acceptable in weldments and selected for processes in which the maximum design temperature exceeds 900°F (480°C). In processes for maximum design temperatures <975°F (525°C), these materials are resistant to sensitization. Type 347 SS is more resistant to sensitization than is Type 321 SS. (4) Stabilized ferritic stainless steels may be substituted for higher grades when superior corrosion resistance is not needed. However, they are susceptible to 885°F (475°C) embrittlement. (5) Stabilized Cr-Ni and nickel-based high alloys are available for processes in which the corrosion resistance of the 300-series is inadequate.

Solution annealing dissolves carbides formed by sensitization. It is required by ASTM specifications for austenitic stainless steel product forms, including castings. However, solution annealing is usually avoided in welds because of distortion problems above 800°F to 850°F (425°C to 455°C).

Spheroidization and *graphitization* can occur in carbon and C-1/2Mo steels >850°F (455°C). Chromium contents of ~0.7 wt% or more prevent these effects. Since most users avoid the selection of carbon steels for use >800°F (425°C), the effects of these two mechanisms are often not considered. However, many plants use carbon steel lined with refractory for such high-temperature services. Refractory failures may occur, resulting in metal temperatures substantially in excess of 800°F (425°C).

Iron carbide (cemenite, Fe_3C) is thermodynamically unstable. Decomposition of cementite in carbon and C-1/2Mo steels is negligible at <850°F (455°C), but accelerates with temperature exponentially. At 900°F (480°C), 50% conversion to graphite occurs in about 10,000 hours, but at 1100°F (595°C) in about 1000 hours.

Cementite decomposition to iron and graphite is called *graphitization.* Decomposition is accompanied by a moderate reduction in the strength, which may accelerate creep damage if the applied stress is large enough to cause creep. Decomposition of the iron carbide can "embrittle" the steel if the graphite that develops forms a continuous (or closely spaced discontinuous) band. Such ruptures are most frequent in C-1/2Mo steel, and this steel is no longer recommended for high-temperature services unless operating stresses are low. Aluminum-killed steels are more susceptible to graphitization than are silicon-killed steels, which are hence preferred for high-temperature services.

Spheroidization refers to the formation of iron carbide spheroids from the pearlite present in most carbon steels, at temperatures >900°F (480°C); the rates are exponential with temperature. However, for sustained high temperatures, graphitization becomes the dominant mechanism. A small amount of spheroidization may be beneficial, since the impact toughness of carbon steel increases with only minor loss of strength. Too much spheroidization causes unacceptable loss of strength. Above 850°F (455°C), with prolonged exposure, carbon steels may be susceptible to stress rupture. Above 1000°F (540°C), oxidation and spalling can result in early failure. Short-term excursions to 1000°F (540°C) may be tolerable if the applied stress is less than the maximum code-allowable stress.

Welding often causes several problems: (1) *Microstructural problems.* Grain coarsening that may reduce toughness; stainless steels may be sensitized. Postweld heat treatments, such as normalizing for ferritic steels and stabilization annealing or solution annealing for austenitic stainless steels, mitigate these problems. (2) *Residual stresses* contribute to cracking. Stress relief by PWHT is usually required for processes sensitive to stress corrosion cracking. (3) *Thermal gradients* cause mechanical distortion. Such problems are usually addressed by a combination of mechanical stabilization, such as bracing, slow heating and cooling, and cold straightening. Cold straightening should be avoided for steels susceptible to strain aging or dynamic strain aging.

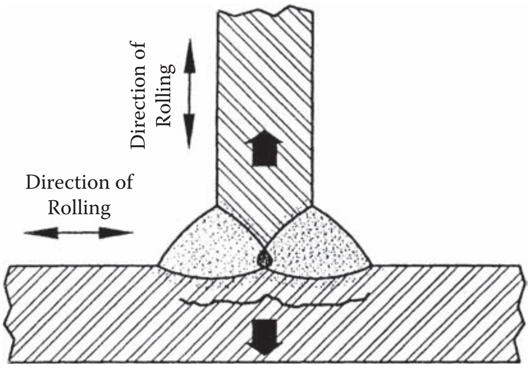

FIGURE 21.11 Lamellar tearing in a T-joint. © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

Welds of dissimilar metals result in: (1) *Warping, buckling, and/or excessive residual stresses* caused by different thermal expansion coefficients. (2) *"Hard spots" in heat-affected zones and fusion zones* are caused by formation of hard intermetallic compounds such as carbides. The heating/cooling cycle can harden HAZs and can cause a sensitized HAZ in nonstabilized alloys. (3) *Galvanic effects* between a sensitized HAZ and its adjacent parent metal can also occur.

Lamellar tearing is an unusual type of failure in plate and plate products, as the weldment cools (Figure 21.11); restraint causes the region just below the weld to be in tension and tearing can occur. (Poor through-thickness toughness is usually caused by the presence of a relatively high density of nonmetallic inclusions, that is, a "dirty" steel.) Lamellar tearing is normally not a problem in plate <1 in. (25 mm) thick.

Methods to avoid lamellar tearing include (1) *Materials control* utilizes plate with a low concentration of nonmetallic inclusions, using purchasing specifications developed for plate resistant to hydrogen-induced cracking (HIC). ASTM A770, "Standard Specification for Through-Thickness Tension Testing of Steel Plates for Special Applications," can be used to ensure plate with proven through-thickness toughness. ASTM A435, "Standard Specification for Straight-Beam Ultrasonic Examination of Steel Plates," ensures that the plate manufacturer or vendor has inspected the plate for injurious nonmetallic inclusions. (2) A *welding technique* option is to use a "butter" layer of low-strength weld metal on the surface of the plate for which lamellar tearing is to be avoided. This technique may require adjusting the weld joint efficiency if the minimum specified tensile strength of the filler metal is less than that of the base metal. Another option is to modify the joint or weld to minimize restraint. Using fillet welds rather than full penetration welds is sometimes useful.

Postweld inspection for lamellar tears is difficult unless the tears penetrate to the surface (usually at the toe of the weld). Dye penetrant inspections are reliable for tears that penetrate the surface. For embedded tears, ultrasonic inspection is sometimes used, but tears are difficult to differentiate from noninjurious inclusions.

Carburization is the development of a carbide-rich layer at high temperatures on a metallic surface exposed to a reducing hydrocarbon environment. Mild carburization of ordinary 300-series austenitic stainless steels is sometimes observed, e.g., in the plenum of a fluid catalytic cracking unit. Special alloys, such as the Alloy 800 series (20Cr-32Ni with Ti and Al) (UNS N08800/8810/8811) or HP-Mod, are generally used in the cracking tubes of ethylene furnaces. Carburization can cause premature failures such as cracking, due to the large difference in the coefficients of thermal expansion between the parent alloy and the carburized layer. Thermal cycling is the normal cause of such failures. Metal loss can also occur by the mechanism known as *metal dusting*. It is observed in the "syngas" process to convert natural gas to hydrogen. This very limited mechanism usually involving reducing hydrocarbon process streams is worst for Fe-Cr or Fe-Cr-Ni alloys having chromium contents of 25% [16] and is very sensitive to temperature. The proba-

bility of dusting increases rapidly at the temperature increases ~850°F (450°C). Process licensors and alloy manufacturers usually provide excellent guidance.

Fuel ash corrosion can be a problem with fuels containing elements that promote corrosion. Major culprits are vanadium and sodium. Above ~1200°F (650°C), vanadium oxide vapor and sodium sulfate react to form sodium vanadate, which reacts with metal oxides on the surfaces of heater tubes, hangers, tubesheets, etc. The resulting slag can become a low-melting eutectic mixture, acting as a flux. The slag dissolves protective metal oxides and prevents their reformation. Sulfur in the fuel contributes to sulfidation and lowers the melting point of the vanadium oxide flux. Such corrosion depends on both the level of metal content of the fuel plus excess air used for combustion. Concentrations of <5 ppmw vanadium appear to have little effect. Concentrations up to ~20 ppmw are regarded as safe at <1550°F (845°C). Alloys rich in nickel and chromium (50Cr-50Ni) offer good protection. Reducing the excess air to <5% can control fuel ash corrosion. Vapor deposition coatings of aluminum and chromium have been tried as tube coatings with some success; various coatings have also been used for turbine blades.

21.4.7 Hydrogen Gas

When selecting a metal, hydrogen service is defined as any service in which the partial pressure of the hydrogen gas exceeds 100 psia (0.7 MPa). Hydrogen gas can cause two problems: *hydrogen embrittlement* (already discussed) and *hydrogen attack.* Hydrogen attack causes internal decarburization and fissuring in carbon and low-alloy steels above ~430°F (220°C). Dissolved hydrogen attacks iron carbide (Fe_3C-cementite), generating methane gas (CH_4), which is trapped in the grain boundaries because the methane molecule is too large for diffusion. As the concentration of methane gas increases, increasing pressure tears the grain boundary apart, first causing fissures, then cracks, then networks of cracks. Simultaneously, the loss of carbides lowers the strength of the material, substantially reducing the expected life of the metal. Both chromium and molybdenum form more stable carbides, and Cr-Mo alloys are preferred in hydrogen service. (Vanadium-enhanced versions of the Cr-Mo often have even greater resistance to hydrogen attack, but are not yet included in the Nelson curves, discussed below.) Unless severely cold worked, austenitic stainless steels are unaffected by hydrogen attack.

Hydrogen attack starts at an exposed surface and proceeds inward via diffusion; detection is relatively easy. The most common inspection technique involves *replicas.* Replication uses metallurgical polishing and etching to prepare the surface for study. A wetted plastic film is then pressed against the surface, producing a negative relief of the surface microstructure. The replica is then examined with a conventional microscope to determine the degree, if any, of decarburization. See ASTM E1351 for guidance on suitable procedures for replication.

The Nelson curves are used to select materials that resist hydrogen attack. Refer to API Publication No. 941, "Steels for Hydrogen Service at Elevated Temperatures and Pressures in Petroleum Refineries and Petrochemical Plants" [3]. Because of the "scatter" in the Nelson curve data, it is common to use the maximum operating temperature plus a 25°F (14°C) margin. Some, however, use a 50°F (28°C) margin. If the maximum design temperature is used for materials selection, the use of an additional operating temperature margin should be unnecessary. For the vertical portion of the curves, it is customary to use a 25 to 50 psia (170 to 345 kPa) margin for the maximum operating hydrogen partial pressure. Compliance with the Nelson curves usually precludes the possibility of hydrogen attack on carbon steel. However, carbon steels damaged by hydrogen blistering or related phenomena can suffer rapid and severe hydrogen attack if stress relieved or postweld heat treated. Hence such treatments should be avoided.

Unintentional materials substitutions have sometimes caused hydrogen attack that resulted in dangerous ruptures. Unfortunately, the Cr-Mo low-alloy steels most often used for high-temperature, high-pressure hydrogen service are not easily distinguishable from ordinary carbon steel. Laboratory testing or on-site testing using portable fluorescent x-ray analyzers distinguishes the Cr-Mo alloys.

As a result, most users employ a *positive materials identification* program, which includes welds as well as parent metals. Positive materials identification testing should be done on installed materials. When this is not practicable, alternatives such as testing immediately before installation are permitted.

Hydrogen attack is accelerated by inclusions and slag-type defects. Therefore, killed steels and inclusion-free welds are often specified. To further protect materials exposed to hydrogen, PWHT is recommended for all Cr-Mo alloy steels. Components cold worked more than 5%, such as cold-formed heads, should be stress relieved. Pockets, such as those created by strip linings, should be avoided. When the metal is exposed to infrequent and short-term transient combinations of high temperature and moderate hydrogen partial pressure, a significant incubation time often occurs before the effects of such attack become detectable. Investigation of incubation times can often justify the choice of a lower cost material of construction. API Publication No. 941 [3] provides details on incubation times. Such analyses are particularly valuable in applications such as bypass loops in which gaseous hydrogen may be blocked in or is stagnant and subsequently heated during start-ups or shut-downs.

To summarize, when selecting materials for gaseous hydrogen service

1. The Nelson curves, utilizing the maximum operating temperature plus 25°F (14°C), should be used.
2. Carbon steels should be killed or otherwise fully deoxidized.
3. Low-alloy steels such as the Cr-Mo steels should be postweld heat treated.
4. Cold-worked materials should be stress relieved.
5. Seamless tubing and pipe are preferred, as they avoid potential problems associated with longitudinal welds.

Hardness controls should be specified as follows:

1. NACE RP0472 [13]. The maximum weld metal hardness permitted for carbon steel is 200 BHN. Weld procedure qualification testing should be done to ensure that HAZ hardnesses do not exceed 248 BHN.
2. NACE MR0175 [2]. This practice, which limits the hardnesses of parent metals and HAZs, should be required. Recommended hardness limits for the weld metal of Cr-Mo low-alloy steels is 225 BHN for $Cr < 3$ and 241 BHN for $3 < Cr < 9$.

Designs for gaseous hydrogen service should include the following features: (1) Plate materials, including clad plate, should be ultrasonically examined for laminations (see ASTM A578). Weld repair of laminations should not be permitted. (2) Pressure-containing and internal attachment welds should be full penetration. (3) Pocketed weldments such as reinforcement pads should be vented. Internal attachment welds that cannot be full penetration, such as tray support welds, should also be vented.

Since hot high-pressure H_2 can crack the Cr-Mo steels favored for this service, the following should be kept in mind: (1) Hydrogen embrittlement can occur at operating temperatures at about <250°F (120°C). This concern is usually addressed by not pressurizing at operating temperatures <250°F (120°C). (2) Delayed hydrogen cracking that can occur in weld repairs subsequent to service. This concern is addressed by an appropriate bakeout prior to repair welding.

21.4.8 Nitriding

Stainless steels and many higher alloys such as Alloy 800 slowly develop a brittle nitride layer if exposed to a nitriding atmosphere at temperatures exceeding about 750°F (400°C). By far the most common nitriding atmosphere is ammonia or a mixture rich in ammonia. Nitriding of stainless

TABLE 21.2
Oxidation/Scaling Threshold Temperatures for Commonly Used Metallic Materials

Material	Scaling Temperature
Carbon Steel	1000°F (540°C)
1-1/4Cr-1/2Mo	1050°F (565°C)
2-1/4Cr-1Mo	1075°F (580°C)
3Cr-1Mo	1100°F (595°C)
5Cr-1/2Mo	1150°F (620°C)
9Cr-1Mo	1200°F (650°C)
12Cr	1500°F (815°C)
3-1/2Ni	1000°F (540°C)
9Ni	1000°F (540°C)
18Cr-8Ni	1650°F (900°C)
Types 309 & 310 SS	2000°F (1095°C)

steels has also been reported with nitrogen-bearing organic compounds such as urea, but not nitrogen. Nitriding usually is much slower than carburization. Special alloys and/or aluminum including aluminum vapor-deposited coatings resist nitriding. Materials selection often accommodates nitriding by providing a nominal *nitriding allowance* such as 1/16 in. (1.5 mm).

21.4.9 Oxidation

All metals and alloys have threshold temperatures above which they become susceptible to rapid scale formation and spalling when heated in air or steam. Table 21.2 shows the oxidation/scaling threshold temperatures for common metallic materials. Materials in applications subject to thickness losses due to oxidation are usually provided with a nominal *oxidation allowance*; 1/16 to 1/8 in. (1.5 to 3 mm) is typical.

Hot lines and equipment are usually thermally insulated to conserve energy and to ensure safe service at temperatures above the oxidation limits of the materials. Care must be taken to ensure that the process stream chemistry is either nonoxidizing or that the process-side surface is protected by an insulating or refractory liner. In such cases, the limiting factor will be the availability of a code maximum allowable stress.

Alloys containing molybdenum can potentially experience *catastrophic oxidation.* The super-austenitic stainless steels such as Alloy AL-6XN, a 21Cr-25Ni-6.5Mo-N alloy (UNS N08367), are an example. A heavy molybdenum oxide scale forms, usually as a result of an improper heat treatment or a severe thermal excursion. Removal of such scales prior to service (or return to service), usually by pickling, prevents this problem.

Heat tinting, such as the blue tinge often seen on welds, is a common condition associated with welds and thermally cut surfaces. For carbon and low-alloy steels, such tinting is usually ignored. However, the subsurface areas of heat-tinted stainless steels may be significantly depleted of chromium. For demanding environments, heat tinting is usually removed by mechanical methods such as grinding or by chemical cleaning or both.

21.4.10 Sulfidation and Sulfidic Corrosion

Sulfur and sulfur compounds attack carbon and low-alloy steels at temperatures exceeding 500°F (260°C) and nickel-base alloys such as Alloy 600 (15Cr-72Ni-8Fe) (UNS N06600) above about

600°F (315°C). The term *sulfidic corrosion* refers to corrosion of carbon and low-alloy steels by sulfur compounds while the term *sulfidation* is normally used for higher alloys. Sulfidic corrosion is usually associated with sulfur in crude oil (as organic sulfides and/or as H_2S). Severe pitting and general wastage can occur in carbon and alloy steels above 500°F (260°C). Corrosion rates are estimated using the McConomy and Couper-Gorman curves.

The original McConomy curves [17] have been found by experience to usually be conservative [18]. They are used for services containing no hydrogen gas. The total sulfur content (in wt%) is not a precise indicator of the corrosivity of a crude oil since not all organic sulfur compounds are corrosive to carbon and alloy steels, even at elevated temperatures. The curves apply to sour crude oils and sour crude fractions, operating at temperatures of >500°F (260°C). They are used for processes containing gases having hydrogen partial pressures no greater than 50 psia (0.34 MPa). They provide *average* corrosion rates and are used to predict the time-to-first leak or to estimate corrosion allowances. (For low-pressure applications, some users utilize the entire wall thickness for making time-to-first leak estimates.) Because of uncertainties, McConomy curve estimates often do not agree with previous plant experience. In such cases, one obviously relies on plant experience with similar operating conditions.

The Couper-Gorman curves [19] are used for sour services with hydrogen gas having a partial pressure of at least 50 psia (345 kPa). Materials selected in compliance with the Couper-Gorman curves must also satisfy the restrictions involving gaseous hydrogen service. When the McConomy or Couper-Gorman curves indicate that carbon steel is appropriate, silicon-killed steels are generally preferred, as they are more resistant to sulfidic corrosion than are aluminum-killed steels. However, coarse-grained silicon-killed steels may be precluded by a requirement for the low-temperature toughness provided by the fine grain practice steels killed with aluminum. When these two curves indicate that the corrosion rates of both carbon or low-alloy steels are sufficiently low, consider the effect of corrosion on downstream equipment. For some processes, equipment such as reactors contain catalyst beds that may be plugged by sulfides. Hence corrosion-resistant steels are needed.

For temperatures at which sulfidic corrosion rates are excessive, two alternatives may be needed: (1) Refractory linings in both vessels and piping. A low iron-containing refractory is required, because spalling of the refractory has been associated with iron oxide contaminants in the refractory. (2) Aluminum diffusion coatings on steel. These coatings are applied by proprietary processes for vapor-diffusing aluminum on and into the steel. For heater tubing, the useful temperatures are extended to 800°F (425°C). Such coatings on low-alloy steels protect heater tubes from external sulfidic corrosion, corrosion-resistant alloys used for close-tolerance components such as internal bolting, and very thin components such as screens and catalyst baskets. Imperfections of the coatings can lead to early failure.

For applications requiring corrosion-resistant alloys, either low-carbon or stabilized stainless steels such as Type 321 SS are normally selected. Sensitization-induced polythionic acid corrosion is a concern in such applications. High-nickel alloys and copper-based alloys often corrode rapidly in the presence of high-temperature sulfur compounds.

Pure liquid sulfur is stored in pits made of Type V concrete. Carbon steel piping is usually specified for the liquid. Nitrogen blanketing or alloys such as Alloy 20 Cb-3 or Type 310 SS are employed since liquid sulfur and air are highly corrosive to carbon steel.

Sulfur and sulfur compounds may cause *sulfidation* of nickel-based alloys >600°F (315°C). The threshold temperature depends on both the process chemistry and the alloy composition. At least one user regards the threshold to be as low as 300°F (150°C) for Alloy 400 (67Ni-30Cu) (UNS N04400) in the presence of hydrogen sulfide. Copper-based alloys corrode quickly and should generally be avoided. Sulfidation can cause pitting, intergranular attack, or fluxing of molten sulfides. Ordinary austenitic stainless steels are subject to fluxing by molten Fe-Ni sulfides. Alloy manufacturer literature and assistance should be sought for differentiating among alloys.

21.5 THE PROCESS OF MATERIALS SELECTION

A four-step materials selection process is described here. In the first step, identify special requirements that will affect materials selection, including the specification of unusual design life and concerns about product contamination. Include such requirements in the "Notes" addendum of the template. Indicate whether operating conditions or design conditions are the basis for materials selection. Second, information about basic metallurgy, corrosion, and degradation phenomena is collected and used to design templates and "Notes" addenda tailored to the specific needs of a plant. Third, materials of construction are selected. Fourth, the materials selection diagram (MSD) is used to check for consistency and to document any special measures needed for corrosion or degradation control.

21.5.1 Designing a Template

The template serves two major purposes: (1) It organizes all the technical data needed for materials selection and (2) on a large job or project, it is a convenient way to transmit process and materials selection information to design engineers.

A template should be as simple as possible. An overly elaborate template is costly and slows the process of materials selection. Decide what information is necessary, then format the template to highlight the required information. After the template has been developed, it is good practice to ask that all requested information be provided, even if the answer may be "trace amount," "not applicable," "per Code," etc. To decide what information should be provided, review the discussions in Section 21.1 regarding template information. The threshold information for the "Notes" addendum of the template is discussed in Sections 21.2 through 21.4; also consider previous experience, plant or pilot plant testing, process licensors, and published literature or material manufacturers.

For small or uncomplicated jobs, a simple template may be preferred. A customized template is not usually needed for replacing or revamping a couple of vessels or a small piping system, or for a unit involving only a few, if any, corrodents. A rubber stamp template, with a process flow diagram, may be used to quickly create a materials selection diagram, as illustrated in Example 21.1.

For jobs involving complex combinations of corrodents, crack-inducing agents, upset conditions, processes, and/or design conditions, a detailed template is usually required. Templates suitable for a refinery are shown in Examples 21.2 (a small job) and 21.3 (a large job).

Many jobs will benefit from a job-specific customized template. The customized template should request information only about corrodents, crack-inducing agents, and upset conditions known to be characteristic to the job. Example 21.4 is a template customized for an ammonia plant. Example 21.5 is a template that could be customized for a chemical plant operated batchwise.

Notes: ______________________________

The template should (1) Accommodate all of the processes and services to be analyzed plus process chemistries. (2) Contain all design information such as temperatures and pressures. Any anticipated operating conditions that affect mechanical design should be indicated. Examples include pressure and/or thermal cycling. This information will be used to prepare the piping and equipment data sheets and to alert designers to special conditions such as cyclic operation. (3) Contain the maximum operating temperatures and pressures. For most mature plant technologies, materials selection is based on operating conditions rather than design conditions. The major exception is for the minimum temperature, for which engineering codes require materials resistant to brittle fracture. (4) Define any upset (nonstandard) and transient design conditions. (5) Contain "Notes" to indicate supplementary materials selection information such as referring to NACE or API documents. The "Notes" section helps describe upset conditions, or a materials testing requirement such as positive materials identification. (6) Include, as an attachment, an addendum (referred to as the "Notes" addendum). It defines temperature, pressure, and concentration threshold values for applicable corrosion and other materials degradation phenomena, as obtained from data supplied by process licensors, or from testing in plants, pilot plants, laboratories, or the open literature. Addendum information helps evaluate risks of early failure. Examples include: (a) a widely used threshold definition for "sour" water is a dissolved H_2S concentration of at least 50 ppmw; (b) austenitic stainless steels are generally resistant to chloride stress corrosion cracking in neutral saline water at less than 140°F (60°C); (c) sensitization-induced intergranular corrosion of low-carbon austenitic stainless steel welded construction is normally not a problem at less than 800°F (425°C).

Notes for Example 21.2.

(1) Corrodents. Indicate:

- (a) Concentrations of acidic components (only if liquid water or other electrolyte is present).
  - (a1) Inorganic or organic acids; indicate in wt% (indicate Total Acid Number if naphthenic acid is present).
  - (a2) Acid gases such as H_2S, NO_2, SO_2, and CO_2 (indicate in mole% if in vapor and wt% if dissolved in water).
  - (a3) Acid salts such as ammonium bisulfide or ammonium chloride (indicate in wt%).
  - (a4) Anticipated pH.
- (b) Oxidants such as oxygen and chlorine (in wt%).
- (c) Other corrodents suspected of being significant, such as dissolved oxygen content in water or microbiological agents.
- (d) Total sulfur:
  - (d1) As wt% sulfur, only if T >500°F (260°C) and the hydrogen partial pressure is <50 psia (0.34 MPa).
  - (d2) As mole% H_2S, only if T > 500°F (260°C) and the hydrogen partial pressure 50 psia (0.34 MPa).

(2) Crack-inducing agents (list only if liquid water or other electrolyte is present [except for H_2]; indicate concentration of the following agents, if present above their threshold concentrations):

- (a) Amines, if present at >2 wt% (indicate wt%). Indicate type of amine.
- (b) Carbonates and bicarbonates, when the concentration of either or both (combined) exceeds 1 wt% (indicate wt%).
- (c) Hydrogen, when partial pressure is 100 psia (0.69 MPa) (indicate either mole% or partial pressure in psia [MPa or kPa]).
- (d) Chlorides, in any concentration (in ppmw).
- (e) Cyanides, if present at >20 ppmw (indicate ppmw).
- (f) NaOH, in any concentration, if T > 115°F (46°C) (indicate wt%).
- (g) Hydrogen sulfide:
  - (g1) Gas phase: the partial pressure of H_2S exceeds 0.05 psia (0.34 kPa) (indicate either mole% or partial pressure in psia [MPa or kPa]).
  - (g2) Sour water: H_2S is dissolved in water at a concentration of at least 50 ppmw (indicate ppmw).
- (h) Other known crack-inducing agents (e.g., HF).

Notes for Example 21.3.

1. Indicate in wt%, only if T > 500°F (260°C) and the hydrogen partial pressure is <50 psia (0.34 MPa).
2. Indicate in mole%, only if T > 500°F (260°C) and the hydrogen partial pressure is at least 50 psia (0.34 MPa).
3. Corrodents. Indicate:
   (a) Mole% of acidic corrodents such as inorganic or organic acids and acid gases such as H_2S, NO_2, SO_2, and CO_2. Indicate Total Acid Number if naphthenic acid is present.
   (b) Wt% of acid salts such as ammonium bisulfide or ammonium chloride.
   (c) Wt% of oxidants such as oxygen and chlorine.
   (d) Other corrodents suspected of being significant such as dissolved oxygen content in water or microbiological agents.
4. Crack-inducing agents (list only if liquid water or other electrolyte is present [except for H_2]; indicate concentration of the following agents, if present above their threshold concentrations):
   (a) Hydrogen, if partial pressure exceeds 100 psia (indicate either mole% or partial pressure in psia).
   (b) Amines, if present at >2 wt% (indicate wt%). Indicate type of amine.
   (c) Carbonates and bicarbonates, either or both (combined) when the concentration exceeds 1 wt% (indicate wt%).
   (d) Chlorides, in any concentration (indicate ppmw).
   (e) Cyanides, if present at >20 ppmw (indicate ppmw).
   (f) NaOH, in any concentration, if T > 115°F (46°C) (indicate wt%).
   (g) Hydrogen sulfide:
      (g1) Gas phase, if the partial pressure of H_2S exceeds 0.05 psia (in either mole% or partial pressure in psia).
      (g2) Sour water, if the concentration of H_2S dissolved in water is at least 50 ppmw (indicate ppmw).
   (h) Other known crack-inducing agents (e.g., HF).
5. Include indication of liquid water, for normal operation.
6. For upset conditions, indicate autorefrigeration, liquid water, wet sour service, carry-over of crack-inducing agents or corrodents, etc. Consider start-ups, shut-downs, regeneration, presulfiding, loss of flow, etc.
7. Provide metallurgy in generic form (CS, 18Cr-8Ni SS, 3Cr-1Mo, etc.).

Notes:______________________________

Notes for Example 21.5.

(1) For batch processes, a template must be prepared for each step in the process. Indicate the step for which the template is intended.

(2) Chemicals present:
   (a) List all chemicals present, including contaminants and impurities as well as the major constituents.
   (b) Indicate if the process fluid is an electrolyte. If not, are other electrolytes present?

(3) Corrodents: Indicate which chemicals are known corrodents, including chemicals known to damage nonmetallic materials by mechanisms such as permeation and swelling.

(4) Crack-inducing agents: Indicate which chemicals are known crack-inducing agents.

(5) Upset conditions: Describe the nature and duration of possible anticipated upset conditions. Consider whether the upset conditions are for start-of-run, end-of-run, both, or will occur during the run. For each upset condition, indicate the presence of corrodents, crack-inducing agents, or electrolytes introduced because of the upset. For autorefrigeration, indicate the anticipated minimum temperature.

21.5.2 Materials Selection Criteria

While the normal criteria for materials selection address design life, sometimes other criteria govern. Examples include using design conditions rather than operating conditions as the basis for materials selection, requirements for unusual reliability or unusually long life, and corrosion debris or product contamination concerns. Such information is sometimes referred to as the *materials selection design basis*. It is helpful to indicate this information in the "Notes" addendum of the template.

21.5.2.1 Product Contamination

Food, drug, polymer, and fine chemical processes are generally sensitive to contamination, including flaking of scales. While carbon steels may have acceptably low corrosion rates, they often result in iron contamination. Damage by *corrosion debris* is a closely related consideration. Examples include processes in which downstream catalysts are damaged by corrosion debris or where debris can affect flow or heat transfer efficiencies or may cause mechanical problems. The amount of corrosion debris depends primarily on the amount of exposed surface area. Packed beds and heat transfer surfaces of heat exchangers are usually the primary sources of corrosion products. Even though the corrosion rate of the exposed material may be acceptable from the design life, the relatively large exposed surface area may contaminate the product.

21.5.2.2 Reliability

Some systems demand operating reliability. For example, fire water systems must have fast response and operation under severe conditions, including hydraulic surges and fire exposure. The latter is often cited as the reason for not using plastic or fiberglass piping in corrosive fire water systems. In other cases, reliability may not be very important, permitting the choice of less expensive materials of construction, for example, drain valves in low-pressure benign services. Some users have design standards and materials selection limitations that override materials selected. Galvanized steel is sometimes prohibited where a plant fire could cause liquid zinc to drip onto austenitic stainless steel piping, vessels, or equipment. Process licensors sometimes override selections made in accordance with a template. Normally, such recommendations are more conservative than those of the template. Nevertheless, process licensor recommendations are always subject to review.

In selecting a material, always remember the "common sense" of materials selection: (1) Ease of maintenance, replacement, and/or repairability of the component being evaluated. For example, for a design that calls for 100% spares (e.g., one pump running, one on standby), ease of maintenance or replacement may permit selection of less expensive, or even nonrepairable, materials such as cast iron pump internals. In some cases, repairability may influence selection, such as using cast steel, which is repairable by welding, instead of cast iron. (2) Plant experience is particularly useful for processes having a broad base of experience and for selecting materials for water services. In some cases, plant experience may indicate that a lower grade of material is adequate even if the available nomographs and corrosion charts indicate otherwise, for example, some high-temperature sulfur services in chemical and hydrocarbon plants. (3) Once the design, operating and upset conditions have been defined for a piping run or equipment item, it is normal to assume that all components are subject to the same exposure factors. Some components may, however, be exposed to less than the full set of template conditions. Blinds in a piping run are a good example. Such blinds are usually used only to isolate the piping run from equipment or other runs, for the purpose of hydrostatic testing or as part of a maintenance procedure. Most blinds will never experience normal operating or upset conditions. In applications in which the piping run requires special materials, the blinds often can be made of carbon steel. Care taken to differentiate among such service-related applications is often rewarded with significant cost savings.

21.5.3 Organizing the Materials Selection Procedure

For selecting a material of construction, a two-stage process is recommended. In the first stage, a template is used to select a material of construction. The first step is to use the minimum design temperature to choose a material of adequate toughness. The maximum design temperature is then used to modify the selection, if necessary, to obtain satisfactory resistance to corrosion or to thermal degradation.

If an upgrade is necessary, one must iterate to ensure that the upgrade material has adequate toughness at the minimum design temperature. In some cases, the upgrade candidates are one or more families of materials such as high alloys. In such cases, alternatives are evaluated before proceeding. The evaluation criteria depend to a large extent on the project objectives and constraints. Minimal cost, minimal maintenance, short schedule, extended design life, and consequences of a leak or rupture are typical objectives or constraints. A checklist is then used to determine if special requirements such as PWHT, hardness controls, external coating, etc., are necessary. The final step is to ensure that the template is properly filled out and that the template contains all necessary notes.

In the second stage, the materials selection information on the various templates is entered on a simplified process flow diagram (PFD), creating a MSD. The MSD is then reviewed for consistency. A checklist determines if factors such as excessive pressure drop must be addressed.

21.5.4 Materials Selection Procedure: Exceptions

The procedure used for materials selection is, for the most part, independent of the component. The primary exceptions are piping, pumps and fabricated equipment.

21.5.4.1 Piping

Materials selected for piping in mild to moderately corrosive services are sometimes less conservative than those for vessels, heat exchangers, tanks, and pumps in the same services. In this case, piping materials may be chosen on the basis of a shorter design life. This is usually justified because piping is easier to inspect, both online and offline. Also, piping is usually easier to replace and does not have the long lead-time problem often associated with fabricated equipment, vessels, etc.

21.5.4.2 Pumps

Guides used to select pumps include API Standard 610, “Centrifugal Pumps for General Refinery Service” [20]; ASME B73.1M, “Specification for Horizontal End Suction Centrifugal Pumps for Chemical Processes” [21]; and ASME B73.2M, “Specification for Vertical In-Line Centrifugal Pumps for Chemical Processes” [22]. API 610 provides considerable guidance on materials selection, but neither ASME B731.3 nor B73.2M do. Pump manufacturers usually provide guidelines for materials selection for specific process applications.

When selecting materials for pumps, first determine if the pump will be operating continuously or intermittently and whether or not it will be spared. Less expensive materials can sometimes be specified for pumps that will be spared because they can be withdrawn from service for repairs. Pumps expected to operate after being stagnant for long periods of time may require either upgraded materials or special lay-up procedures that control corrosion.

21.5.4.3 Fabricated Equipment

Fabricated equipment such as blowers, turbines, lube oil skids, etc. is usually ordered as “Manufacturer’s Standard” for the intended service. Other “standard equipment,” such as valves, is also

usually supplied with off-the-shelf materials of construction. Most often, any deviations in materials proposed by the fabricator or supplier will exceed the minimum material of construction selected in accordance with the template. However, the proposed materials should be reviewed for compliance with template requirements, including any special fabrication specifications such as PWHT for process reasons, NACE MR0175 [2], and safety and design life requirements.

Equipment to be subjected to two or more sets of process conditions may require two or more templates. Examples include: (1) For shell and tube heat exchangers, use one template for the shellside and another for the tubeside. (2) For separators and distillation towers, use one template for the overhead section and another for the bottoms section. Towers with multiple feeds and/or draws usually require multiple templates.

21.5.5 Grouping Process Regions

When different sections of the process are exposed to essentially the same environment, they can be grouped together for materials selection. The following example is for a refinery; only four types of commodities are needed. (1) *Hydrogen and hydrogen mixtures.* Either pure hydrogen gas or commodities that are mixtures of hydrogen gas with other components, such as hydrocarbons. (2) *Hydrocarbons.* Commodities that are hydrocarbons or mixtures of hydrocarbons with other materials such as water, hydrogen, steam, etc. (3) *Noncorrosive gases.* Commodities such as nitrogen and dry plant air at ambient temperature. (4) *Other services.* Commodities such as amines, cooling water, fire water, and chemicals such as sulfur, caustics, acids, oxidants, etc.

21.5.6 Materials Selection Procedure

The first step is to consider the effect of the design temperatures.

21.5.6.1 Low Temperature

Ensure that the upset conditions listed in the template have been considered in establishing the minimum design temperature. A candidate material of construction must comply with minimum code requirements for low-temperature toughness. As the template information is subsequently reviewed for the effects of corrosion, crack-inducing agents, embrittlement, etc., make sure that the low-temperature toughness requirements are retained after making any changes in materials.

21.5.6.2 High Temperature

The preliminary material of construction should be checked for the risk of thermally induced degradation at the maximum design temperature: (1) Is it susceptible to thermally induced embrittlement or thermal degradation that could case failure during high-temperature service? For example, creep embrittlement and spheroidization or graphitization. (2) Will sustained operation at the maximum design temperature cause the material to be brittle at lower operating temperatures? Sigma-phase embrittlement of stainless steels is an example. (3) Will sustained operation at the maximum design temperature cause the material to be susceptible to corrosion at lower temperatures? Polythionic acid attack of stainless steels is an example.

The material is upgraded as necessary, always ensuring that it has adequate toughness at the minimum design temperature. The suitability of the upgraded material for the anticipated corrosion/degradation environment will be evaluated later. If sustained operation at the maximum design will cause the material to be brittle at lower operating temperatures, the design engineer should prepare appropriate operating instructions. Next, the candidate material is evaluated for the anticipated external environment, e.g., external chloride stress corrosion cracking, induced by a marine atmosphere. Next, the following considerations of corrosion, upset and transient conditions, and final review are organized to use the grouped process regions mentioned above.

21.5.6.3 Corrosion

The maximum design temperature should be used for assuring corrosion resistance, as follows:

Hydrogen and hydrogen mixtures: The Nelson curves [3] are used for all hydrogen services, including any mixtures of hydrogen with other commodities. Establish the minimum acceptable material, using the maximum design temperature or the maximum operating pressure plus a design margin (usually 25°F or 50°F [14°C or 28°C]). The material selected will be the minimum acceptable material for pressure containment.

Hydrocarbons: The McConomy [17] or Couper-Gorman [19] curves are used for streams containing either sulfur and/or H_2S for temperatures exceeding 500°F (260°C). When using the Couper-Gorman curves, choose the curve (either naphtha or gas oil diluent) most similar to the process stream hydrocarbon. If an 18Cr-8Ni SS is indicated, select a stabilized grade (e.g., Type 321 SS) if the design temperature exceeds 800°F (425°C). If naphthenic acid attack is probable, Type 316 SS or Type 317 SS ("L" grade if it is to be welded) or Types 316Ti or 316Cb SS (for plate and plate products) should be selected. In the "Notes" space on the template, indicate that the molybdenum content of the Type 316 grades shall not be <2.5 wt%. The following notes should be included for stainless steels: (1) for Types 316 and 316L, air and/or liquid water must be excluded during shut-down; or (2) the operating manual should include instructions regarding a neutralizing wash during the front end of a shut-down. Refer to NACE RP0170, "Protection of Austenitic Stainless Steel from Polythionic Acid Stress Corrosion Cracking During Shutdown of Refinery Equipment" [14].

If hydrogen is involved in the process, the material selected for resistance to sulfur must also meet the minimum requirements, based on the Nelson curves. In many cases, combined hydrogen-sulfur or hydrogen-hydrogen sulfide service require cladding or overlays, to provide resistance to the effects of high-temperature sulfidic corrosion and hydrogen attack, at an affordable cost.

Carbon steel will be selected for most hydrocarbon services, the major exception being for temperatures exceeding 800°F (425°C). Carbon steel is a viable candidate for higher temperature services under some circumstances: (1) For low-pressure applications such as decoking, carbon steel is sometimes used up to 1000°F (540°C) despite its tendency to graphitize above 800°F (425°C). (2) In some low-pressure services with intermittent excursions exceeding 1000°F (540°C), carbon steel is chosen, usually with the expectation of early replacement. (3) For higher pressure applications, the minimum acceptable material will be 1-1/4Cr-1/2Mo. Above 1050°F (565°C), a higher chromium alloy is required. (4) Internal refractory lining can extend the usefulness of carbon and low-steel alloys at temperatures above their oxidation threshold temperatures.

Noncorrosive gases: Carbon steel is the normal material of construction.

Other services: For chemicals, refer to Section 21.4 for guidance on materials selection for common chemicals. For other chemicals, refer to the available literature. For proprietary technologies, follow the guidance of the process licensor. Such guidance is always subject to review for compliance with safety and design life requirements. Plant experience and pilot plant testing, in some cases, will indicate suitable materials.

Extensive literature is available on various water services. Whenever possible, start with plant history, utilizing the same or similar water chemistries. Up to about 200°F (93°C), paint coatings may control corrosion in immersion service.

If corrosion concerns require a material upgrade, the upgraded material should have adequate toughness at the minimum design temperature. If the upgrade involves evaluating one or more families of materials, make sure that the job or project objectives and constraints, such as minimal cost or consequences of a leak or rupture, are considered. Complete the evaluation and choose a candidate material before proceeding.

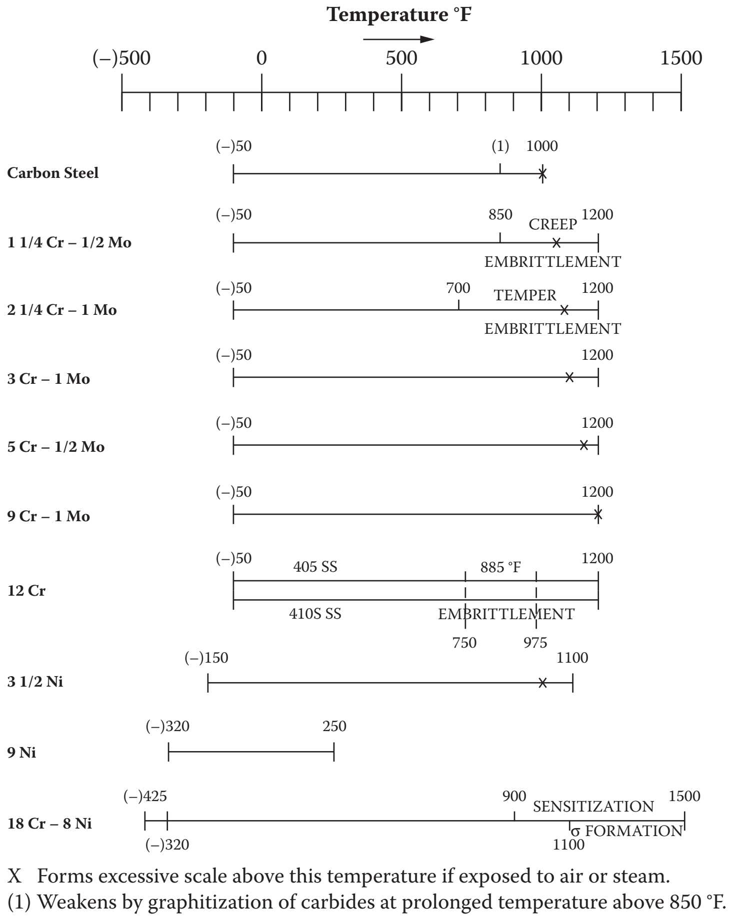

FIGURE 21.12 Materials selection as a function of temperature. (The upper value of the temperature range represents the limit for which code-allowable stresses are available.) © Copyright by Marcel Dekker, Inc.; reprinted with permission [5].

21.5.6.4 Upset Conditions: Review

Several items on the template should be reviewed, as follows:

1. All material selections for conditions above 1000°F (540°C), to avoid oxidation, scaling, or spalling problems. Figure 21.12 is useful for evaluating such problems, including thermally induced embrittlement >700°F (370°C).
2. For carbon steel in hydrogen stress cracking services, determine if heavy section/sharp thickness gradients such as thick nozzles will be required. Such gradients may indicate a need for HIC-resistant plate and PWHT to prevent stress-oriented hydrogen-induced cracking. Determine where HIC-resistant plate is to be used for vessels, heat exchangers, and/or piping. Determine if normalizing and PWHT should be specified.
3. Review all carbon steel templates for which PWHT is indicated. Consider the maximum operating pressure. If it is <65 psia (0.45 MPa) or if the combined stress in tension is less than the 10% rule, PWHT may be unnecessary.
4. Corrosion allowance is probably unnecessary for pressures <65 psia (0.45 MPa), particularly for piping.

5. Consider recommending "L" grades if nonstabilized austenitic stainless steels have been recommended and welding is part of the fabrication process. This will minimize potential problems caused by sensitization, and the "L" grades are easier to weld.
6. For fired heaters subject to creep problems, make sure that the tube metal temperature was considered in materials selection. In the absence of better information, assume the fire-side temperature is 100°F (38°C) higher than the process temperature. (If tube-side fouling is anticipated [e.g., coke formation], assume the tube metal temperature is 150°F [85°C] higher than the process temperature.) If necessary, make a note on the template to ensure that creep is accommodated during design of heater tubes, in accordance with API 530 [23].
7. For all heat exchangers, evaluate the effect of leaks that permit mixing of the nonprocess side with the process side. In some processes, leaks require an immediate shut-down. In such cases, an upgrade in materials may be justified. In addition, evaluate the potential effects of a loss of flow on both the nonprocess and process sides. If such events are regarded as likely, an upgrade in materials may be required. For shell-and-tube heat exchangers, make sure that the front- and backside metallurgies and corrosion allowances of the tubesheet(s) are consistent with the channel and shellside processes, respectively.
8. Indicate in the "Notes" space of the template: (a) Where galvanic couples or alloy crevices are exposed to electrolytic corrosion, cathodic protection may be needed (for example, at tube-to-tubesheet joints in heat exchangers). (b) For austenitic stainless steels exposed to chloride-bearing external environments, a note requiring external coatings to prevent stress corrosion cracking or HAZ pitting may be needed. (c) Where an alternate process may provide better or more economical service, indicate the alternative. For example, steam tracing to keep water from condensing in a carbon steel line containing CO_2, versus using austenitic stainless steel as the material of construction. Such notes should be discussed with process engineers or designers during subsequent review(s) of the MSD. (d) For processes in which hydrogen stress cracking may occur, identify weld joints having significantly mismatched component thicknesses. Joints such as tray attachment welds and tube-to-tubesheet welds could have excessive weld metal and HAZ hardnesses and may need PWHT.

Indicate special corrosion-based requirements, such as

- Hardness limits in accordance with NACE MR0175 [2] and NACE RP0472 [13] for hydrogen stress cracking services.
- Paint/coating requirements for insulated piping and equipment or buried piping.
- Paint/coating and cathodic protection for submerged or buried structures or piping.
- Coatings/cathodic protection for the internal surfaces of tanks or vessels in corrosive service.

Complete the final steps in the materials selection process:

1. For each template, make sure that the metallurgy, valve trim, PWHT, and corrosion allowance requirements are filled in.
2. Use the "Notes" space on the template to indicate special requirements such as inspection categories, positive material identification, special flange face machined finishes, etc.
3. Specify PWHT in the template only if required by the process, for example, carbon steel in amine service. If PWHT is required, but not for process reasons, indicate "per code."

21.5.7 Materials Selection Diagram

Obtain a simplified process flow diagram; it need not contain detailed process data. All piping and equipment for which templates have been generated should be indicated, using the same stream

numbers and equipment designations utilized on the respective templates. This PFD should show design temperatures and pressures for all piping and equipment. There should be sufficient room to create a "Notes" section, which includes any special materials selection requirements such as concerns about product contamination or operating reliability. Templates should be included as attachments.

The preliminary material selections are entered on the simplified PFD, along with corrosion allowances and any special features such as hardness controls or PWHT. Use arrows with legends, color codes, dotted or dashed lines, or some other method to identify the material/corrosion allowance/fabrication requirements for each pipe run and piece of equipment. In most cases, the "Notes" section simplifies the identification process, since many of the process services will refer to common notes. Examples include NACE hardness controls, PWHT, requirements for internal and/or external paint coatings, anodic or cathodic protection, and design-related measures such as a requirement for self-draining. This generates the materials selection diagram. The MSD is useful for several activities:

1. Compare the metallurgies, corrosion allowances, and fabrication requirements of the incoming and outgoing lines for each piece of equipment versus those of the equipment. This is a consistency check. Highlight any inconsistencies for later resolution.
2. If materials selection depends on corrosion control by process-related measures (such as chemical treatment), these should be indicated on the MSD. Indicate the intended injection points and the type of chemical to be injected. Examples include corrosion inhibitors, scale inhibitors, biocides, pH control chemicals, wash water, etc. Also indicate the location of proposed corrosion monitoring and sampling sites. If anodic or cathodic protection is to be part of the corrosion control design, the MSD or its "Notes" section should indicate the piping and/or equipment to be protected.
3. If degradation processes such as high-temperature embrittlement or autorefrigeration will affect operating procedures such as pressurization during start-up, indicate such limitations as general notes to the MSD.
4. Check for large pressure drops such as those that can occur at control valves. Determine if pressure drops will induce corrosive flashing. Flash spools or splash plates may be required downstream of the affected control valve.
5. Check for potential "mixing point" corrosion problems. A typical example of this type of problem occurs where a nominally noncorrosive electrolyte such as water is mixed with a dry acid gas or acid salt. The turbulence associated with mixing usually requires a "mixing" spool of corrosion-resistant material for at least 10 pipe diameters downstream of the mixing point. Neutralization may also be required.
6. Indicate convenient specification breaks. Specification breaks are points where the materials of construction change from one type to another.
7. Indicate the need for check valves, to protect upstream piping and equipment from damage by corrosive reverse flows. In most cases, an upgrade of the upstream piping is less expensive and more reliable than a corrosion-resistant alloy check valve.

If review of the MSD causes any changes in the templates, make sure that the changes are documented.

21.6 CONCLUSIONS

The procedure we have discussed is not a "cook book" process. Prior plant experience should always be an important part of the materials selection process. Common sense plays a key role in evaluating candidate materials. Time should be taken to determine the leeway provided by ease of maintenance, repairability, and sparing. In some cases, these considerations require upgrading of the materials or fabrication procedures (e.g., PWHT). In other cases, it may make sense to recom-

mend changes in the design conditions or in the process itself, in order to specify a lower cost or more reliable material. Finally, unusual project conditions, such as an anticipated short design life or concern about product contamination, will often lead to nonconventional material selections.

Sometimes a user pursues a more conservative course and demands a more expensive material or material processing that exceeds the minimum requirements, for example, PWHT when it is not otherwise required by the construction code and is not justified by the process. Once the user understands the reasons for the recommended material or material processing, the issue becomes a management decision. Occasionally, a user will demand the use of a material that will not meet the minimum requirements. In this situation, safety and design life requirements as well as potential consequences should be reviewed and the results documented to the user.

Finally, new materials and materials technologies are continually coming into the market. In some cases, conditions will encourage their use on a prototype basis. However, experience with prototype technologies strongly suggests that it is best to let someone else be the first to try them. Correcting unanticipated problems can be difficult and costly.

22.1 OVERVIEW OF SOLID/LIQUID SEPARATION

22.1.1 Introduction

Solid/liquid separation (SLS) is encountered in many processes ranging from raw material purification, products separation, to waste management. SLS operations include straining with screens; cake, deep-bed, and membrane filtration; expression; gravitational sedimentation; sedimenting or filtering centrifugation; hydrocycloning; and flotation. Due to the complex nature of fluid/particle systems and a general lack of fundamental training, selection of proper SLS equipment and optimum operating conditions are always challenges for engineers.

In designing SLS processes, it is essential to have information on filtration and settling properties such as settling velocities, cake permeabilities, cake resistances, etc., and other properties including particle size, particle size distribution, slurry concentration, etc. In general, knowledge and experience reside in equipment suppliers, and users frequently furnish vendors with slurry samples for testing and recommendations. Potential problems include aging of slurries and changes in characteristics while being transported and handled by laboratory technicians. In addition, plant process variation and improper sampling (Svarovsky 1990) may lead to unrepresentative samples. Users should carefully evaluate all steps involved in sampling, shipping, testing, and analysis. Another challenge users face is appropriate decision making for equipment selection and system design among the bewildering variety of SLS equipment and techniques provided by manufacturers.

22.1.2 Particles

In the area of SLS, liquid can be water, oil, solvent, or solutions; and solids are particles with sizes starting in the molecular range and continuing up to millimeters. In general, particles have odd shapes. “Size” or “dimensions” cannot be answered with a single arithmetic number. Nevertheless, it is useful to have some idea of the size of apertures in a screen or membrane that permit passage of a particle. In the size range of importance in SLS, a micrometer (μm; 1 μm = 0.001 mm), which is often called a micron, is frequently employed. The limit of visibility of particles is frequently said to be 40 to 50 microns. With an increased rate of development of particle technology, emphasis has shifted to smaller particles; and the nanometer (1 nm = 0.001 μm; 1 angstrom = 0.1 nm) has come into prominence. The nanometer is used extensively in electronic circuits, nanotubes, thin films, foils, etc.

22.1.3 Classification of SLS Operations by Particle Size

Separation operations are frequently classified according to the size of particles. No precise size definitions exist for terms such as ultra-, micro-, nano-, colloidal, and fine particle filtration. Different authors use different nomenclature in classifying separations in terms of “size.” A simplified classification is shown in Table 22.1.

22.1.4 Solid/Liquid Separation Operations

22.1.4.1 Sedimentation

Separation involving sedimentation is dependent upon settling velocity, which requires a difference in density between solid particles and the suspending liquid. Gravitational sedimentation operations are divided into clarification and thickening. Clarification involves dilute suspensions and frequently has the objective of liquid recovery. Thickening refers to solid recovery by forming more concentrated slurries. Particle size, liquid and particle densities, and liquid viscosity are important factors in sedimentation processes.

TABLE 22.1
Terminology in Relation to Size Range

Size (μm)	Terminology	Examples	Solid/Liquid Separation Method
0–0.001	Ionic	Aqueous salts	Nanofiltration, reverse osmosis, chromatography
0.001–0.1	Macro-molecular	Virus, colloids	Ultrafiltraton
0.1–10	Fine particle	Pigments, clay, bacteria	Microfiltration, cake filtration, deep-bed filtration, centrifugation
10–100	Medium size	Bacteria, yeast, fibers, fine sand	Cake filtration, gravity sedimentation, floatation, cycloning
100–1000	Large	Coarse sand	Screens, shakers

22.1.4.2 Straining

Screens with openings smaller than the particles are used to remove the particles (Figure 22.1a). Screens, strainers, and bag filters belong to this category. Bar screens and trash rakes are employed for removal of large debris. Traveling, passive, vibrating, and rotating screens are employed. Sieves have openings ranging from 25 μm (400 mesh) to 8 mm (2 1/2 mesh). Larger sizes are specified by the actual size of the aperture. Shale shakers are screens used for separating cuttings from drilling fluids in the production of petroleum. Bag filters represent the simplest and most commonly used type.

22.1.4.3 Cake Filtration

In cake filtration (Figure 22.1b), solids and liquid are separated by filter medium, which retains the solids as a cake and permits the liquid to pass through under pressure, vacuum, or centrifugal forces. At the start of filtration, some particles may pass through the medium, and the filtrate may be turbid. Once the cake is formed, it becomes the primary filter medium and particles finer than the openings of the medium can be separated.

22.1.4.4 Cross-Flow Filtration

Cross-flow filtration (Figure 22.1c) is principally used on difficult to filter materials. When a cake of low permeability forms, filtration rates can drop to unacceptable values. The cake thickness can be reduced by introducing shear forces at the cake surface. Low-shear cross-flow operation is accomplished by pumping slurries through channels with porous walls or through porous tubes. Rotating turbines or mixers are used in high-shear devices. Cross-flow filtration is essentially a filter-thickening operation in which the suspension thickens as it flows through the unit. Ultimately, the concentration reaches a point where pumping or mixing is no longer feasible. Due to the fine

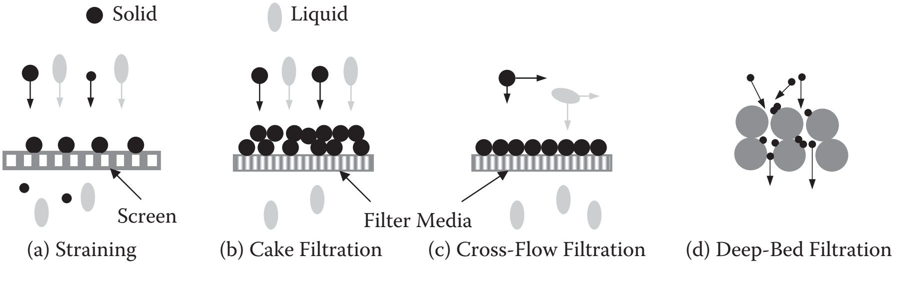

FIGURE 22.1 Schematic mechanisms of three types of filtration.

particles involved, the cross-flow filtration mechanism is almost exclusively used in membrane filtration applications.

22.1.4.5 Deep-Bed Filtration

In deep-bed filtration (Figure 22.1d), particles are caught inside rather than on the surface of the filter medium. Examples of deep-bed filters are granular beds and some cartridge filters. These filters are used for dilute suspensions (<100 ppm) which contain fine particles that are not easy to be removed by sedimentation or cake filtration. They form highly resistant cakes and are preferably removed in the pores of granular beds and cartridge filters.

22.1.4.6 Centrifugation

Centrifugation increases the separating driving force by developing centrifugal forces on particles. A difference in density between the liquid and the particles is also a prerequisite. Centrifuges are employed in filtering and sedimenting modes. The terms *perforated bowl* and *solid bowl* differentiate the two types of operations.

22.1.4.7 Washing

Following cake or sediment formation, removal of soluble materials by washing is a common operation. Washing can be accomplished by reslurrying or washing involving displacement and diffusion. A clean liquid is used in this step.

22.1.4.8 Deliquoring

Deliquoring is accomplished by expression or blowing with gas. Expression operations include squeezing with stationary diaphragms, moving belts, rollers, or screws.

22.1.4.9 Membranes Filtration

Membranes are used for a wide variety of separations. A membrane serves as a barrier to some particles while allowing others to selectively pass through. The pore size, shape, and electrostatic surface charge are fundamental to particle removal. Synthetic polymers (cellulose acetate, polyamides, etc.) and inorganic materials (ceramics, metals) are generally the principal materials of construction. Membranes may be formed with symmetric or asymmetric pores, or formed as composites of ultra thin layers attached to coarser support material. Reverse osmosis, nanofiltration, ultrafiltration, and microfiltration relate to separation of ions, macromolecules, and particles in the 0.001 to 10 μm range (Rushton et al. 1996).

22.1.4.10 Hydrocyclone Separation

Hydrocyclones (see Figure 22.55) are closely related to centrifuges in that centrifugal forces effect the separation of particles. Rotational motion is effected by bringing the slurry radially into the upper periphery of the cyclone at high velocity. Solids are thrown out to the wall, flow down the inclined walls, and exit at the bottom. In general, hydrocyclones operate as classifiers with large particles in the underflow and small particles in the overflow.

22.1.4.11 Flotation

Flotation is commonly employed for beneficiation of minerals. The valuable components are separated from the waste or gangue by preferential floating of one of the components to the top while the other sinks to the bottom. Organic collectors preferentially wet one of the materials and

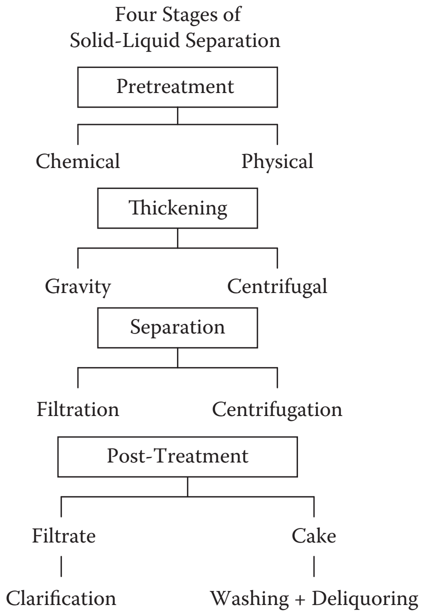

FIGURE 22.2 Stages of solid/liquid separation.

render it hydrophobic. Frothers are added to the vigorously agitated mixture. Air bubbles attach to the collector-mineral particles, which then rise and are removed along with the froth or foam.

22.1.5 Stages of Solid/Liquid Separation

Separation of solids from liquids usually consists of four stages including pretreatment, thickening, separation, and post-treatment, as shown in Figure 22.2.

An overall perspective is essential to solution of SLS problems which are basically complex. Engineers must consider the four steps and their interrelationships in approaching system design or improving existing operations.

Frequently, slurries settle slowly, and are difficult to filter or centrifuge. Pretreatment techniques such as coagulation and flocculation or filter aid addition can be employed to improve separation characteristics. When a suspension consists of fine particles that are difficult to separate, increasing the effective size through aggregation or flocculation leads to improved separability. Aggregated particles are called flocs. A floc is illustrated in Figure 22.3. Degradation of flocs by shear forces is a problem in coagulation and flocculation. It is necessary to study the effects of pumping and

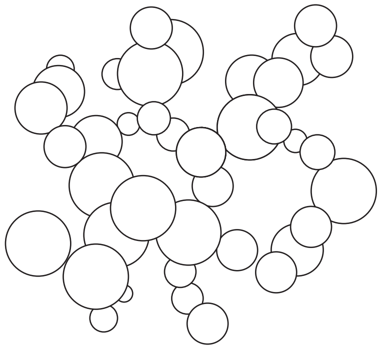

FIGURE 22.3 Arrangement of flocculated particles.

mixing on the possible breakup of the aggregated particles. Filter aids are inert material that can be used to increase the cake porosity and decrease the cake resistance so as to improve the filterbility of the process material.

Thickening frequently follows pretreatment and can be achieved by gravity, centrifugal, or cross-flow filtration. For large-scale operations, removal of liquid is generally accomplished more economically in gravity thickeners as compared to filters and centrifuges. The core separation step can be accomplished with filters or centrifuges, which are necessary for producing cakes with a high percentage of solids. Following separation, both cake solids and filtrate may require further processing in post-treatment operations. Various expression operations are used to reduce the liquid content. Filtrates from filters, centrates from centrifuges, and the overflow from thickeners generally contain suspended solids. Further clarification using cartridges, membranes, or deep beds provides a means for meeting specifications on the product liquid. To reduce the mother liquor in the cake, washing can be applied. Reslurrying wash is more effective, but more wash liquid and additional separation steps are required. Cake washing by displacement followed by diffusion, although less effective, is more convenient.

The following summarizes the elements of the four stages:

1. Pretreatment
   a. Aggregation of particles through use of
      (1) Bi- and tri-valent metallic ions (coagulation)
      (2) Polyelectrolytes (flocculation)
      (3) pH control
   b. Physical processes
      (1) Control of crystal size
      (2) Adjusting temperature
   c. Addition of filter aids to increase cake permeability
2. Thickening and clarification
   a. Gravity sedimentation
   b. Cross-flow filtration (to minimize cake thickness)
      (1) Low-shear operation with flow through porous tubes and parallel to cake surface
      (2) High-shear operation with rotating turbines
3. Separation (production of cakes or sediments)
   a. Pressure and vacuum filtration
   b. Centrifugal filtration
   c. Centrifugal sedimentation (decanters)
4. Post-treatment
   a. Washing by displacement and dilution reslurrying
   b. Deliquoring (reducing liquid content of cakes)
      (1) Expression (cake squeezing)
      (2) Utilizing of high pump pressure
      (3) Drainage under vacuum
      (4) Blowing with gas
      (5) Drainage in filtering centrifuge under high centrifugal forces
      (6) Reducing differential between scroll and centrifuge bowl rotational rates to increase detention time of cake
   c. Clarification of filtrate, centrale, or thickener overflow with flow-through membranes, cartridges, or granular beds

22.2 PRETREATMENT—COAGULATION AND FLOCCULATION

Suspensions generally contain a proportion of particles in the colloidal range. Stable colloidal systems with small particles do not form aggregates when there are large, mutually repulsive

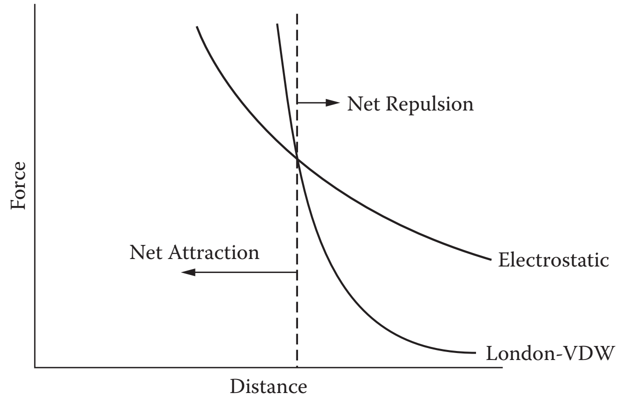

FIGURE 22.4 Interparticle forces.

electrostatic charges. Pretreatment operations aim at neutralization of the repulsive force and stimulation of particle aggregation.

22.2.1 Interparticle Forces and Zeta Potential

Most particles suspended in water and wastewater, e.g., clays, silica, hydrated metal oxides, paper fibers, biological cells, etc., possess negative surface charges in the neutral pH range. The repulsive electrostatic forces due to the electrostatic surface charge and the attractive London–van der Waals (LVDW) force represent the two principal forces among particles. In Figure 22.4, the electrostatic and LVDW forces are shown as a function of the distance r between particles. Repulsive electrostatic forces vary with the inverse square (r^{-2}) of the distance between particles. Attractive LVDW forces vary inversely with the sixth power (r^{-6}) of the distance. In order for particles to be coagulated, the LVDW forces must be greater than the electrostatic forces. In Figure 22.4, as the distance r decreases, the LVDW force increases very rapidly; and at the point, where the two forces intersect, the net force is zero. At a shorter distance, the net force is attractive; and the particles form aggregates that increase the ease of separation. The magnitude of electrostatic force of colloidal particles is evaluated by the term "zeta potential" explained as follows:

A particle in a suspension with negative electrostatic surface charge is shown in Figure 22.5. Positive ions in the solution are attracted to the negatively charged surface where they may be strongly adsorbed. The adsorbed layer remains rigidly attached and forms what is known as the Stern layer with a thickness equal to δ. Outside the Stern layer is a diffuse layer in which negative ions outnumber positive ions and balance the excess in the Stern layer. The electrostatic potential at the particle surface A decreases through the Stern layer along AB and along BC in the diffuse layer and reaches zero at point C, where the bulk of the solution is encountered. The Stern layer and diffuse layer are called double layers. They are important in determining forces between colloidal particles. Zeta potential BC is the difference between the charge at the edge of the Stern layer and the bulk of the suspending liquid, as shown in Figure 22.5a,b. High zeta potential leads to stability of colloidal systems. The relationship of colloid stability to values of zeta potential is shown in Table 22.2.

Zeta potential can be measured by tracking the rate of a negatively or positively charged particle moving across an electric field. The most common commercial instrument is the zeta meter. It can be expensive and requires some operational experiences to get reliable testing results.

22.2.2 Coagulation and Flocculation

Coagulation generally refers to aggregation by charge neutralization with inorganic salts, and flocculation is brought about by large molecular weight polyelectrolytes. Coagulation and floccu-

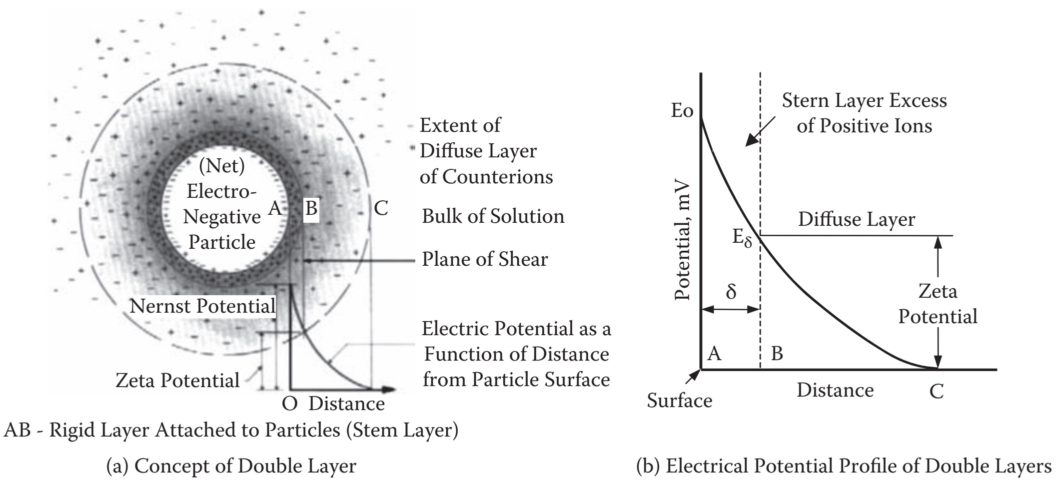

FIGURE 22.5 a, b: Double layer.

TABLE 22.2
Stability of Suspensions with Relation to Zeta Potential

Stability Characteristics	Avg. Zeta Potential (mV)
Maximum agglomeration and precipitation	0 to +3
Range of strong agglomeration and precipitation	+5 to –5
Threshold of agglomeration	–10 to –15
Threshold of delicate dispersion	–16 to –30
Moderate stability	–31 to –40
Fairly good stability	–41 to –60
Very good stability	–61 to –80
Extremely good stability	–81 to –100

From Riddick (1968)

lation processes can be evaluated and controlled by zeta potential in relation to the stability of suspensions, as shown in Table 22.2.

According to Table 22.2, zeta potential values less negative than –15 mV usually represent the onset of agglomeration. A plateau region marking the threshold of either coagulation or dispersion exists from about –14 mV to –30 mV. Values more electronegative than –30 mV generally represent sufficient mutual repulsion to result in stability (i.e., no agglomeration). When coagulation is the desired end, the zeta potential must be rendered less electronegative in order to reduce the forces of mutual repulsion. Gentle agitation will then create impingements of particles that enter the region where the short range LVDW forces can furnish the attraction required to cause agglomeration. Maximum coagulation usually occurs in the zeta potential range of 0 to +3 mV. One example of the effect of type and dosages of metal coagulants on zeta potential according to Riddick (1968) is given in Figure 22.6.

Various salts of aluminum, calcium, and iron, and a few acids and bases used as coagulants are listed in Table 22.3.

As can be seen in Figure 22.6, there is a distinct difference in the effect of the coagulants depending on the valence of the ions in accord with the Schultz-Hardy rule, which states that the salt concentration required to neutralize an electrostatic charge is inversely proportional to the sixth

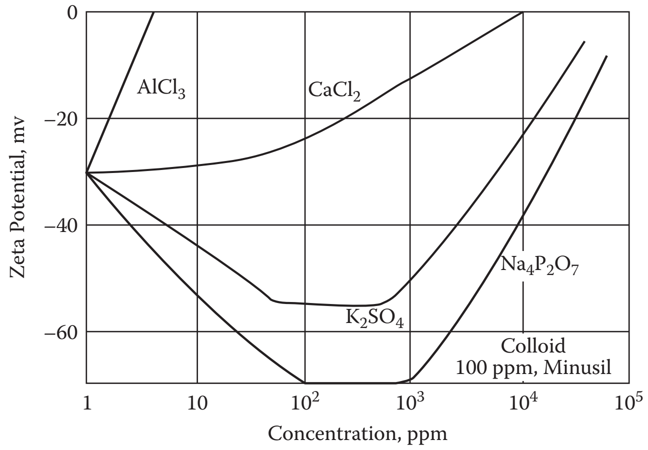

FIGURE 22.6 An example of the impact of type and dosage of electrolyte on zeta potential.

TABLE 22.3
Inorganic Coagulants

Chemical Name	Common Name	Formula
Acids		
Hydrochloric acid		HCl
Sulfuric acid		H_2SO_4
Bases		
Calcium hydroxide	Slaked lime	$Ca(OH)_2$
Sodium hydroxide		NaOH
Salts		
Aluminum chloride		$AlCl_3$
Aluminum chlorohydrate		$Al(OH)_2Cl$
Aluminum sulfate		$Al_2(SO_4)_3$
Calcium chloride		$CaCl_2$
Calcium oxide	Quick lime	CaO
Ferrous chloride		$FeCl_2$
Ferric chloride		$FeCl_3$
Ferrous sulfate	Copperas	$FeSO_4$
Ferric sulfate		$Fe_2(SO_4)_3$
Sodium aluminate	Soda alum	$NaAlO_2$

power of the valence. Although not precisely correct, the rule correctly predicts that the quantity of $AlCl_3$ to achieve zero potential is much less than that of $CaCl_2$. In general, Al^{+3} and Fe^{+3} have proven to be more effective in the coagulation of negatively charged particles. On the other hand, the pyrophospate ion $P_2O_7^{-4}$ is highly effective in increasing the negative nature of the particles and leads to a highly stable colloidal suspension. This property makes phosphate ions useful components of detergents.

In addition to coagulation with electrolytes or polyelectrolyte by controlling the zeta potential, agglomeration is usually accomplished by employing a long-chain polymer to provide mechanical bridging, which is called flocculation. Coagulation and flocculation can occur simultaneously or with some degree of overlapping.

FIGURE 22.7 Jar test apparatus.

There are natural flocculants like Guar gums or starches, but synthetic polyacrylamide derivatives are the predominant flocculants used today. They are commonly referred to as “polymers” in the industry. Polymer manufacturers apply their proprietary recipe in attaching different functional groups to the polyacrylamide backbone to make cationic, anionic, or neutral flocculants. Type of charge, charge intensity, and the molecular weight are used to categorize flocculants. Since charge neutralization is not the primary mechanism for flocculation, neutral or even anionic flocculants may work well for negatively charged particles.

The commercial polymers are in the form of powder, emulsion, or water solution. They need to be diluted before being used to floc the particles. Emulsion polymers require vigorous mixing to “invert” the mixture from water emulsion in polymer to polymer solution in water. Some polymers will be wasted if mixing is not sufficient. For the powder form polymers, medium to longer agitation time is required to completely dissolve the polymer. If the polymer is in a water solution, light mixing is sufficient. Excess mixing can cause the breakage of the polymer chain and loss of polymer activity. Therefore, it is important to consult with the polymer suppliers about the proper mixing methods. After dilution, the polymer solution should be allowed to sit for 1 to 2 hours. This is for the polymer chain to “stretch out” so the full bridging effect of polymers can be utilized.

For laboratory usage, normally a 0.5% stock solution is prepared and should be discarded after one week due to the reduction in polymer activities. Further dilution to 0.05% is necessary before adding to the slurry. The shelf-life for the 0.05% solution is about 1 to 2 days, so fresh samples need to be prepared daily. For plant applications, a polymer solution of 0.5% should be prepared in the storage tank and added to the slurry in a mixing tank or by in-line injection with sufficient mixing.

22.2.3 Laboratory Tests

The efficiency of the coagulation-flocculation process depends on the type and dosage of the coagulant or flocculant, suspension pH, sequence of chemical addition, intensity and duration of mixing, retention time, etc. (Bratby 1980). Due to the complexity of the SLS process, lab testing is usually necessary to determine an efficient and economic coagulation and flocculation operation. A procedure for lab scale testing of polymer selection for wastewater and sludge treatments was developed by the Water Environment Research Foundation (Dentel 1993). A standard jar test apparatus is frequently used for assessing the performance of coagulation and flocculation processes (Figure 22.7). It consists of a rack of stirrers, driven by one motor, under which 600-mL, or preferably 1-L, glass beakers are arranged (Bratby 1980). Before the jar test, criteria for evaluation of coagulation or flocculation must be determined. The most common criteria to evaluate the performance of coagulation or flocculation process are listed as follows:

1. Settling velocity, supernatant turbidity, and volume fraction of solids of the sediment (average solidosity)
2. Filtration rate, specific cake resistance, CST (capillary suction time; slurry is poured into a small cylinder placed on a filter paper [see Figure 22.62a]. A cake is formed and filtrate is sucked out radially. The time required to pass between two fixed radii is termed CST), filtrate turbidity, and cake solidosity
3. Determining the time from coagulant addition to the first appearance of a visible floc
4. Visually recording and comparing flocs as they are formed
5. Floc density measurements
6. Zeta potential

Criteria (1) can be evaluated by sedimentation experiments and (2) can be tested by vacuum, pressure filtration, or CST experiments. Filtration and CST experiments will be discussed in Section 22.7.

A jar test procedure based on the bench stirrer method is basically as follows:

1. Choose the desired coagulant and/or flocculant and the desired dosage.
2. Prepare the coagulant and flocculant samples according to the guidelines in the previous section.
3. Measure and pour slurry samples into each beaker (Figure 22.7).
4. Mix the coagulant or flocculant at a chosen dosage with slurry: place the beakers with slurry under the bench stirrer with paddles centered in the beakers, approximately 1 in. from the surface of the sludge sample. Use graduated syringes or graduated cylinders to add various dosages of chemicals to each of the beakers. Mix the chemicals and slurry for 30 to 60 sec, with a paddle speed of 200 rpm for thorough chemical/particles mixing. Then reduce the speed to 30 rpm for sufficient time (1 to 15 min) to allow the flocs to grow.
5. Results evaluation based on specific criteria.

A jar test evaluation based on sedimentation rate as a function of coagulant or flocculant concentration is shown in Figure 22.8. Intervening time between coagulant and flocculant additions is a third variable. Results of CST (Dentel 1993) as a function of polymer dosage from CST test are shown in Figure 22.9. Minimum dosage of coagulants or flocculants can be determined from the two plots.

In wastewater and sludge treatment plants, the lab-scale jar test is used to predict full-scale performance of additives. Testing in the full-scale plant under controlled conditions is ideal but is seldom done. Tiller undertook full-scale tests in urban wastewater treatment plants using belt presses or centrifuges (Tiller and Li 2001b, 2002). Normally, the optimization of polymer usage is determined by the dryness of the dewatered sludge and overall economics are often neglected. In Tiller's test, an economic analysis based on the cost of the polymer and the cost of gas to dry solids is shown in Figure 22.10. Although increased polymer dosage led to increased cake solids as shown in Figure 22.11, the cost of additional polymer exceeded the cost of drying the sludge. Therefore, the total cost increases as more polymer is used.

22.3 PRETREATMENT—FILTER AIDS

"Filter aids" are inert materials that can be used in filtration pretreatment. The principle characteristics of filter aids are (1) increasing cake permeability, (2) increasing cake porosity, and (3) increasing cake rigidity (decreasing cake compactibility).

There are two objectives related to the addition of filter aids. One is to form a layer of second medium that protects the basic medium (filter cloth) of the system. This is commonly referred to

	Typical Conditions	
Stage	**Time, Min**	**Agitation, rpm**
Coagulation	5	100
Dispersion of Flocculant	1	100
Flocculation	3	40
Sedimentation	5	10

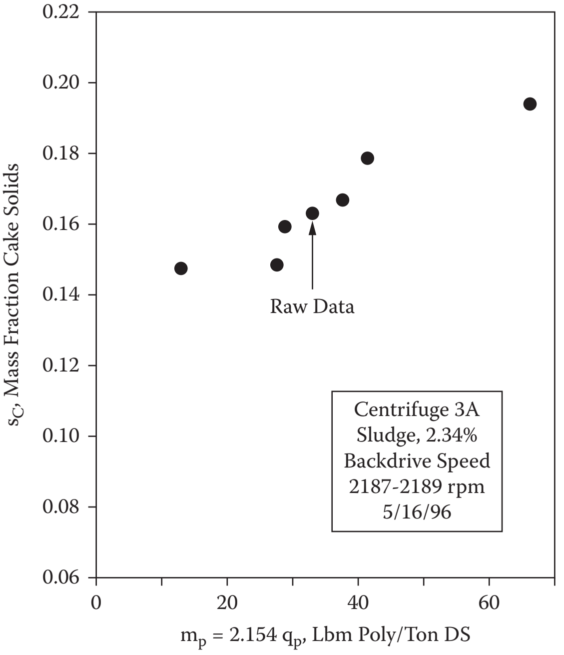

FIGURE 22.11 Cake water content against polymer dosages in Tiller's full-scale test, 1 lbm = 0.4535 kg.

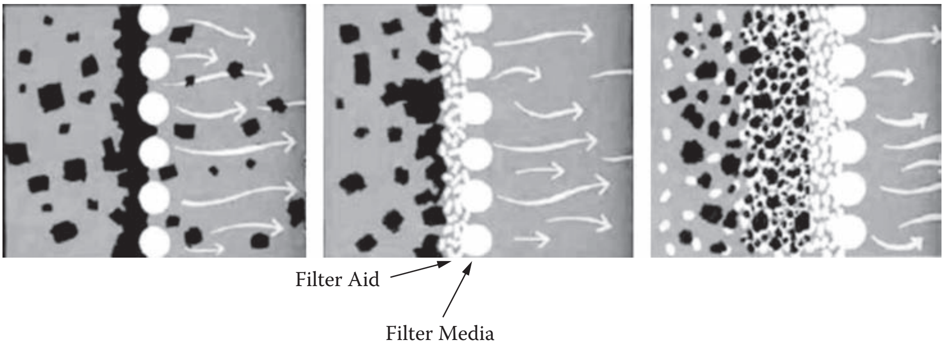


(a) Filtration without Filter Aid (b) Filtration with "Pre-coat" (c) Filtration with "Admix" and "Pre-coat"

FIGURE 22.12 Mechanism of filtration with filter aids.

as a "precoat." When the slurry is very dilute, a thick precoat may function as the medium in a deep-bed filtration. The second objective of filter aids is to improve the flow rate. In such cases, the filter aid is termed as "admix" or "body feed." Filtration without precoat, with precoat, and with precoat and admix is shown in Figure 22.12 (Eagle-Pitcher Minerals, 1970).

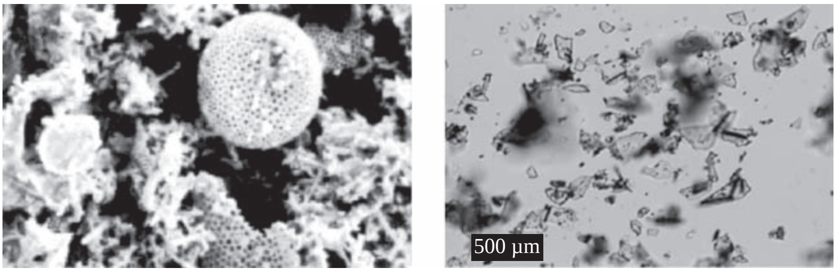
Commonly used filter aids include diatomaceous earth, perlite, asbestos, cellulose, agriculture fibers, etc.

22.3.1 Diatomaceous Earth

Diatomaceous earths (DE) are the skeleton of ancient diatoms (Figure 22.13a) mined from ancient seabeds, processed, and classified to make different grade of filter aids. Diatomaceous earth is the most commonly used filter aid today. However, the crystalline type DE is a suspicious carcinogen and inhalation needs to be avoided during handling.

Used as a precoat, a finer grade DE may be employed to increase the clarity of filtrate. In Figure 22.14 (Tiller 1978), an example of the size of solid particles removed by different grades of DE is shown based on laboratory tests. The smaller the filter aid particle size, the smaller the process particles can be removed. However, the filtration rate is lower. There is always a balance between initial filtrate clarity and filtration rate. The particle size capture by various filter aids may also vary because of liquid viscosity, surface charge, etc.

When DE is used as an admix to produce a less resistant cake, selection of the type and amounts of filter aids depends on laboratory tests with a constant pressure filter cell. A graph illustrating the effect of filter aid addition on the average flow rate is shown in Figure 22.15 (Tiller 1978). Overdose of filter aid resulted in a decrease of filtrate rate.



(a) Diatomaceous Earth (b) Perlite

FIGURE 22.13 Typical filter aids.

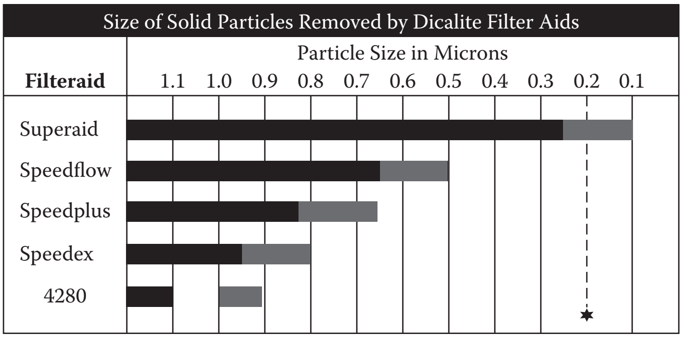


FIGURE 22.14 Chart showing the sizes of particles removed by five grades of Dicalite DE filter aids.

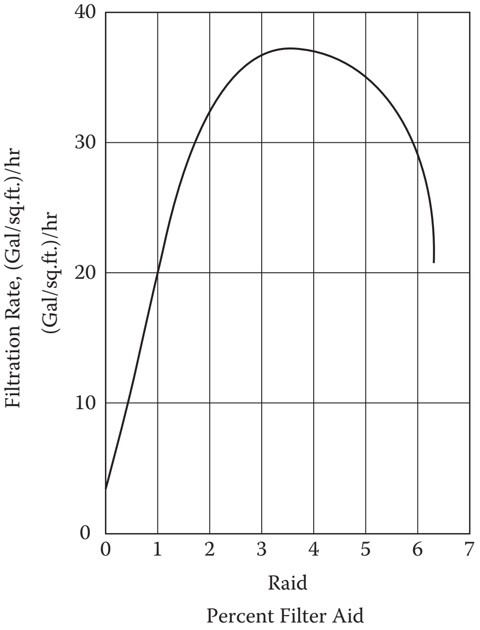

FIGURE 22.15 Optimum amount of filter aids for maximum flow.

Usually, as a filter aid is added to a system, the average flow rate is increased. However, the added solids not only decrease the percentage of product solids in the cake, but also fill the cake space sooner in batch pressure filters. Therefore, cycle analysis must be applied for determination of the optimum amount of filter aid addition. Discussion and calculation of cycle rates are presented in Section 22.8.5.

22.3.2 Perlite

Perlite is another important silica based mineral filter aid. It is a particular variety of naturally occurring glassy volcanic rock, characterized by onionlike, splintery breakage planes (Figure 22.13b). After crushing, this rock will expand with heat to about 10 times its original volume.

There are differences between DE and perlite. First, the bulk density of perlite is less than that of DE. The density difference affects dosage and percentage of product solids in a cake. Second, a packed bed of perlite will not produce the same degree of clarity as diatomite. However, due to the potential industrial hygiene issues by inhalation, perlite has replace DE in some applications.

22.3.3 Other Filter Aids

Other materials used as filter aids include asbestos, cellulose, rice hull ash, paper fibers, etc.

Cellulose is widely used for filtration of products that cannot tolerate silica. The filterability of cellulose is not as good as DE or perlite, but cellulose can be incinerated. Calcined rice hull ash and fibers from used newspapers are newly available filter aids. They are used for wastewater sludge dewatering as well as other applications.

22.4 FILTRATION FUNDAMENTALS

22.4.1 Theory

Solid/liquid separation involves the relative motion of liquid and solids. The liquid may move faster in operations like filtration or the particles may have greater velocity as in thickening and sedimentation. Several classes of problems arise depending on the size, shape, state of aggregation, and concentration of particles in slurries. Particles involved in conventional separation operations range from the millimeter size to macromolecules measured in nanometers. The properties and separation methods vary enormously in accord with size and degree of flocculation. Flocs arising in pretreatment processes are deposited at a cake or sediment surface under a null stress in thickeners, filters, and centrifuges. As increasing deposits cover the surfaces, developing stresses continually compact the particulate bed primarily by particle movement into open pores. Principal sources of stress are (1) unbuoyed weight in gravity thickeners, (2) centrifugal forces in filtering and sedimenting centrifuges, (3) pump pressure converted into friction drag, and (4) surface forces developed by pistons or pressure actuated impermeable diaphragms.

Basic elements required for developing the theory of flow through compactible, porous cakes include:

1. Static force balance over cake yielding the compressive stress in the matrix of particles. The sum of the accumulative frictional drag and body (gravitational or centrifugal) forces per unit of cross-sectional area is called "effective pressure," a term first used in soil mechanics.
2. Relationship of superficial liquid flow rate q to liquid pressure gradient, Darcy's law.
3. Empirical constitutive equations relating permeability K, specific resistance α, and solidosity (vol fraction of solids) ε_s, to the effective pressure.
4. Integration of the Darcy equation to obtain flow rate as a function of the pressure drop across the cake Δp_c, and the thickness L, or the volume of solids per unit area ω_c.
5. Overall material balances involving slurry, filtrate, and cake and determination of pressure and filtrate volume as a function of time.

Conventional filtration theory is based on a two-resistance model in the form

$$q = \frac{dv}{dt} = \frac{p}{\mu\left(R_c + R_m\right)} = \frac{p}{\mu R} \tag{22.1}$$

where R_c and R_m are the cake and supporting medium resistances, R is the total resistance, p is applied pressure, ν is filtrate volume/unit area of filtration, and t is time. As flow is laminar, the viscosity μ is separated from the resistances. The cake resistance is given by the product of the average specific resistance α_{av} and the volume of inert cake solids/unit area, ω_c, leading to

$$q = \frac{dv}{dt} = \frac{p}{\mu\left(\alpha_{av}\omega_c + R_m\right)} \tag{22.2}$$

Although the usual definition encountered in the literature employs w_c, mass of solids/unit area, there are distinct advantages accruing to the use of volumetric units in simplicity of formulas, correlations, and predictive power. The dimensions of α depend on whether ω_c (m^3/m^2) or w_c(kgm/m^2) is used. The two quantities are related by $w_c = \rho_s\omega_c$, where ρ_s is density of solids. Resistance takes the form of $R = p/\mu q$ with dimensions $1/L$. Cake resistance is given by

$$R_c = \alpha_{av}\omega_c = \alpha^*_{av} w_c \tag{22.3}$$

where the superscript is used to differentiate the two types of specific resistance. The units of α_{av} and α^*_{av} are, respectively, $1/L^2$ and L/M. A closely packed bed of 10 μm spheres would be expected to have a specific resistance α of about 3.0E(12)m^{-2}. The resistance of the bed to flow would depend entirely on the size and shape of the pores and would be independent of the mass inside the particles. Using α^* requires that 3.0E(12)m ^{2} be divided by the particle density, thereby leading to different values for every material for geometrically identical beds. Correct comparison of the resistances of different materials can only be made with the specific resistance as used in Equation (22.2) with dimensions of L^{-2}.

Integration of Equation (22.2) to obtain filtrate volume as a function of time t requires:

1. Specification of pump characteristics, that is, p as a function of q with constant pressure and constant rate being important special cases.
2. Relation between ν and ω_c or w_c as obtained from a volumetric or mass balance over slurry, cake, and filtrate.
3. Equations relating the average values of the specific resistance α_{av}, permeability K_{av}, and volume fraction of solids in the cake ε_{sav} to the pressure drop Δp_c across the cake.

Before using Darcy's law to theoretically develop Equation (22.2), simplified procedures used by many authors (Rushton et al. 1996; Svarovsky 1990) will be employed to derive volume vs. time equations. Although widely used and valuable in interpreting data, highly significant information important to full-scale operation is missed when Equations (22.1) and (22.2) are the sole basis for developing the theory of cake filtration.

Although Equation (22.2) is often considered to be a "fundamental" formula governing filtration, it must be used with caution. It is very useful in analysis when viewed as an empirical approximation. It provides an instantaneous picture of the relationship among the variables, which include the instantaneous flow rate q, applied pump pressure p, and volume ω_c or mass w_c of solids/unit area.

22.4.2 Material Balance

Volumetric and mass balances are necessary in developing filtrate volume/unit area v as a function of t. A schematic diagram in Figure 22.16 shows how the slurry relates to the cake and filtrate. Quantities necessary for balances include:

		Concentration of Solids	
	Total Solids	Slurry	Cake
Volume basis	ω_c, vol./unit area	ϕ_s, vol. fraction	ε_{sav}, av. vol. fraction
Mass basis	w_c, mass/unit area	s, mass fraction	s_c, av. mass fraction

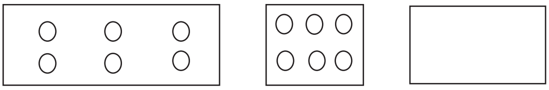

FIGURE 22.16 The volume or mass of slurry equals the volume or mass of cake and filtrate.

Other quantities needed are cake thickness L and liquid density ρ_L. A volumetric balance leads to slurry volume = cake volume + filtrate volume:

$$\frac{\omega_c}{\phi_s} = \frac{\omega_c}{\varepsilon_{sav}} + v = L + v \tag{22.4}$$

where L is cake volume/unit area and ω_c is ε_{sav} L. Equation (22.4) can be rearranged into the convenient form

$$v = \left(\frac{\varepsilon_{sav}}{\phi_s} - 1\right)L = \left(\frac{1}{\phi_s} - \frac{1}{\varepsilon_{sav}}\right)\omega_c \tag{22.5}$$

A mass balance leads to slurry mass = cake mass + filtrate mass:

$$\frac{w_c}{s} = \frac{w_c}{s_c} + \rho_L v \tag{22.6}$$

Solving for v yields

$$v = \left(\frac{1}{s} - \frac{1}{s_c}\right)w_c \tag{22.7}$$

Introducing cake thickness into the mass relations requires that the average mass fraction of cake solids s_c be converted to the average volumetric fraction ε_{sav} as follows:

$$\varepsilon_{sav} = \frac{s_c / \rho_s}{s_c / \rho_s + (1 - s_c) / \rho_L} \tag{22.8}$$

where ρ_s is density of the solids. A similar equation can be used for the slurry with s replacing s_c and φ_s replacing ε_{sav}. The vol/unit area of solids is given by

$$\omega_c = \varepsilon_{sav} L = \frac{w_c}{\rho_s} = \frac{s_c / \rho_s}{s_c / \rho_s + \left(1 - s_c\right) / \rho_L} L \tag{22.9}$$

A relation similar to Equation (22.5) takes the form

$$v = \left(\frac{1}{s} - \frac{1}{s_c}\right) w_c = \left(\frac{s_c}{s} - 1\right) \frac{L}{s_c / \rho_s + \left(1 - s_c\right) / \rho_L} \tag{22.10}$$

It is clear that the volumetric balance leads to easier to handle expressions.

22.4.3 Volume vs. Time

Solving for ω_c in Equation (22.5) yields

$$\omega_c = \frac{\phi_s}{1 - \phi_s / \varepsilon_{sav}} v = cv \tag{22.11}$$

Substituting for ω_c in Equation (22.2) and rearranging the terms leads to

$$\frac{p}{\mu} dt = \left(\alpha_{sv} cv + R_m\right) dv \tag{22.12}$$

Historically, this equation has been integrated assuming α_{av}, ε_{sav}, and c to be constant even though they vary. When the variation is not large, integration from $t = 0$, $v = 0$ to (t, v) yields a parabolic relation in the form

$$\frac{pt}{\mu} = \alpha_{av} c \frac{v^2}{2} + R_m v \tag{22.13}$$

This is the well-known parabola that has been used extensively to calculate α_{av} and R_m based on ν vs. t data for constant pressure filtrations performed in the laboratory. It must be used with caution.

22.4.4 Data Analysis

A simplified but useful approach to analysis of constant pressure data can be developed with the use of Equations (22.12) and (22.13) placed in resistance form. Dividing Equation (22.12) by dv and Equation (22.13) by v produces

$$\frac{p}{\mu}\frac{dt}{dv} = \frac{p}{\mu q} = \alpha_{av} cv + R_m \tag{22.14}$$

$$\frac{p}{\mu}\frac{t}{v} = \frac{p}{\mu q_{av}} = \frac{1}{2}\alpha_{av} cv + R_m \tag{22.15}$$

where $q_{av} = v/t$ is the average rate and $q = dv/dt$ is the instantaneous rate. Substituting R_c for $\alpha_{av}cv$ leads to

$$R = p / \mu q = R_c + R_m \tag{22.16}$$

$$p / \mu q_{av} = 0.5R_c + R_m \tag{22.17}$$

These relationships between the resistances and pressure drops are illustrated in Figure 22.17. Plots of data in accord with Equations (22.14) and (22.15) are shown in Figure 22.18. Line *AB* corresponds to Equation (22.14) and line *AC* to Equation (22.15). Both lines have the same intercept, point *A*, which is the medium resistance. The slopes are in a ratio of 2:1 and yield α_{av} and $\alpha_{av}/2$. Although it is easier to plot $(p/\mu)(t/v)$ vs. v and avoid the difficulty of obtaining differential dt/dv required by Equation (22.14), we strongly recommend plotting both. Nevertheless, most investigators have simply plotted t/v vs. and have not used the resistance forms that we advocate. As filtration data are seldom precise and a number of important factors have been neglected in deriving Equations (22.14) and (22.15), plotting both equations provides a basis for detecting errors and deviations from the simplified parabolic theory.

As the volume vs. time data are parabolic, the construction in Figure 22.19 can be employed to obtain the slope, dv/dt, of the v versus t data. If two points $A(t_1, v_1)$ and $B(t_2, v_2)$ are chosen, the slope of *AB* is precisely equal to the tangent taken at *M* where = $(v_1 + v_2)/2$ but not at $(t_1 + t_2)/2$. This procedure provides a convenient method for obtaining slopes directly from experimental data. Frequently it is necessary to smooth the data before starting the analysis.

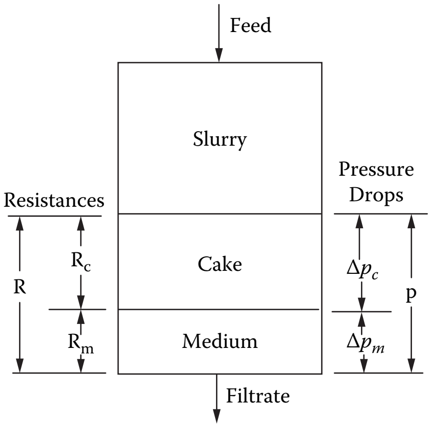

FIGURE 22.17 Diagram illustrating the relationship between pressure drops and resistances.

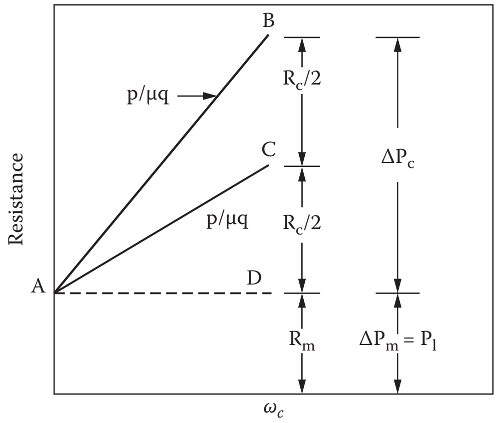

FIGURE 22.18 Plots used to obtain resistances and the average specific resistance.

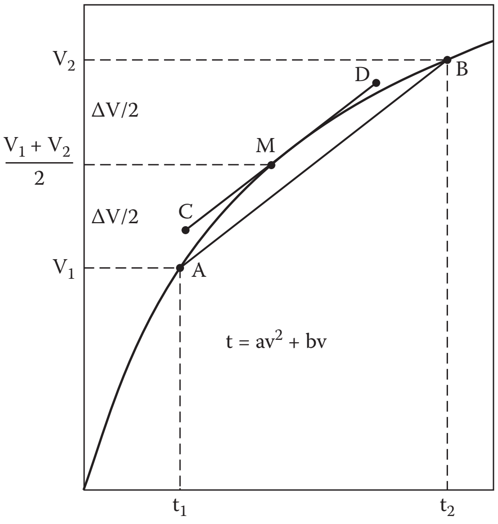

Obtaining Derivatives of Parabolas

FIGURE 22.19 Tangent representing *dt/dv* as parallel to arc.

Example 22.1

An aqueous suspension of calcium silicate (ρ_s = 1950 kg/m^3) at 20°C was filtered at a constant pressure of 68.9 kPa in a small press with an area of 428.7 cm^2. The slurry concentration was 0.495% by weight and the average moisture content of the cake was 70.63% by weight. Calculate the specific and medium resistances on the basis of the following data (Hosseini 1977):

Time, sec.	70	93	120	152	187	227	270
Vol. of filtrate, liters	5	6	7	8	9	10	11

It is necessary to calculate the volumetric slurry concentration ϕ_s and the average cake porosity ε_{sav}. Using Equation (22.8) with ϕ_s and s replacing ε_{sav} and s_c leads to

$$\varphi_s = \frac{0.00495/1950}{0.00495/1950 + (1 - 0.00495)/1000} = 0.002545 \tag{22.18}$$

where the density of water at 20°C is 1000 kg/m^3. The suspension is very dilute. Calculating ε_{sav} based on s_c = 1.0 0.7063 = 0.2937,

$$\varepsilon_{sav} = \frac{0.2937/1950}{0.2937/1950 + 0.7063/1000} = 0.1758 \tag{22.19}$$

The volume/unit area ω_c of inert solids is related to the filtrate volume/unit area by

$$\omega_c = v \Big/ \left(\frac{1}{0.002545} - \frac{1}{0.1758} \right) = v/(393 - 5.7) = 0.00258v \tag{22.20}$$

The ratio p/μ = 68,900/0.001 = 6.89E(7) is required for calculating the resistance terms

TABLE 22.4
Calculations for Example 22.1

Time t, sec	V, m³	Filtrate V, m³/m²	$(v_1 + v_2)/2$	Cake ω_c =.00258v	dvldt $(v_2 - v_1)/(t_2 - t_1)$	P/μq	P/μq$_v$
				v/0.04287			
70	.005	0.117		3.02 E(4)			4.14 E(10)
			0.129	3.32	10.0 E(4)	6.89 E(10)	
93	.006	0.140		3.36			4.58
			0.152	3.92	8.52	8.09	
120	.007	0.163		4.20			5.07
			0.175	4.52	7.50	9.19	
152	.008	0.187		4.83			5.60
			0.199	5.14	6.57	10.5	
187	.009	0.210		5.43			6.14
			0.222	5.74	5.75	12.0	
227	.010	0.233		6.02			6.71
			0.245	6.33	5.58	12.3	
270	.011	0.257		6.64			7.24

$$p / \mu q_{av} = 6.89E(7)t / v \tag{22.21}$$

$$p / \mu q = 6.89E(7)\left(t_2 - t_1\right) / \left(v_2 - v_1\right) \tag{22.22}$$

Table 22.4 provides a systematic procedure for obtaining the terms required to obtain the average specific resistance α_{av}. The first two columns provide the raw volume (m³) vs. time (sec). The third column represents the total volume divided by the area (= 0.04287 m²). The fourth column corresponds to the average volume in accord with the construction shown in Figure 22.4. Equation (22.11) is used to obtain ω_c in the fifth column. The rate $q = dv/dt$ corresponding to the average volume is shown in the sixth column. Calculations for columns 4 and 6 follow for the first two points:

$$v = \left(v_1 + v_2\right) / 2 = \left(0.117 + 0.140\right) / 2 = 0.129m \tag{22.23}$$

$$dv / dt = \left(v_2 - v_1\right) / \left(t_2 - t_1\right) = \left(0.140 - 0.117\right) / \left(93 - 70\right) = 10.0E(10)\ 1 / m \tag{22.24}$$

The two resistance terms are calculated and placed in the last two columns, thus

$$p / \mu q = 68{,}900 / \left(0.001 \cdot 10E\left(-4\right)\right) = 6.89E\left(10\right) 1 / m \tag{22.25}$$

$$p / \mu q_{av} = \left[68{,}900 / 0.001\right] \cdot \left(70 / 0.117\right) = 4.14E(10) 1 / m \tag{22.26}$$

Two lines are drawn through the two sets of points in Figures 22.5 such that they both have the same intercept and the slopes are in the ratio of 2 to 1.

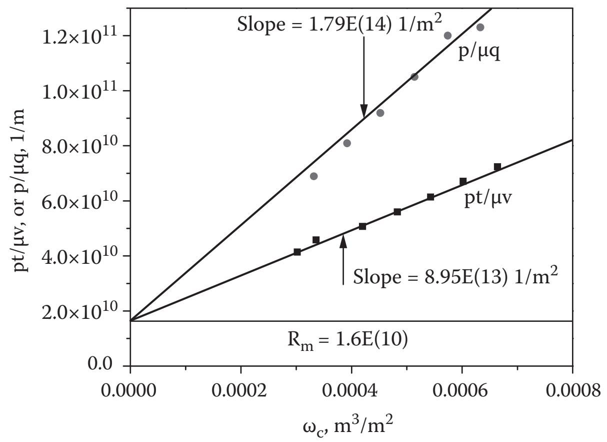

FIGURE 22.20 Resistance plot used to obtain medium and specific resistances.

The lines shown in Figure 22.20 yield R_m = 1.6E(10) 1/m, and α = 1.69(14) 1/m². The specific resistance on a mass basis can be obtained from Equation (22.3) as

$$\alpha^*_{av} = \alpha_{av} / \rho_s = 1.69E(14)/1950 = 8.67E(10)\ m/kg \tag{22.27}$$

The use of units m/kgm predominates in the literature. If regression techniques had been employed with the points in Figure 22.20, two lines with different intercepts and slopes not in the ratio of 2/1 would have resulted. The construction and methodology illustrated in example 22.1 represent a compromise, and there is generally no precise answer.

22.4.5 Deviations From Parabolic Theory

The equations employed in Example 22.1 require that the t versus v relation be a perfect parabola in constant pressure filtration. Errors are both theoretical and experimental. Introducing a suspension into a filter and suddenly increasing the pressure to the operating value results in a transient state in which a finite time is required to reach equilibrium conditions. If high pressures are involved, it is undesirable to raise the pressure too suddenly. Most slurries undergo some sort of pretreatment and mixing to improve filtration characteristics. If insufficient time is allowed for equilibrium to be reached, the cake permeability and porosity of successive layers will change continuously. Aging is an almost universal problem making it unwise to use other than fresh slurries. Biological solids are particularly susceptible to change.

Sedimentation in the filter vessel is a difficult problem that is frequently neglected. If vertical surfaces are involved, the cake will be thicker at the bottom compared with the top. In filters with horizontal surfaces, dense particles settle and increase the slurry concentration at the cake surface. Destruction of aggregates may occur during pumping, pouring, and mixing. Tiller, Hsyung, and Cong (1995) analyzed the sedimentation problem and developed approximate techniques to obtain the average specific resistance.

Slurries frequently involve a wide range of particle sizes that include submicron particles in the Brownian diffusional region. When cakes are deposited, the finest particles may diffuse into the filtrate and continuously clog the supporting medium, leading to increasing values of R_m. Tiller and Leu (1984) showed that clogging was a major problem in the removal of ash and asphaltenes from liquefied coal.

Processing of liquefied coal in a pilot plant at Wilsonville, Alabama, provides a good example of filtration operations that deviate from the simple constant pressure equations. After liquefying

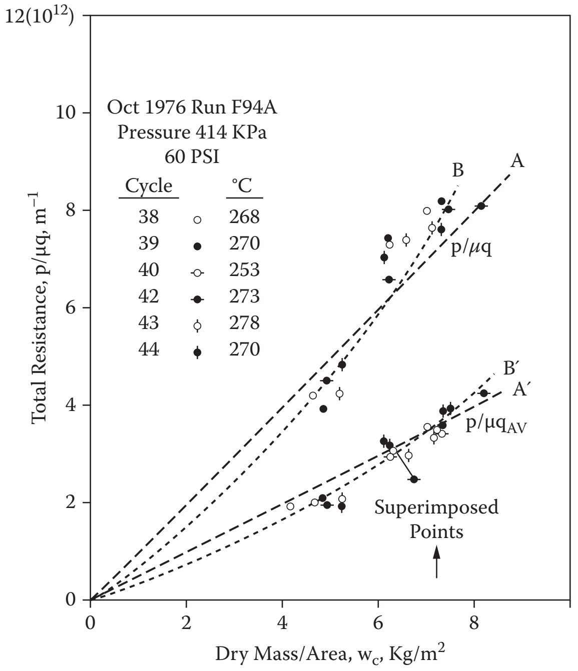

FIGURE 22.21 Clogging phenomena.

the coal, submicron particles arising from mineral residue and colloidal asphaltenes were removed in a horizontal leaf filter with centrifugal cake removal. A resistance plot for a series of six separate runs is shown in Figure 22.21. A straight line *A* was drawn through the $p/\mu q_{av}$ points. A second line *A* with twice the slope was drawn through the $p/\mu q$ data. It is clear that it is impossible to draw two lines independently through the two sets of points that have the same R_m and α_{av}. The location of the points along *BC* that lies above *OA* is an indication that total resistance is increasing more rapidly than predicted. As solid densities were not known, w_c was used rather than ω_c.

If only the $p/\mu q_{av}$ points had been plotted, it would have been assumed that $R_m = 0$ and that α^*_{av} was constant and equal to 5.0E(11) m/kg. As q_{av} represents an average rate over the entire cycle, it does not reflect instantaneous conditions. On the other hand, $q = dv/dt$ as it appears in Equation (22.2) corresponds to the instantaneous state of the cake prior to the averaging process resulting from integration. The specific resistance α_{av} in Equation (22.2) represents the value at a specific time. In the integrated form of Equation (22.13), α_{av} corresponds to the average over the entire cycle. Examination of Figure 22.21 indicates that the $p/\mu q$ plot is responding more rapidly than the $p/\mu q_{av}$ plot to the appearance of increased resistance. Tiller, Hsyung, and Cong (1995) showed that similar behavior accompanies the presence of sedimentation on horizontal cakes formed during constant pressure filtration. In general, whenever the $p/\mu q$ plots yield tangents with negative intercepts as in Figure 22.21 unaccounted for, resistances have appeared that were not involved in Equations (22.13) and (22.14). In the case of the filtration of the liquefied coal, transport and diffusion of sub-micron asphaltenes and mineral residue in the pores of the cake led to increased medium and cake resistances.

Theoretical problems with the traditional theory of the parabolic equation relate to the assumption of constant α_{av} and ε_{sav}, both of which are functions of the pressure drop across the cake. The pressure drop Δp_c varies when centrifugal and constant rate pumps are employed. Even in constant pressure filtration, Δp_c varies with time. At $t = 0$, there is no cake, and all of the pressure is absorbed by the medium, as shown in Figure 22.22. As the cake builds up, the flow rate q drops; and the pressure drop across the medium, p, decreases in accord with Equation (22.28):

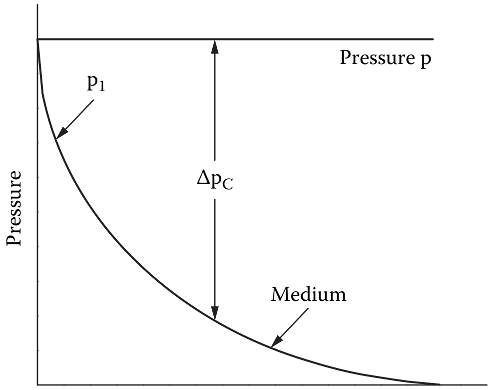

FIGURE 22.22 Variation of Δp_c.

$$p_1 = \mu q R_m \tag{22.28}$$

The time required for p_1 to drop to a negligible value may vary from seconds to a relatively lengthy period. Nevertheless, it is apparent that as long as $R_m > 0$, there cannot be a filtration with constant Δp_c, and the simplified analysis shown in Figures 22.18 and 22.20 must be used with caution.

In Figure 22.23, a plot of $p/\mu q$ vs. ω_c is illustrated for a constant pressure filtration in which R_m is not negligible. As Δp_c increases with time, the slope of the curve and α_{av} also increase. The total resistance is given by the curve *ABD*, and the cake resistance R_c is represented by *BC*. In accord with Equation (22.3), α_{av} is obtained by dividing R_c by $\omega_c(AC)$. As point moves up the curve, the angle of the triangle *ABC* increases and ultimately approaches the slope given by *BD*. The pressure drop across the cake can be calculated from

$$\Delta p_c = \left(\frac{R_c}{R_c + R_m} \right) p \tag{22.29}$$

Equation (22.29) can be used when pressure is constant or a function of time.

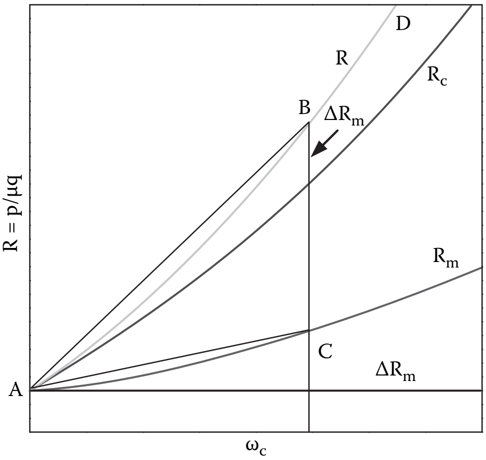

FIGURE 22.23 Medium and cake clogging.

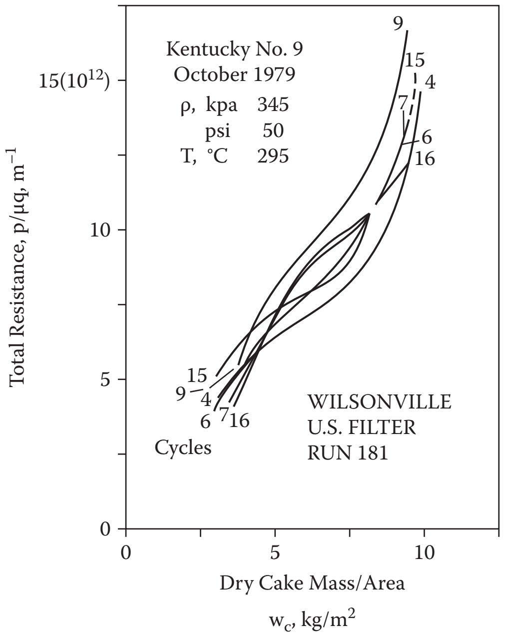

FIGURE 22.24 Clogging Phenomena in liquefied coal industry (10).

In Figure 22.24, resistance plots for $p/\mu q$ versus w_c are shown for a series of runs involving Kentucky No. 9 liquefied coal filter in the U.S. Filter Co. vertical leaf filter. They follow the general trends of filtrations subject to both medium and cake clogging as illustrated in Figure 22.23.

22.4.6 Filtration of Super-Compactible Materials (Tiller and Li 1999, 2000, 2001a)

The simplified theory used to develop Equation (22.13) giving filtrate volume as a function of time is based on having constant values of the average specific resistance and the average cake solidosity. In order to derive more basic equations, it is necessary to integrate local values based on Darcy's law to obtain equations relating average values of solidosity, specific resistance, and permeability as functions of the pressure drop across the cake.

22.4.6.1 Effective Pressure

It is generally assumed that the structure of a sediment or cake is a unique function of the local stress or effective pressure (termed compressive pressure by W.K. Lewis). A filter cake is shown in Figure 22.25 along with the spatial coordinate x and the material coordinate ω that represents the volume/unit area of solids in the distance x. The cake deposited on the filter medium grows as solids are deposited on the surface where the spatial coordinate $x = L$, and the pump or applied pressure is p. As the liquid flows through the cake, the hydrostatic pressure p_L drops and finally exits at the medium with a value equal to p_1. As the liquid flows through the pores, a drag force dF is exerted on each particle (Figure 22.26). The sum of all the forces on the particles equals the total drag F_s. The term F_s is the cumulative drag on particles, communicated from particle to particle and increasing in the direction from $x = L$ to $x = 0$. Assuming the accelerations of the liquid and solid are negligible and neglecting inertial terms, a stress balance is written over the portion of the cake lying over x and L. The total force Ap at the cake surface given by the product of p and the

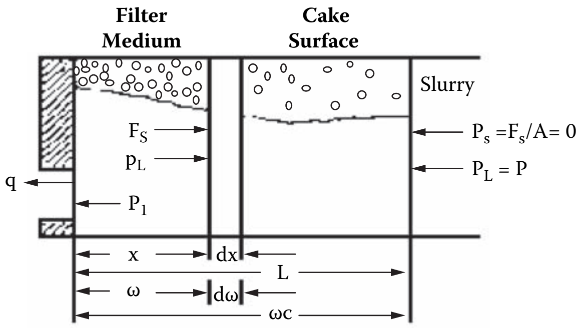

FIGURE 22.25 Diagram of a filter cake with spatial *x* and the material coordinate.

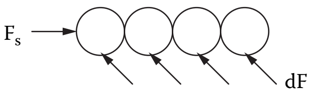

FIGURE 22.26 Fractional drag in a particulate bed.

area A must be balanced by an equal force at position x. Assuming that there is point contact among particles and that the local liquid pressure p_L is effective over the entire cross-sectional area leads to

$$Ap_L + F_s = Ap \tag{22.30}$$

Dividing Equation (22.30) by A and then defining the compressive drag or effective pressure by $p_s = F_s/A$, we have

$$p_L + p_s = p \tag{22.31}$$

The drag on the particle is an accumulation of form drag force resulting from friction along the surface of the particles and is transmitted through the point contacts over which the stress acts. The term p_s is a fictitious pressure used for convenience. It is called "effective pressure" in soil mechanics. In actual cakes, of course, there is a small area of contact, and the pressure at the contact points is much larger than the average given by p_s.

In thickening and centrifugation when gravitational and centrifugal stresses are involved, Equation (22.31) is replaced by more complex expressions Tiller and Hsyung (1993).

The quantities p_L and p_s vary with position and time and are functinos of (x,t). The applied pressure is either constant or a functin of time alone. If we take differentials with respect to x in the interior of the cake at constant t, we have

$$dp_s + dp_L = 0 \tag{22.32}$$

The effective pressure increases and hydraulic pressure decreases as the liquid flows from the upstream face of the cake toward the filter medium.

Variations of the hydraulic and solid or effective pressures in a typical filter cake are illustrated in Figure 22.27. The liquid pressure drops from the pump pressure at the cake surface to a value p_1 at the medium. At the surface of the cake where $p_L = p$, the effective pressure is zero as no drag on the particles has developed. Consequently, the surface layer of the cake is unstressed, and the solidosity has its minimum value at that point. The solidosity reaches a maximum at the medium

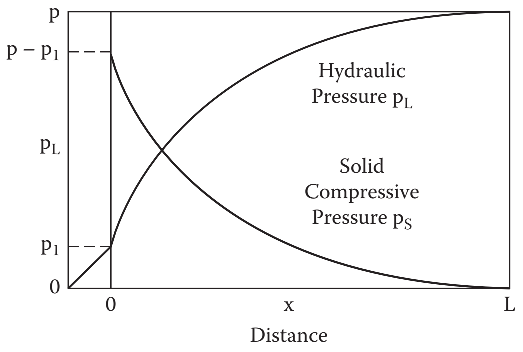

FIGURE 22.27 Variation of hydraulic and effective pressures in a compressible filter cake.

where the effective pressure has risen to its maximum value and equals the pressure drop across the cake. Whereas the solidosity at the cake surface theoretically remains the same regardless of the pressure drop, the solidosity at the medium increases as the pressure drops becomes larger.

22.4.6.2 Darcy's Law

The Darcy equation was first developed to describe the linear flow of liquid through incompressible sand beds in the form

$$q = \frac{K_{av}\Delta p}{\mu L} \tag{22.33}$$

in which K_{av} the average permeability was a constant for the sand bed; and Δp was the overall pressure drop across the sand bed of thickness L.

Differential forms involving both spatial and material coordinates illustrate the relationship of local values of permeability and specific resistance α to the gradients of p_L with respect to x and ω:

$$q = \frac{K}{\mu}\frac{dp_L}{dx} = \frac{1}{\mu\alpha}\frac{dp_L}{d\omega} \tag{22.34}$$

The spatial coordinate x is the distance from the medium, and the material coordinate is the volume of solids/unit area in distance x as shown in Figure 22.25. The volume of solids $d\omega$ in dx is related to local solidosity by

$$d\omega = \varepsilon_s dx \tag{22.35}$$

Integrating Equation (22.35) from $x = 0$ to L and $\omega = 0$ to ω_c produces

$$\int_0^{\omega_c} d\omega = \omega_c = \int_0^L \varepsilon_s dx = \varepsilon_{sav} L \tag{22.36}$$

where ε_{sav} is the average solidosity of the cake. Substituting Equation (22.35) into Equation (22.34) yields the following relationship involving the characteristic parameters, α, and ε_s:

$$K\alpha\varepsilon_s = 1 \tag{22.37}$$

As K, α, and ε_s are functions of frictional effective pressure p_s rather than hydraulic liquid pressure p_L, it is necessary to replace dpL by $-dp_s$ in Equation (22.34). Making this substitution yields

$$q = -\frac{K}{\mu}\frac{dp_s}{dx} = -\frac{1}{\mu\alpha}\frac{dp_s}{d\omega} \tag{22.38}$$

To integrate the particulate Equation (22.38), K and α must be provided as functions of p_s.

22.4.6.3 Empirical Constitutive Equations

Empirical models of local solidosity, permeability, and specific resistance as functions of p_s can be in many forms. Tiller and Leu (1980) presented the following equations:

$$\left(\frac{\varepsilon_s}{\varepsilon_{so}}\right)^{1/\beta} = \left(\frac{K}{K_o}\right)^{-1/\delta} = \left(\frac{\alpha}{\alpha_o}\right)^{1/n} = 1 + \frac{p_s}{p_a} \tag{22.39}$$

in which p_a is an empirical parameter; and β, δ, n are cake compactibility coefficients. They provide a measure of the rate of change of ε_s, α, K with p_s. As a rough approximation, the exponents can be related by

$$\delta / 5 = n / 4 = \beta \tag{22.40}$$

22.4.6.4 Integration of the Darcy Equation

Combining the boundary conditions at the cake surface ($x = L$ or $\omega = \omega_c$, $p_s = 0$) and at the medium ($x = 0$ or $\omega = 0$, $p_s = \Delta p_c = p - p_1$) with the empirical constitutive equations ([Equation (22.39)]; assuming q is independent of x and is only a function of t, the particulate structure Equations (22.38) can be integrated to yield

$$\int_o^L \mu q dx = \mu q L = K_{av}\Delta p_c = \int_o^{\Delta p_c} K_o\left(1 + p_s / p_a\right)^{-\delta} dp_s = \frac{K_o P_a}{1-\delta}\left[\left(1 + \frac{\Delta p_c}{p_a}\right)^{1-\delta} - 1\right] \tag{22.41}$$

and

$$\int_0^{\omega_c} \mu q d\omega = \mu q \omega_c = \Delta p_c / \alpha_{av} = \int_0^{\Delta p_c} \frac{dp_s}{\alpha_o\left(1 + p_s / p_a\right)^n} = \frac{p_a}{\alpha_o(1-n)}\left[\left(1 + \frac{\Delta p_c}{p_a}\right)^{1-n} - 1\right] \tag{22.42}$$

These two equations give an instantaneous view of the cake and provide relationships among q, ω_c, L, K_{av}, α_{av}, and p_c. Equations (22.41) and (22.42) can be easily solved for q as a function of L or ω_c and Δp_c. Dividing Equation (22.42) by (22.41) leads to

$$\frac{\omega_c}{L} = \varepsilon_{sav} = \varepsilon_{so}\left(\frac{1-\delta}{1-n}\right)\frac{\left(1+\Delta p_c / p_a\right)^{1-n}-1}{\left(1+\Delta p_c / p_a\right)^{1-\delta}-1} \tag{22.43}$$

where $1/\alpha_o K_o$ has been replaced by ε_{so} in accord with Equation (22.37). It is clear from the above equations that the flow rate and the volume fraction of cake solids are dependent on the null-stress cake structure parameters ε_{so}, K_o, α_o, and cake compressibility coefficients n, δ, β.

22.4.7 Strange Behavior of Super-Compactible Materials

The relative compactibility of cakes can be crudely classified in accord with the magnitudes of n and δ as shown in Table 22.5.

The cake compactibility parameters for an incompressible material carbonyl iron, a moderately compactible kaolin flat D, and a super-compactible activated sludge are given in Table 22.6.

For super-compactible materials when $n > l$ and $\delta > 1$, $(1 - n)$ and $(1 - \delta)$ are negative; and Equations (22.42) and (22.43) are best rearranged as follows:

$$\mu q\omega_c = \Delta p_c / \alpha_{av} = \frac{p_a}{\alpha_o\left(n-1\right)}\left[1-\frac{1}{\left(1+\Delta p_c / p_a\right)^{n-1}}\right] \tag{22.44}$$

$$\varepsilon_{sav} = \varepsilon_{so}\left(\frac{\delta-1}{n-1}\right)\frac{1-1/\left(1+\Delta p_c / p_a\right)^{n-1}}{1-1/\left(1+\Delta p_c / p_a\right)^{\delta-1}} \tag{22.45}$$

As Δp_c increases indefinitely in Equation (22.44), (22.45), the term with Δp_c in the denominator approaches zero. Plots of calculated values of flow rate and average solidosity as functions of pressure drop across cakes with $\omega_c = 0.02$ m³/m² are shown in Figures 22.28 and 22.29 for the three materials listed in Table 22.6. Whereas the flow rate q increases linearly with Δp_c for

TABLE 22.5
Classification of Cake Compactibility

Incompressible	$n = 0$	$\delta = 0$
Moderately compactible	$N \approx 0.4$–0.7	$\delta \approx 0.5$–0.9
Highly compactible	$N \approx 0.7$–0.8	$\delta \approx 0.9$–1.0
Super-compactible	$n > 1$	$\delta > 1.0$

TABLE 22.6
Cake Compactibility Parameters for Three Materials

Materials	ε_{so}	α_0, m^{-2}	β	n	δ	p_a, Pa
Carbonyl Iron, grade (Grace 1953)	0.575	2.34(E13)	0.001	0.005	0.006	—
Kaolin flat D (Chen 1986)	0.14	2.98(E13)	0.12	0.4	0.52	11
Activated sludge (Kwon 1995)	0.05	3.62(E14)	0.26	1.4	1.66	190

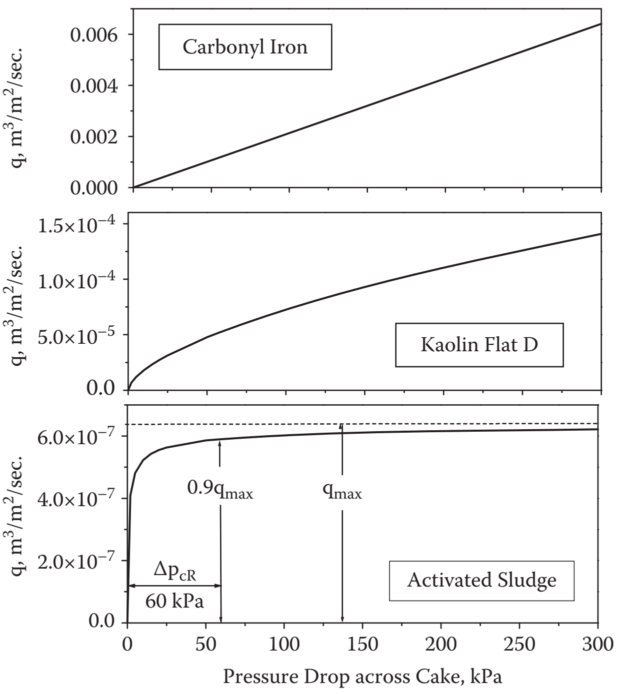

FIGURE 22.28 Variation of q against Δp_c.

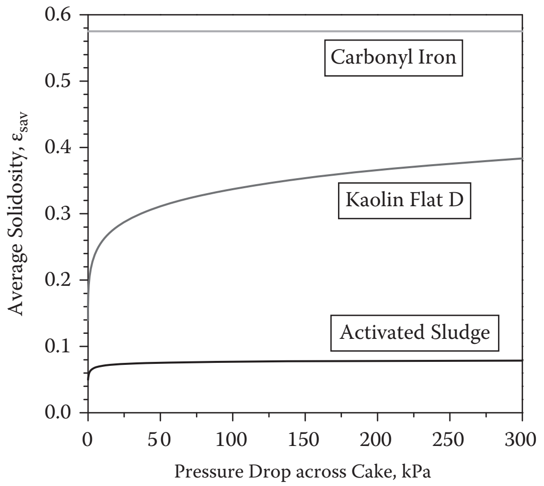

FIGURE 22.29 Variation of ε_{sav} against Δp_c.

incompressible materials like carbonyl iron, it increases with a power of Δp_c, which is less than unity for compactible materials like kaolin. Unfortunately, for super-compactible materials with $n > 1$ and $\delta > 1$, increasing the pressure drop beyond some low value has negligible effect on the flow rate and average solidosity, and both q and ε_{sav} approach maximum values.

22.4.8 Critical Pressure Drop

As Δp_c approaches infinity, the limiting values of the flow rate and average solidosity become

$$q_{\max} = \frac{p_a}{\alpha_o (n-1)\mu\omega_c} \tag{22.46}$$

$$\varepsilon_{sav,\max} = \varepsilon_{so}\left(\frac{\delta - 1}{n-1}\right) \tag{22.47}$$

Dividing Equation 22.34 by Equation (22.46) and dividing Equation (22.45) by Equation (22.47) provides the ratios of the flow rate and the average solidosity to the maximum values:

$$q / q_{\max} = \gamma = 1 - \frac{1}{\left(1 + \Delta p_c / p_a\right)^{n-1}} \tag{22.48}$$

$$\varepsilon_{sav} / \varepsilon_{sav\max} = \lambda = \frac{1 - 1/\left(1 + \Delta p_c / p_a\right)^{n-1}}{1 - 1/\left(1 + \Delta p_c / p_a\right)^{\delta-1}} \tag{22.49}$$

Substituting Equation (22.48) into Equation (22.49) yields a relationship between γ and λ:

$$\lambda = \frac{\gamma}{1 - (1-\gamma)^{(\delta-1)/(n-1)}} \tag{22.50}$$

For activated sludge, when $\gamma = 0.90$, and $\lambda = 0.92$, the pressure reaches a critical point where a further increase of pressure drop will have little effect on flow rate or average solidosity as shown in Figures 22.28 and 22.29. A critical pressure drop can be defined as that value at which q reaches 90% of its ultimate rate given by Equation (22.48).

$$\Delta p_{cR} = p_a\left[\left(\frac{1}{1-\gamma}\right)^{1/(n-1)} - 1\right] = p_a\left[\left(\frac{1}{1-0.9}\right)^{1/(n-1)} - 1\right] = p_a\left[10^{1/(n-1)} - 1\right] \tag{22.51}$$

Equation (22.51) can be applied to calculate the operational pressure beyond which a further increase of pressure will have little effect on either the flow rate or the average cake solidosity. For the activated sludge in Table 22.5, if $\gamma = 0.90$, the critical pressure drop across the cake calculated from Equation (22.51) is 60kPa (8.7 psi), which corresponds to the results shown in Figures 22.28 and 22.29.

22.5 SOLID/LIQUID SEPARATION EQUIPMENT AND OPERATION

An overview of some of the major types of equipment in relation to the four stages of SLS is provided in Figure 22.30. After inorganic salts and polymers have been used in the pretreatment, the resulting slurry is fed to a gravity thickener. The overflow from the thickener passes through a deep-bed for removal of fine particles. The underflow goes to the solids separation operations, which are classified according to the driving force, e.g., gravity, vacuum, pressure, or centrifugal.

Gravity separation involving large particles is usually accomplished with screens that may be stationary, vibrating, or rotating cylinders. Large screens have slot openings greater than 0.5 in.

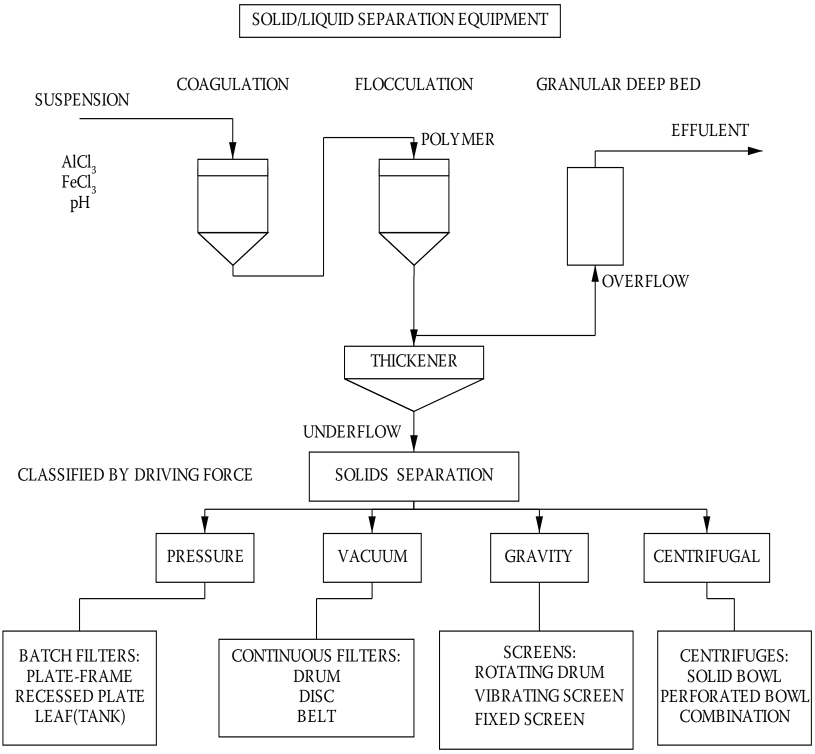

FIGURE 22.30 Equipment used for the four stages of solid/liquid separation.

and small screens have openings of less than 0.5 in. Slot openings in rotary screens run from 0.01 to 0.1 in. (254–2540 μm). Micro-screens frequently fall in the 15 to 60 micron range.

In vacuum filtration, the driving force (~20 in Hg = 10 psi, 1 psi = 4895 Pa) is slightly higher than the gravity. The vacuum operation frequently is tied in with continuous equipment such as drum, disc, or belt filters, in which cake is removed continuously. As the permeability of cakes diminishes, pressure becomes an important element in producing a satisfactory flow rate. Pressure filters are operated in the range of 30 to 60 psi and sometimes up to 100 psi. In contrast to vacuum filters, pressure filters normally operate in batch mode. In addition to vacuum and pressure, centrifugal forces are also used to increase the driving force in separation of particles from liquids.

Solid/liquid separation equipment can be also classified according to the principle of each unit operation, which is presented in Section 22.1.4. A list of equipment based on operating principle is given in the next section.

22.5.1 Batch Pressure Filters

Pressure filters are usually operated batch-wise. The batch pressure filters can be classified as tank (pressure vessel) filters or presses. Tank filters have filter elements of different types mounted in pressure vessels. Tank filters are divided into pressure nutsches, leaf filters, candle or tubular filters, bag filters, and cartridge filters. Presses (see Figure 22.38) consist of a series of filter surfaces (plates). The elements are mounted on a frame and are pressed together mechanically.

22.5.1.1 Pressure Nutsches

Nutsche filters contain a single horizontal filtering surface in a pressure vessel. Gas is used to provide pressure for filtration and avoid the use of a high-pressure pump. Due to the limited filtration

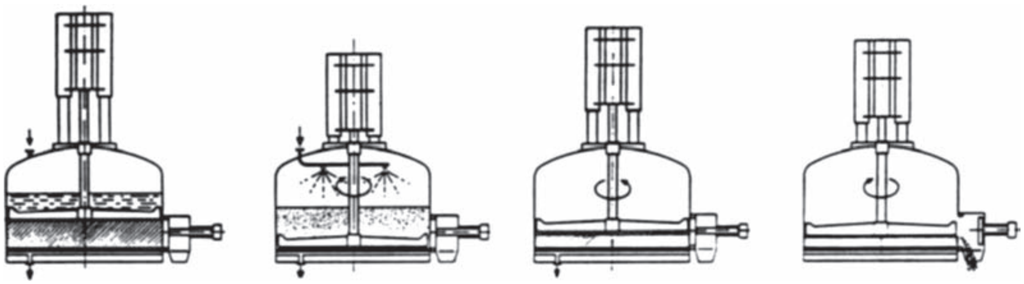

FIGURE 22.31 Operation of and automatic Nutsche filter.

area, they are often operated with thick cakes and are suitable for small batches. Automatic nutsches are available to perform reaction, crystallization, filtration, reslurry washing, drying, and cake discharging in the same vessel. GMP (Good Manufacturing Practices of FDA) design is also available for processing different pharmaceutical materials. Operation of an automatic nutsche filter is shown in Figure 22.31.

22.5.1.2 Leaf Filter

In comparison with nutsche filters, leaf filters provide more filtration area in the same volume of a pressure vessel. They are more suitable for handling larger quantities of slurry. Leaf filters can be subdivided into four classes in accord with the vertical or horizontal position of the tanks and leaves. In Figures 22.32 and 22.33, vertical leaves are shown in vertical and horizontal tanks. For vertical leaf filters, to prevent cake dropping, the cake thickness is normally restricted to 3.5 to 4.0

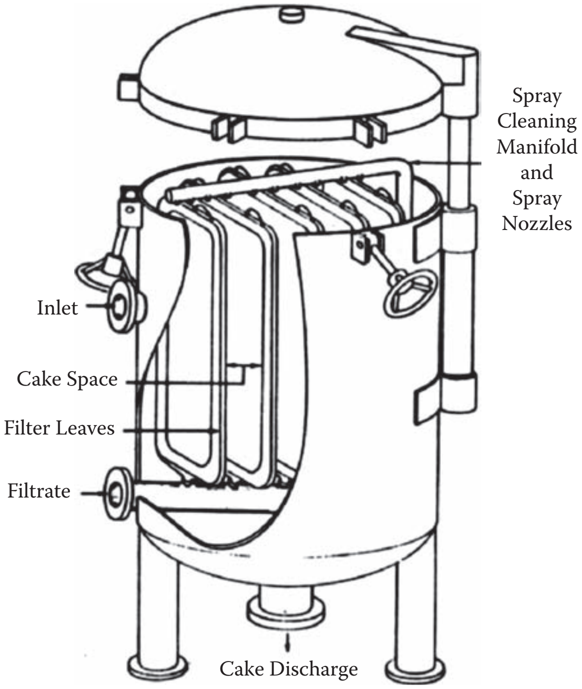

FIGURE 22.32 Vertical tank vertical leaf filter.

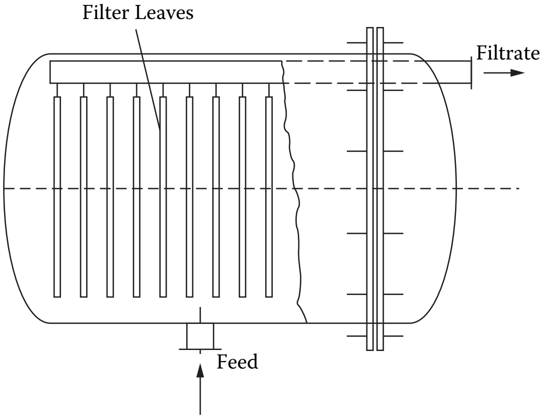

FIGURE 22.33 Horizontal-vessel, vertical-leaf filter.

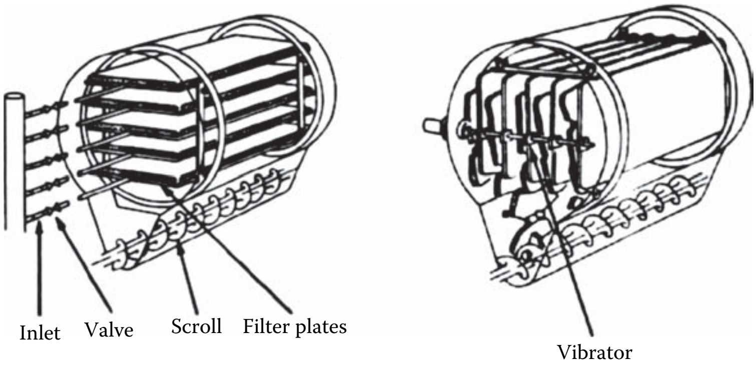

FIGURE 22.34 A Sparkler leaf filter with leaves in horizontal position during precoat, filtration, washing, and drying and vertical position during the cleaning cycle.

cm. A space of ~2.0 cm must be maintained between the cakes to prevent arching and facilitate discharge. Cake discharge from the vertical leaves can be accomplished by manual means, vibration, rotation at a slow speed against blades, blow back of gas, or by flushing with liquid. Horizontal leaves assure uniform deposition and washing. However, cakes are not easy to remove from the horizontal leaves. Centrifugal action provided by rotating of leaf bundles is used for cake discharging in some designs of horizontal leaf vertical tank filters. In general, cake can be discharged more easily from vertical leaf-type filters. A kind of leaf filter from Sparkler Filter, Inc. uses leaves in horizontal position during precoat, filtration, washing, and drying, but in vertical position during discharging and cleaning as shown in Figure 22.34. The design combines advantages of horizontal leaf and vertical leaf, and can provide completely automatic operation.

Pressure vessel filters are useful where noxious vapors are involved, and a completely closed system is desirable.

22.5.1.3 Candle Filter

Tubular filter elements contained in a matching vessel are known as candle filters. A typical candle filter (Purchas 1981) is shown in Figure 22.35. The filter vessel may contain one or more filter candles. The advantage of candle filters is the capability of back pulsing (with dry gas) or back-washing (with liquid) to automatically discharge the cake as shown in Figure 22.36. Some designs

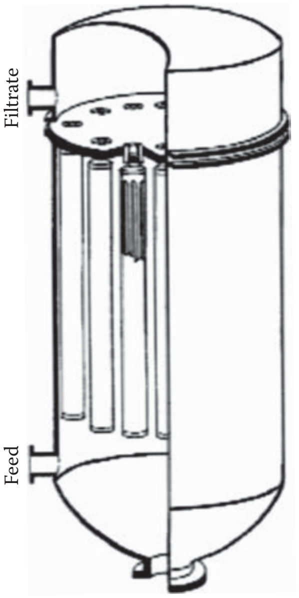

FIGURE 22.35 A candle filter.

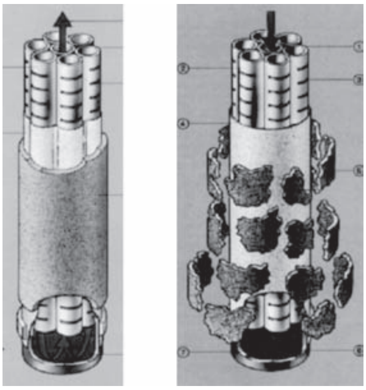


(a) Filtration (b) Back Pulsing

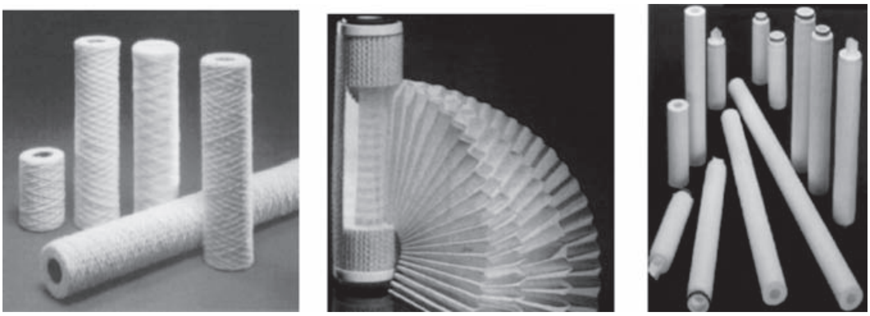
FIGURE 22.36 a, b: Filtration and back pulsing.

use registers with easy release devices to permit easy isolation of separate candle bundles in case of candle failures, as well as elimination of heavy head plate.

The candle filter element can be textile cloth over a supporting tube, sintered metal, ceramic or spaced rings. It can also be used for air or gas filtration. Metallic candles are particully suited for high temperature applications.

22.5.1.4 Bag Filters

Disposable bags made of synthetic fibers are fitted into a simple pressure vessel to remove particles from liquid. Such filters are least expensive and very commonly used. Due to the limited surface area, the solid loading should be very low in a bag filter unless the solids can form a permeable cake. It is important to replace the bag when pressure reaches 1 kg/cm^2 (15 psi) before it is



(a) Wound Cartridge (b) Pleated Cartridge (c) Melt Blown Cartridge

FIGURE 22.37 a–c: Cartridge filters.

completely plugged. Otherwise, a liquid full bag needs to be removed, resulting in product loss and industrial hygiene concerns for the operators.

22.5.1.5 Cartridge Filters

Cartridge filters are very commonly used. In industrial processes, usage of bag filters or cartridge filters is greater than other SLS equipment combined. Three types of cartridge filters are shown in Figure 22.37.

In string wound cartridge, fiber yarn is wound around a mandrel to form a depth medium. Filtration is primarily done by deep-bed filtration and the separation efficiency is poorer than the pleated type. Because string wound cartridges are less expensive, they are commonly used as the prefilter in front of the more expensive pleated cartridges. Pleated cartridges are fabricated by pleating fabric sheet to provide additional surface area and strength. The filtration mechanism is surface straining so the filtration efficiency curve is steeper. They are used when high collection efficiencies for specific particles are required. The mechanisms of melt blown or resin bonded cartridges are deep-bed filtration, that will be discussed later.

A term called the β ratio is commonly used to describe the filtration efficiency of cartridge filters. The β ratio is calculated by

$$\beta \text{ ratio} = C_{\text{feed}} / C_{\text{filtrate}} \tag{22.52}$$

where C_{feed} and $C_{filtrate}$ represent the particle count per unit volume in the feed and filtrate.

22.5.1.6 Filter Presses

Filter presses play an important role in SLS since the nineteenth century. They are used when enclosed operation is not required. An excellent treatment of practical problems encountered with presses was provided by Alliot (1920). There are basically three types of filter presses: plate and frame, recessed, and membrane (diaphragm).

A plate and frame filter press is illustrated in Figure 22.38. A filter medium (usually cloth or paper) placed over a grooved plate serves as the support for the cake, which is deposited in an adjoining frame. Plates and frames are alternated as shown in Figure 22.38. The media serves as the gasket when mechanical closure is effected. Where washing is desired, every other plate is constructed so that liquid can be passed from one plate through the cake to the opposite plate. Thus the wash liquid passes through two cakes. Feed to a plate and frame press is generally through openings at the bottom corner. Large, dense particles tend to settle out, producing a nonuniform

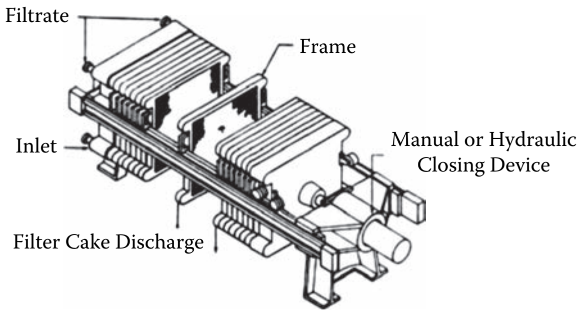


FIGURE 22.38 Plates and frames are alternated on a widebar mechanism.

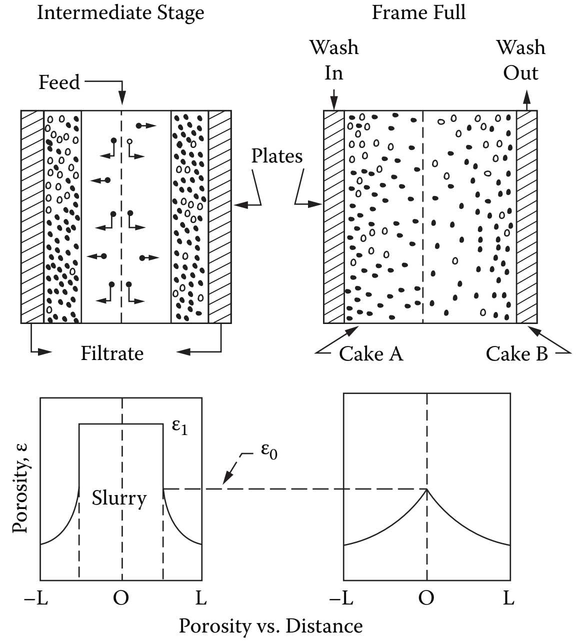

FIGURE 22.39 Ideal cake deposition in a press showing two cakes being laid down simultaneously.

cake with a greater permeability at the bottom. Upward feed has the advantage of reducing sedimentation tendencies.

In Figure 22.39, idealized deposition of cakes in a press is shown. Slurry enters the frame and deposits cakes on plates on either side as illustrated. The cakes, *A* and *B*, build out from the plates and meet at the center when the press is full. The cake surfaces meet at the dotted centerline, and a porosity vs. distance curve is developed as shown. Porosity varies from a maximum ε_0 at the unconsolidated cake surface to its minimum value ε_1 at the medium. In the washing mode for presses, liquid flows in one plate, passes through both cakes, and exits from the opposing plate. It traverses cake *A* in reverse flow with respect to the filtrate. The reversal in flow direction brings about a marked change in the frictional stresses and causes the cake to compact.

The recessed plate press as shown in Figure 22.40 does not require a frame. The edges of the plate are extended outward, leaving a space for a cake. Recessed plate presses are somewhat simpler than plate and frame presses. A center feed as shown in Figure 22.40 is common with recessed plates.

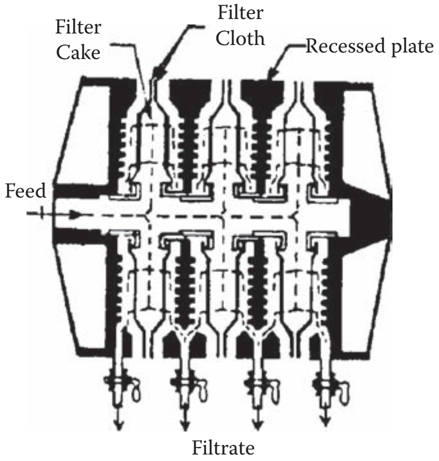

FIGURE 22.40 The recessed plate provides space for cakes and eliminates the need for frames.

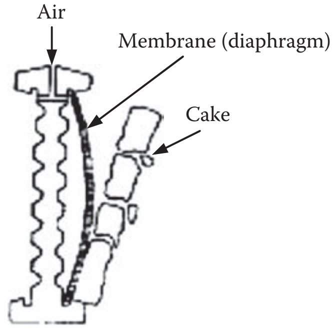

FIGURE 22.41 The membrane filter press.

A membrane filter press is shown in Figure 22.41. The impermeable flexible membranes, or diaphragms, are attached on the recessed plates. At the end of cake formation, the membranes can be inflated by air or pressured water to squeeze the cake for further cake deliquoring. This type of filter provides drier cakes compared with traditional plate and frame of recessed plate filter presses.

22.5.2 Continuous Filters

Continuous filters can be classified into rotary drum (Figure 22.42), disc (Figures 22.42, 22.43, 22.44), horizontal belt (Figure 22.45), table, and tilting pan. Drum filters are further divided according to the method used for cake removal. Most continuous filters use vacuum, and are best suited for materials that permit a reasonably fast rate of cake buildup. Continuous filters work best on medium-sized particles in the range of 5 to 50 μm. Larger particles generally exert minor capillary forces; therefore, cake drying or "drainage" can be accomplished by sucking air through the cakes under vacuum.

22.5.2.1 Rotary Drum and Disc Filters

The salient features of rotary drum and disc filters are illustrated in Figure 22.42. The rotary drum consists of a cylindrical drum having a permeable surface revolving partially submerged in a slurry. Disc filters consist of a series of thin discs revolving on a common shaft and partially submerged in a slurry, which is also shown in Figure 22.43. Continuous filters are normally used for materials

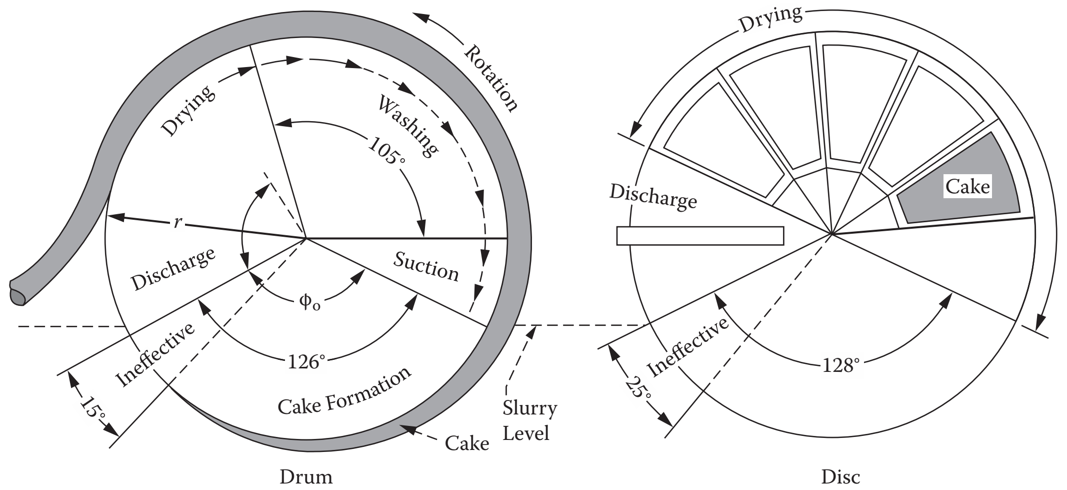

FIGURE 22.42 Cycles for disc and drum filters show cake formation, suction, washing, drainage, and discharge sections.

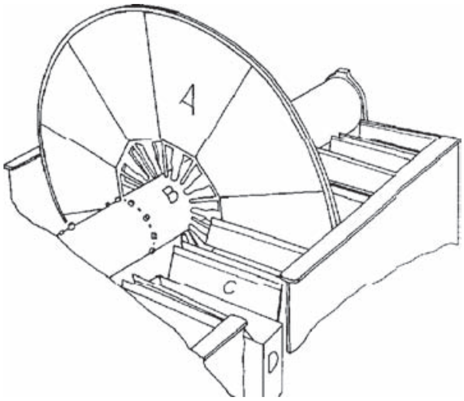

FIGURE 22.43 Isometric view of disc filter.

that are relatively concentrated and easy to filter. Rates of cake buildup are usually measured in cm/min. Submergence normally runs from 25% to 75% of the radius (40% being quite common) with rotation speeds from 0.1 to 3 rpm. With those conditions, filtration times usually range from 5 sec to 7.5 min. Drum diameters typically run from 1.8 to 3.6 m (6 to 12 ft), although larger values may be encountered.

A pressure differential is usually maintained between the outer and inner surfaces by means of a vacuum pump. However, the discs or drum can be enclosed and operated under pressure. In addition to the vacuum or pressure, each point on the periphery of the drum or disc is subjected to a hydrostatic head of slurry. With 40% submergence and a 12 ft (1 ft = 0.3048 m) diameter, the hydrostatic head ranges up to 5.7 ft, which is a significant fraction of the driving force in a vacuum filtration. As the slurry may have a density greater than water, the effective head may be as high as 6 to 7 ft.

The cycle shown in Figure 22.42 for a rotary drum filter consists of

1. Period during which the vacuum source is blocked to prevent air from being drawn through the medium. No filtration takes place.

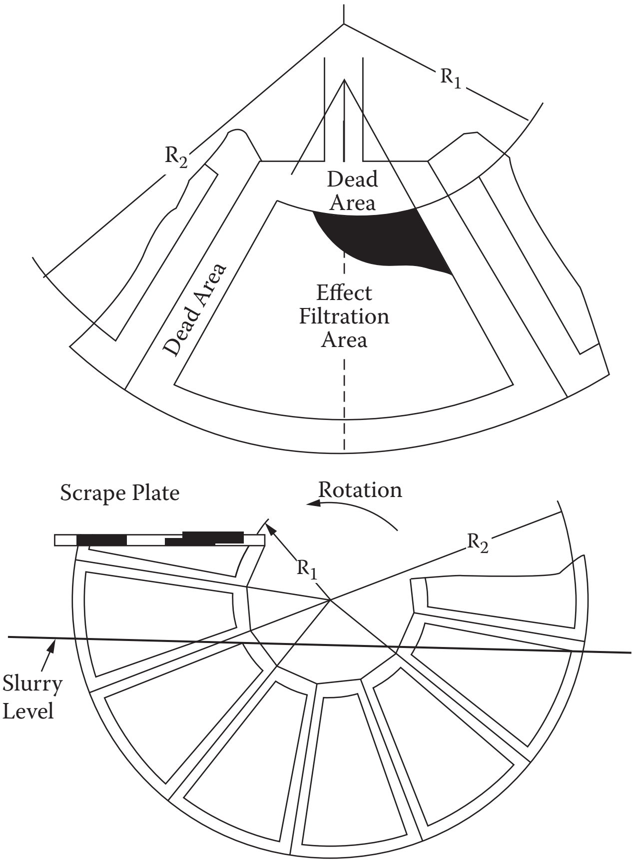

FIGURE 22.44 Horizontal filter illustrating filtration, washing, and drainage stages.

2. Cake formation period.
3. Emergence from slurry with suction causing some drainage to occur.
4. Application of a spray for displacement washing.
5. Drainage period that is frequently called *drying,* although no evaporation takes place. Steam heating reduces viscosity and surface tension and permits improved drainage. Displacement by influx of air may occur.
6. Cake discharge.

Although processes requiring the three steps of cake formation, washing, and drainage (drying) can be more easily done on a drum or horizontal belt filter, drainage can also be accomplished with discs. As illustrated in Figure 22.43, the filter consists of a series of discs *A* that rotate on a common axis in a slurry. The cake is scraped off at *C* and dropped into discharge chutes *D.* Each chute receives solids from facing sides of adjacent discs. The discs are divided into sections that have individual connections to the vacuum and air for the filtering, drainage, and blow zones. Piping is enclosed in the central revolving barrel connected to a wear plate that contacts a control block. Filtration takes place on both sides of the disc. Vacuum is applied inside, and the filter cake is deposited on the disc surface as it rotates through the slurry with only a part of the disc being submerged. At the end of the cycle, the vacuum is broken and the cake discharged. Cake removal from a rotary drum filter is carried out by a number of methods that are related to the properties of the cake and how it sticks to the medium. In Table 22.7, the minimum cake thickness for discharge is shown for different types of drums.

TABLE 22.7
Minimum Cake Thickness Design for Discharge

Filter Type	Minimum Cake Thickness (in.)
Drum	
Standard scraper	1/4
Belt	1/8 to 3/16
Roll discharge	1/32
Coil	1/8 to 3/16
String discharge	1/4
Horizontal belt	1/8 to 3/16
Disc	3/8 to 1/2

Comparison of disc and drum filters indicates that the former may be expected to give two to three times the flow rate of the latter for equal floor space and the same radii. For the disc filter, there is an optimum value of the inner radius (R_1 of Figure 22.44) that yields a maximum flow rate. The optimum ratio of inner to outer radii varies from about 0.6 to 0.75 and is independent of the properties of the slurry (Tiller 1974).

The cake formation time in drum and disc filters is strictly limited to about 40% of the cycle. The times required for adequate washing and drainage are a direct function of solid properties and cake thickness. The form time only occupies about 12% of the circumference. The various stages on the horizontal filter are completely adjustable, and the entire filter surface can be utilized in contrast to the limitations of the disc or drum types.

22.5.2.2 Horizontal Belt Filter

A horizontal filter is shown in Figure 22.45. It occupies more space than drum and disc filters for the same filter area. Normally drum or disc filters are more economical. When settling is acute, belt filters must be used in preference to the drum with the downward facing surface and the disc with the vertical filter surface.

22.5.2.3 Indexing Belt Filter

Like horizontal belt filters, the indexing belt filters are operated semicontinuously under vacuum or pressure. The belt is stationary during filtration and indexes forward for cake discharge. Dispos-

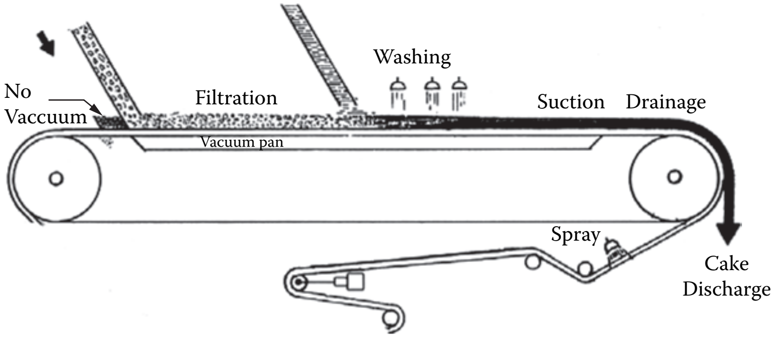

FIGURE 22.45 A continuous horizontal filter.

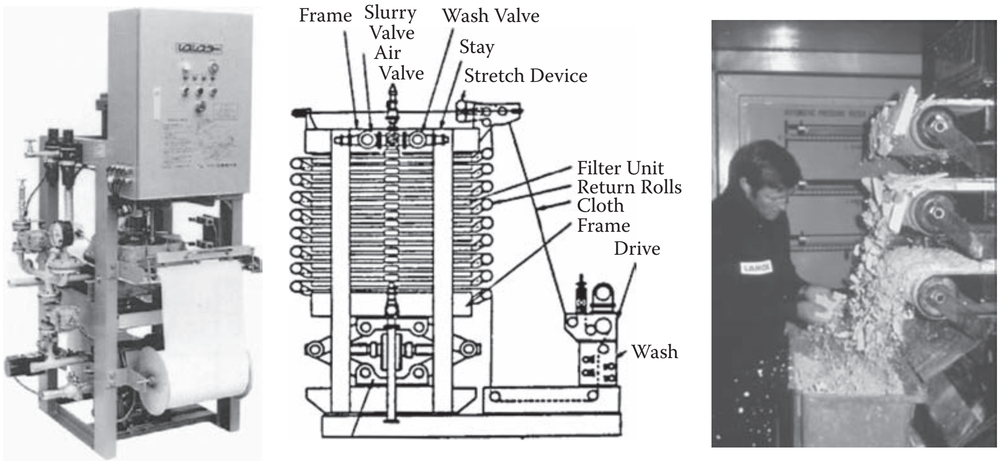

(a) With Disposable Media (b) Tower Press

FIGURE 22.46 Indexing belt figures.

able media are employed when solids tend to stick to or blind the media (Figure 22.46a). They are especially useful for small waste stream clarifications. A few of these filters can be stacked to increase the filtration area and are called tower presses (Figure 22.46b). In tower presses, only permanent belts are used.

22.5.3 Deep-Bed Filter

Deep-bed filters are employed for slurries with very dilute concentration (<100 ppm = mg/L). The deep beds are in the form of granular media (sand, crushed anthracite coal, garnet) or cartridges (Figure 22.37), which are cylinders containing a variety of materials for trapping the particles. An example of the widely application of cartridge filters is removing particles from lubricating oils in automobiles and trucks.

A typical depth-type cartridge is shown in Figure 22.47. They are disposable. The illustration shows an outer region with large pores and high permeability and an inner region with smaller pores. This gradient design provides filtration efficiency without sacrificing on-line life.

Sand and anthracite are the two most commonly used media in granular bed filters. Single, dual, or multiple media can be used. Finer granular provides higher filtration efficiency but has a

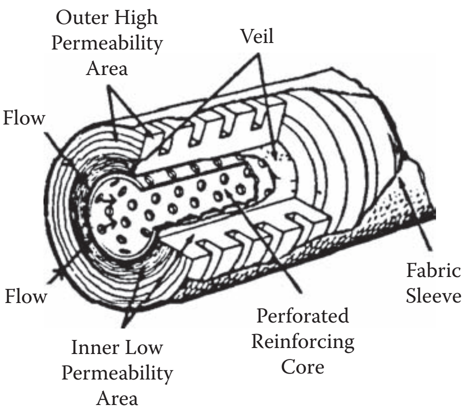

FIGURE 22.47 Johns-Manville cartridge.

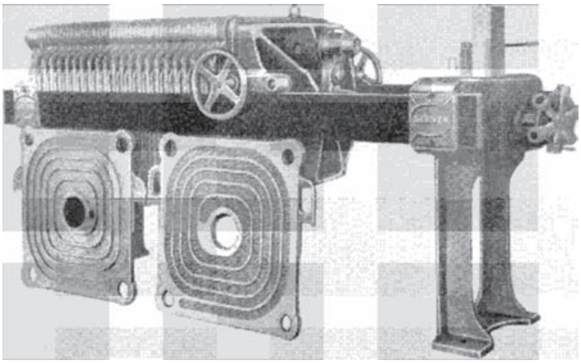

FIGURE 22.48 Shriver continuous cross-flow filter thickener.

smaller bed porosity to accommodate the filtered particles. Coarser granular offers more solid loading capacity but with lower filtration efficiency. Dual or multiple media offer the advantage of graded porosity in the bed to enhance solids loading capacity while maintaining the filtration efficiency. In the filtration process, as the deposit builds up, the permeability ultimately drops to a point where the bed must be regenerated. Backwash is generally used to remove the deposit. Air scours can be employed to improve the cleaning efficiency. The backwash water flow rate is roughly twice the filtration rate. Insufficient backwash rate is the common reason for sand filter failure in the field. Even with good backwashes, the granular media need to be replaced every 4 to 5 years.

There are three basic types of granular bed filters: gravity, pressure, and continuous backwash. Higher filtration rate means a higher filter capacity. However, the higher the feed rate, the lower the filtration efficiency. The proper filtration rate for a particular application is best determined by experimenting with the actual filter. The normal operating range is 1 to 5 gpm/ft^2 (gpm: gallon per minute; 1 gallon = 0.003785 m^3; 1 ft = 0.3048 m) for gravity filters, 7 to 10 gpm/ft^2 for pressure filters and 3 to 6 gpm/ft^2 for continuous filters (Chen 2002). The filtration efficiency also depends on the granular size and bed height and is difficult to predict by theories. Any attempts to deviate from the manufacturer's specifications depend on test data.

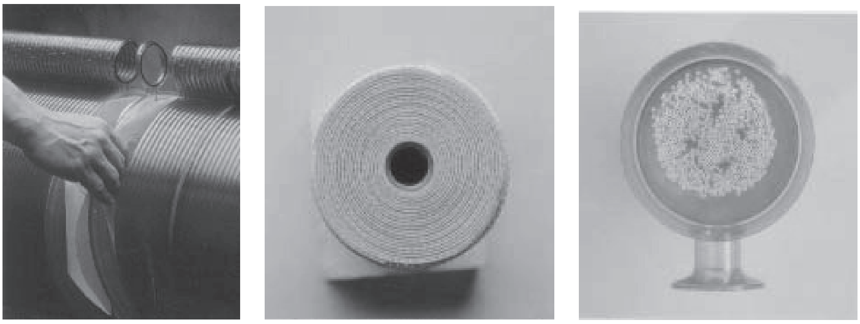
22.5.4 Cross-Flow Filters

In cross-flow filtration (Figure 22.1c) or delayed cake filtration, the slurry flows parallel to the cake surface with sufficient velocity to prevent partially or entirely the deposition of cake. It is used successfully to increase flow rate in membrane filtration. It is also employed for concentrating and recovering very fine particles in dilute suspensions when deep-bed or cake filtration would not be applicable. In Figure 22.2, cross-flow filtration is employed for both slurry concentrating or thickening (stage 2) and separation (stage 3).

There are basically two types of cross-flow filters. One is without rotating element in which slurry is usually pumped into the filter in the direction parallel to the filter media to produce a cross flow. A modified plate-and-frame filter press provides channels through which the slurry flows (Figure 22.48). There are also units equipped with rotating elements. Either the agitator or the turbines are attached to a rotating shaft.

22.5.5 Membrane Filters

The major application today for cross-flow filtration is in the membrane filtration for bioprocessing or fine particle separations. Based on the size of the particles separated, membrane filtrations are categorized as microfiltration (MF), ultrafiltration (UF), nanofiltration (NF). and reverse osmosis (RO). The ratings of MF membranes are by micron ratings, just like other fabric filter media. In



(a) Flat Sheet (b) Spiral (c) Hollow Fiber

FIGURE 22.49 Typical continuous thickener.

UF and NF, a term called molecular weight cut off (MWCO) is used. MWCO means molecules with molecular weight greater than the MWCO will be rejected by this membrane.

Membrane filters come in three configurations: flat sheet, spiral, and hollow fiber (Figure 22.49). Flat sheet membranes can be attached to the plates and by stacking many plates to achieve a large filtration area. The suspension flows across the membrane surface while the permeate flow through the membrane to the collection channels at the edge of the plates. This configuration is most suitable when concentrated suspension is encountered (a few wt%). The manufacturers tend to make special cassettes or plates that are not interchangeable with other suppliers' products.

Spiral elements are the most popular form of membrane filter today due to their relatively low cost. The membrane in a spiral element is wrapped with spacer sheets into a cylinder (Figure 22.49b). The suspension is flowing in parallel to the axis of the cylinder and the permeate flows spirally into the center collecting chamber. Although the design favors low solid concentrations, it is possible to run suspensions with high solid concentrations in a spiral membrane filter.

In hollow fiber systems (Figure 22.49c), a bundle of hollow fibers are contained within a shell and the suspension flows inside the hollow fiber and the permeate is collected in the shell side. Hollow fibers are best suitable for applications without solid particles. In addition to the above three types, there are also rotating discs, annual gap, and vibrating disc systems for membrane cross-flow filtration.

There are two modes that can be used to operate a membrane filter, concentration or diafiltration. In concentration operations, the permeate passes through the membrane and is collected as a filtrate while the retentate (the unfiltered part) is recycled back to the feed vessel. As more and more permeate is removed, the solid concentration in the retentate increases until the desired concentration is reached or the cross flow becomes inefficient due to the high viscosity. The retentate concentration can be calculate as (Cheryan 1998)

$$C_{retentate} = C_{initial}\left(\frac{V_{initial}}{V}\right)^{R} \tag{22.53}$$

where $C_{retentate}$ and $C_{initial}$ are the solid concentration in the retentate and the initial suspension, and $V_{initial}$ and V are the initial volume and current volume of the retentate in the feed tank. R is the rejection ratio of the species of interest. $R = 1 - C_{permeate}/C_{retentate}$.

In the diafiltration mode, fresh liquid is added to the retentate to maintain a constant retentate volume. This method is useful if some dissolved material in the retentate needs to be extracted to the permeated side. The concentration of retentate can be calculated as (Cheryan 1998)

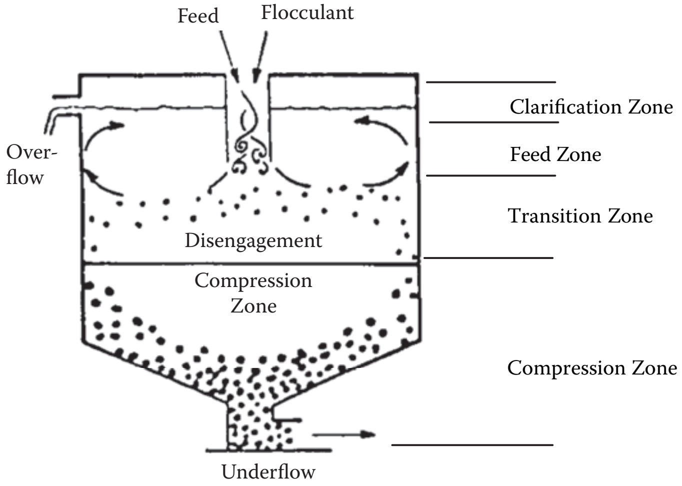


FIGURE 22.50 Typical continuous thickener.

$$C_{retentate} = C_{initial} e^{\frac{V_{permeate}}{V_{initial}}(1-R)} \quad (22.54)$$

where $V_{permeate}$ is the total volume of permeate collected at the time.

22.5.6 Thickening and Clarification

Clarification and thickening are generally related to dilute suspensions. Clarifiers are employed to remove small quantities of solids where the liquids are the main product. Thickeners are used to concentrate dilute suspensions in preparation for further separation in filters and centrifuges. Thickeners frequently lead to the removal of a large fraction of the liquid in a slurry. Gravitational settlers are usually employed for clarification or thickening. A schematic continuous gravity thickener is shown in Figure 22.50. In the figure, a clear liquid overflows the top while a thickened sediment flows out of the bottom as underflow. Thickeners are widely used in fields such as water treatment, aluminum, coal, pulp and paper, cement, and sugar manufacturing.

Usually, there are four zones in a thickener: the clarification zone, the feed zone, the transition zone, and the compression zone. Not all of these zones will be present for all types of slurries. Liquid flows out of the feed zone, up through the clarification zone, and toward the overflow. Below the feed is the transition zone, where the particles start a downward motion. The concentration just below the supernatant-suspension (or sediment) interface assumes a value dictated by the dominance of either free settling or the presence of a compacting sediment. The region containing the particles offers resistance to liquid flow and accepts only a portion of the liquid. The remainder reverses direction and exits as overflow. Under steady-state conditions, both solids and liquid fluxes are constant and independent of depth in the suspension and/or sediment zone. No liquid is squeezed out and upward in the sediment unless channels exist.

A clarifier is designed by keeping the particles from flowing out of the clarifier. In order to do so, the liquid rising rate Q_o/A must be less than the particle settling rate u_s ($Q_o/A \leq u_s$). Therefore, the area of a clarifier can be calculated by

$$A = \frac{Q_o}{u_s} \quad (22.55)$$

where A is the area of the clarifier and Q_o is the overflow rate. The particle settling rate can be estimated with the Stokes' settling equation

$$u_{S,Stoke} = \frac{(\rho_S - \rho_L) g d_p^2}{18\mu} \tag{22.56}$$

where ρ_S and ρ_L are densities of particle and liquid, respectively, g is the gravity acceleration, d_p is the particle diameter, and μ is the liquid viscosity. In a real suspension with a large range of particle size distribution, a cut particle size would be used for Equation 22.56. With known settling velocity u_s, Equation (22.55) can be used to design a clarifier to retain certain sized particles.

Stokes' equation is derived based on a spherical particle settling in an infinite liquid without the interference of other particles. Equation (22.56) becomes less accurate when the solid concentration increases. For suspensions with higher solid concentrations (approximately >1 wt%), the solid particles tend to settle together due to particle–particle interactions. It is called zone settling. For this type of settling, Stokes' law no longer applies and the settling rates are no longer dependent on the particle size but more dependent on the solid concentrations. Although there are correlations to calculate the zone settling velocity, it is better to run a settling test to obtain the settling velocity.

Almost all the design methods for continuous gravity thickener in the zone settling region are based on the following equation (Coe and Clevenger 1916):

$$G_T = \frac{u_S}{\frac{1}{C} - \frac{1}{C_u}} \tag{22.57}$$

where G_T is the total solid flux in the thickener, C and C_u are the solid concentration in the thickener and in the underflow, and u_s is the zone settling velocity corresponding to C that can be obtained by a batch settling test as shown in Figure 22.51. With known $u_s \sim C$ values, solid flux G_T as a function of C at a desired C_u can be calculated based on Equation (22.57), and is shown in Figure 22.52. The smallest G_T at point A represents the bottleneck for solid flux in the thickener. The area (A) of the thickener is designed based on this limiting flux ($G_{T,min}$):

$$A = \frac{Q_{feed} \cdot C_{feed}}{G_{T,\min}} \tag{22.58}$$

For even higher solid concentrations where the particles are in contact with each other, "free settling" phenomena is replaced by "compression" or "consolidation." The Coe and Clevenger–type design methods are not sufficient. Sediment height and consolidation effect need to be included in the thickener design (Tiller and Tarng 1995).

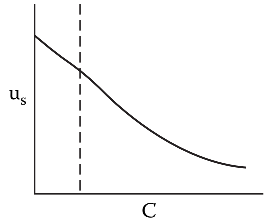

FIGURE 22.51 Settling test for thickener.

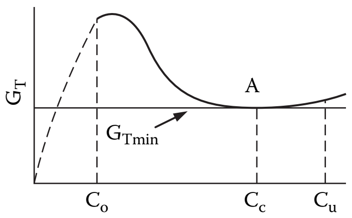

FIGURE 22.52 Designing settler.

22.5.7 Centrifugation

In centrifugation, high-speed rotating equipment is used to generate centrifugal forces as the driving force for separation. Centrifuges can be operated as classifiers, settlers, and filters. The centrifugal acceleration is calculated by $r\Omega^2$, where r = radius and Ω = angular velocity in radians/sec.

Stacked disc centrifuges (Figure 22.53a) are composed of a stack of closely spaced (a few millimeters) discs rotating at high speed (~6000 to 8000 *g*-force). This type of centrifuge is useful to separate fine particles. The narrow gaps between discs greatly reduce the distance for the particles to travel before they settle to the discs. For very dilute suspensions, a solid wall bowl is used. The machine is manually opened to clean the solid in the centrifuge. The bowl can also be automatically opened during the operation to discharge the collected solids. For even higher solid applications, a series of nozzles are installed along the periphery of the bowl to continuously discharge the solids.

Solid bowl decanters operate at lower *g*-forces (~2000 *g*-force) and normally are used for suspensions with high solid concentrations. The slurry enters the decanter as shown in Figure 22.53b. The solids settle out and are conveyed by a scroll mechanism, turning at a lower or faster speed than the bowl, toward the discharge. The clear liquid moves to the cylindrical (right) end and flows over weirs and is removed as *centrate*, corresponding to the filtrate. The region to the right of the slurry inlet is called the *pond.* The solids are conveyed to the conical (left) end along with some liquid, moving up an inclined portion of the bowl (called *beach*) and discharged as the cake.

In filtering centrifuges, the solids settle out as in the decanter. However, the liquid flows in the same direction and out through the perforated bowl. As the liquid flows in the same direction as the solids, it increases the rate of deposition. In addition, as the liquid flows through the cake, the frictional effect results in sharply increased stresses on the cake. At low rotation speeds, the stress due to the frictional flow may be larger than the centrifugal body forces (Tiller and Horng 1983).

Filtering and sedimenting centrifuges operate in sizes from 6 to 60 in. and 500 to 10,000 rpm. The rpm and bowl diameter are limited by the peripheral speed Ωr_b (maximum about 350 ft/sec) (Ambler 1997). A speed of 275 ft/sec corresponds to the heavy dots in Figure 22.49.

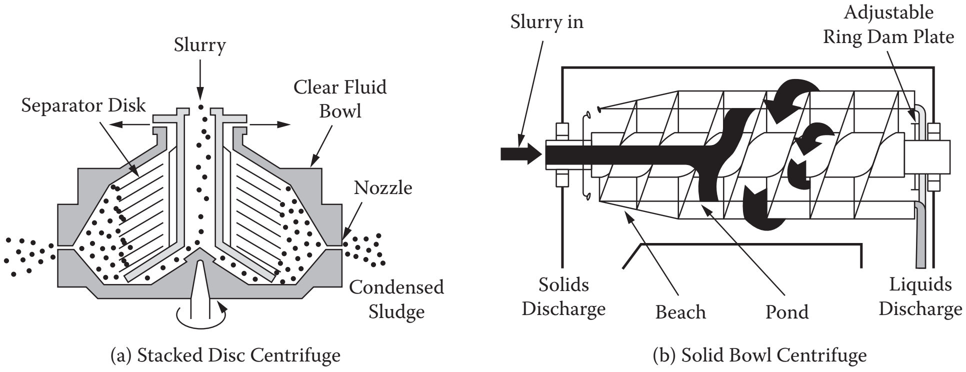

FIGURE 22.53 Typical centrifuges.

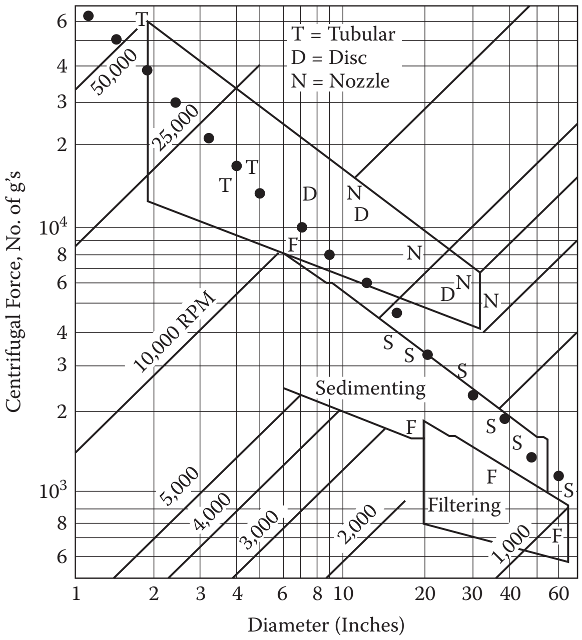

FIGURE 22.54 Classification of centrifuges.

In general, sedimenting centrifuges have smaller diameters and operate at higher speeds in comparison with filtering centrifuges. As a rough guide, centrifuges are designed to operate below the heavy dotted lines in Figure 22.54. The precise location of the dotted line depends up the elasticity and strength of the materials of construction.

In Figure 22.54, centrifuges are classified according to bowl diameter and the number of *g*-forces, which is defined by $r_b\Omega^2/g$, where r_b is the bowl radius. For a dilute suspension with particles in the free-settling region, the higher acceleration for small diameter units leads to improved rates of sedimentation. Tubular and disc types are used primarily for clarification where the throughput rate of solids is small. Solid bowl decanters can be used for processing large solid flow rates.

Compaction forces developed in filtering centrifuges differ markedly from those encountered in sedimenting centrifuges. In sedimenting centrifuges, the solids flow radially toward the bowl and displace liquid, which must then flow radially inward and resulting drag on the particle delays sedimentation and compaction. In a filtering centrifuge, liquid and solids flow in the same direction. Frictional drag due to the liquid flow through the cake adds to the centrifugal body force. The relative magnitudes of the centrifugal and drag induced stresses are important to understanding operating conditions necessary to produce the desired compaction (Tiller and Hsyung 1993).

22.5.8 Hydrocyclone

The hydrocyclone also utilizes the centrifugal forces to separate solid particles. With centrifuges, the equipment is rotating, but hydrocyclones are stationary and the centrifugal force is generated by the rotating of the liquid. A hydrocyclone is normally composed of a cylindrical and a conical part (Figure 22.55). The feed slurry is tangentially fed into the cylindrical section, the clear liquid (overflow) comes out of the top of the cylindrical section (called the vortex finder), and the stream with more solids is discharged from the conical end (underflow).

The construction of hydrocyclones is very simple and therefore very economical compared to all the other solid/liquid separation equipment. However, low efficiencies in separation is the major disadvantage.

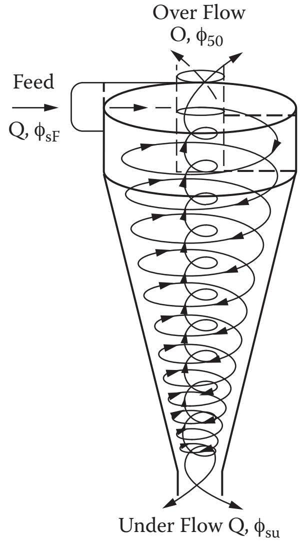

FIGURE 22.55 A hydrocyclone.

There are numerous models to predict the separation efficiencies in hydrocyclones. One example is (Besendorfer 1996):

$$X_{50} = 10 \cdot D^{0.66}\left(\frac{0.53-\phi_{sf}}{0.53}\right)^{-1.43} \cdot \sqrt{\frac{1.65}{\rho_S-\rho_L}} \cdot \Delta P^{-0.28} \cdot \mu^{0.5} \qquad (22.59)$$

where X_{50} is the *cut size,* which means the particle size (in μm) with 50% separation efficiency in this hydrocyclone. D is the hydrocyclone diameter (in inches) at the cylindrical section. ϕ_{sf} is the feed slurry concentration expressed in volume fraction. ρ_s and ρ_L are densities of particle and liquid in g/mL. ΔP is the pressure drop (in psi) between feed and overflow. It needs to be noted that all the models [including Equation 22.59)] require validation with the actual hydrocyclone system under study. Severe discrepancy between operating data and model prediction values are possible (Chen 2004).

22.5.9 Expression Equipment

The extent of flocculation in the pretreatment step can have profound effects on the behavior of cakes and sediments in the succeeding stages. As flocs grow in size, the floc encompasses a growing proportion of liquid. Sedimentation velocities increase, and it appears that separation will be facilitated. However, the highly porous floc produces a cake with a high porosity (may be on the order of 95%), which may have unfavorable filtration characteristics. Because of the high porosity, the cake frequently must be squeezed in an expression operation to reduce the liquid content. Decreasing the liquid content of cakes has become a major objective of many SLS processes. Although the term *dewatering* is widely used, *deliquoring* is more general and covers both aqueous and nonaqueous liquids. Deliquoring operations consist of expression (squeezing), blowing, sucking with a vacuum, and gravitational and centrifugal drainage.

Figure 22.56 shows the mechanically deliquoring of flocculated, fragile and high porosity cakes by a belt filter press. In the process, large flocs settle out rapidly on the porous belt, and the liquid drains through quickly, producing a very soupy cake. Expression (the fourth stage of Figure 22.2) of the liquid from the cake is essential. It is accomplished by the squeezing action of the two

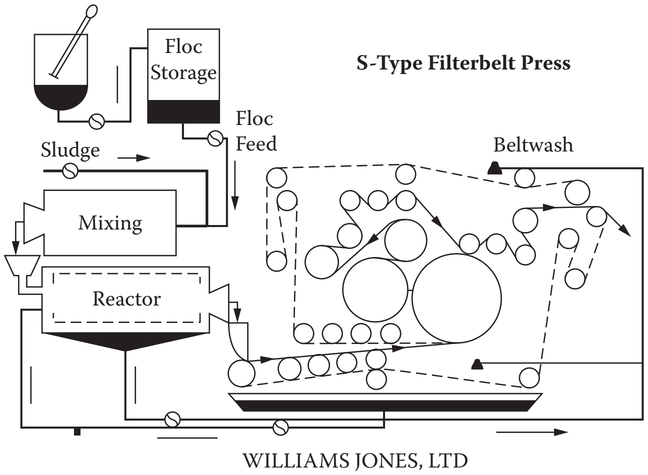

FIGURE 22.56 Deliquoring of flocculated, fragile cakes.

moving belts. A belt filter press is a common type of equipment used for deliquoring activated sludge at many wastewater treatment plants.

A laboratory instrument called a crown press is the best bench device to simulate belt filter press performance.

There are also compression filters which are operated at high pressures. These units are operated in batch mode. The filter press discussed earlier can be equipped with a diaphragm to squeeze the cake after filtration. They are commonly called membrane presses although they have nothing to do with the microfiltration membranes. One variation of the membrane press is the horizontal diaphragm press which also has a diaphragm to compress the cake, but the filter surface is horizontal instead of vertical as in membrane presses. For very high pressure expression, tubular presses can provide squeezing pressures as high as 2000 psi.

22.6 CAKE WASHING

22.6.1 Displaced Washing and Repulping

Cake washing can be classified by (1) displacement washing: using clear liquid to displace mother liquor in the cake; and (2) repulping: diluting with liquid, and filtering again. Initial liquid leaving the cake in displacement washing as shown in Figure 22.57 has a concentration equal to that of the mother liquor. When approximately half (a large variation in this value can be encountered with non-Newtonian liquids, nonuniform cakes, or where there is cake cracking) of the original liquid has been displaced, fresh wash breaks through, and the exit concentration begins to drop rapidly. Displacement becomes inefficient, and solute removal is controlled by diffusion from relatively stagnant areas. Where high degrees of solute removal are essential, it may be useful to follow displacement washing by reslurrying and replacing the displacement process. Only displaced washing will be discussed in this section.

22.6.2 Terms and Definitions for Displacement Washing

Wash ratio j: a ratio equaling the total volume of wash liquid exiting a cake to the volume of void of the cake.

Mother liquid concentration, C_o: concentration of liquid remaining in the cake before washing.

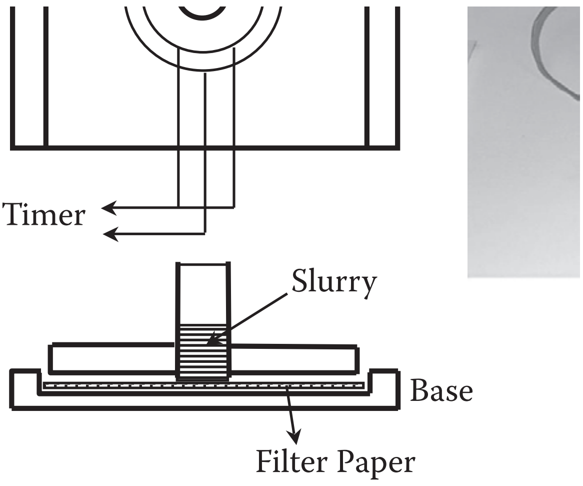

FIGURE 22.57 Displacement washing.

Instantaneous wash liquid concentration, C_w: instantaneous concentration of wash liquid when it is exiting the cake.

Average wash liquid concentration, C_{wav}: average concentration of total wash liquid coming out of the cake.

Average concentration of liquid in the cake, C_{av}: average solute concentration of total liquid remaining in the cake.

22.6.3 Washing Curves

Washing curves are used to describe washing efficiency. Frequently washing curves are represented by plots of C_w/C_o as functions of wash ratio j as shown in Figure 22.58. The ratio of C_w in mass to C_o indicating wash efficiency is constant for a portion of the wash cycle and drops rapidly after the wash ratio j increases beyond 0.6. The drop starts to slow down when the wash ratio j reaches about 1.5 when diffusion washing becomes the dominate factor. Solute is not uniformly distributed

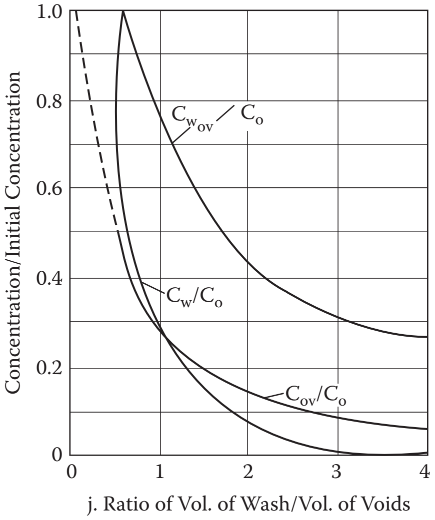

FIGURE 22.58 Washing curves.

in the cake, and it diffuses in accord with concentration gradients established in the interstices of the particulate bed. The average value of all of the accumulated wash C_{wav} divided by C_o lies above the instantaneous curve. The average value of solute in the liquid in the cake C_{av} is also shown in Figure 22.58.

The washing curves can be obtained by experimental data of C_w as the function of time, and instantaneous volume of washing liquid with time. Interpretation of experimental data must be approached with caution. At the beginning of the washing cycle, the conduits leading from the filter unit will be full of filtrate. Any curves that are drawn to show the percentage of solute remaining in the cake must take into account the solute in the body of the filter as the well as solute in the cake.

22.7 LABORATORY SLS TEST

22.7.1 Laboratory SLS Test

Separations can be classified as dealing with homogeneous or heterogeneous systems, e.g., fluid/particle systems. Homogeneous separations such as distillation, absorption, and extraction represent mature technologies where the fundamentals have been translated into well-developed design procedures with competing software programs being widely available. On the other hand, heterogeneous separations or fluid/particle separations involve more complex, less-well-understood phenomena. Parameters such as settling velocity in sedimentation and porosity and permeability of filter beds in filtration are very much depended on experimental results. Laboratory testing necessarily plays an important role in control and design of fluid/particle separation systems.

Objectives of laboratory SLS tests include

- Cake filtration characteristics such as porosity, permeability, specific resistance, and cake compactibility parameters n, β, δ, $\alpha_o \varepsilon_{so}$, or p_a in Equation (22.29)
- Selection of filter media
- Selection of filter aids
- Selection of coagulations and flocculants
- Cake washing efficiency
- Settling velocity for thickener design and scale-up

Parameters involved in SLS tests fall into the following criteria:

- Particle characteristics: Particle size distribution, mean particle size, particle shape, density, chemical content, etc.
- Slurry characteristics: Concentration, pH, conductivity, zeta potential, particle settling velocity, rheology characteristics, etc.
- Sedimentation characteristics: Variation of interface of slurry and clear liquid against time, zone-settling region and compaction region, settling velocity
- Filtration characteristics: Volume of filtrate versus time, filtrate rate, volume of filter cake, cake porosity, clarity of filtrate, clogging of filter media, effect of slurry concentration on filtrate rate and filtrate clarity, effect of slurry viscosity on filtrate rate and media clogging, etc.

Major methods for obtaining test data in SLS can be classified as follows:

1. Flow under gravitational head
   a. Filtration with falling head
   b. Filtration with constant head

2. Constant pressure filtration
    a. Vacuum leaf (Figure 22.59a)
    b. Buchner funnel (Figure 22.59b)
    c. Plate frame filter press (Figure 22.60)

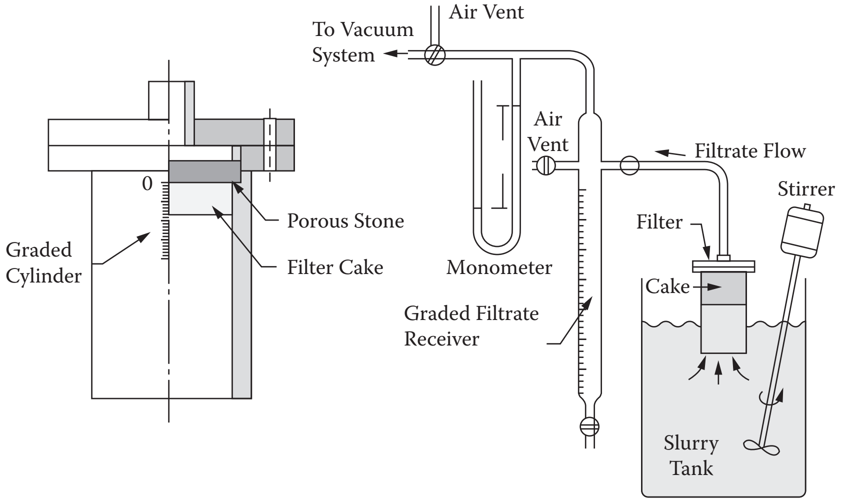

FIGURE 22.59a Vacuum horizontal leaf test filter.

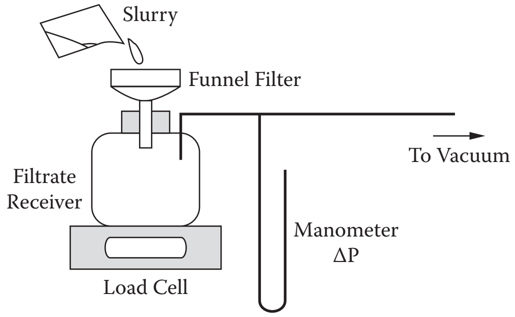

FIGURE 22.59b Vacuum Bucher funnel.

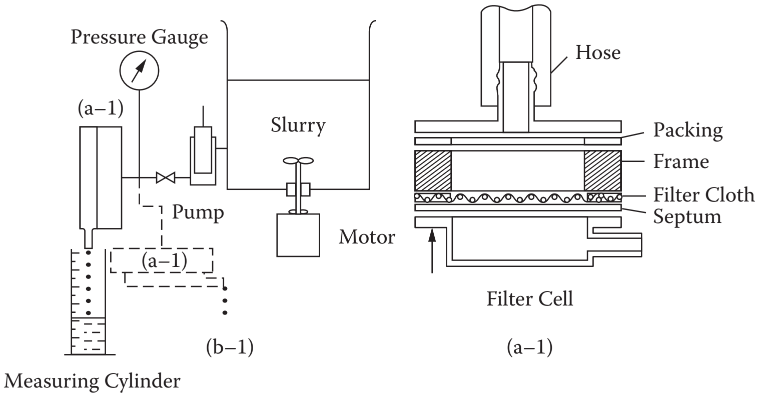

FIGURE 22.60 Plate-and-frame filter press.

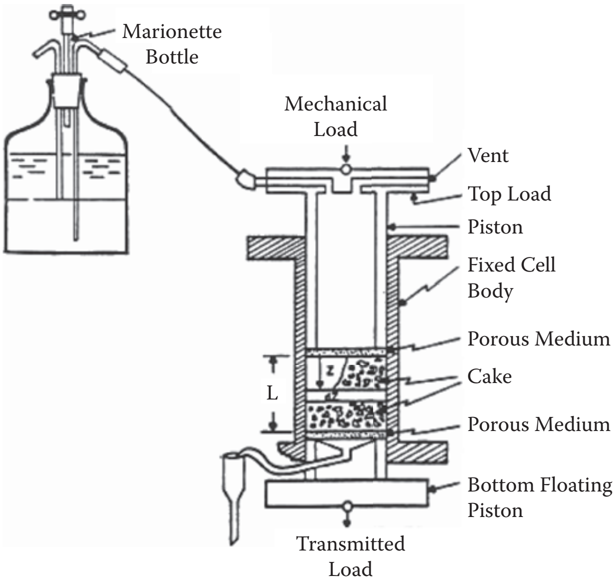

FIGURE 22.61 Compression permeability cell.

3. Constant rate filtration
4. Variable pressure and variable rate filtration
5. Compression-permeability cell (Figure 22.61)
6. Capillary suction time apparatus (Figure 22.62)
7. Batch sedimentation test
8. Flocculation and coagulation jar test (Figure 22.7)
9. Lab scale belt press (crown press)
10. Lab scale filtering or sedimenting centrifuges.

Constant pressure filtration under vacuum or in a small bomb powered by gas pressure has been the favorite method for obtaining filtration data. Constant rate filtration offers the advantage of providing data for different pressures in one run. It simulates the industrial filter operation where

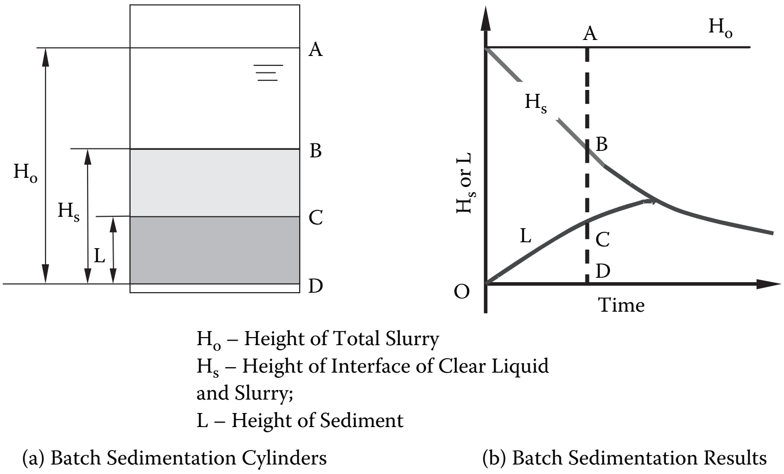

FIGURE 22.62 Capillary suction time apparatus.

the rate is constant but the pressure drop gradually increases. Variable-pressure, variable-rate filtration is similar to constant-rate operation but has the advantage of not requiring an absolutely constant rate. As the calculated flow resistance varies with the square of the rate, small errors in constant rate testing are magnified in determining resistance.

The capillary suction apparatus is particularly useful for rapid screening involving small samples. A tube containing several milliters of slurry is placed on filter paper. The liquid is sucked out of the tube and flows in a radial or rectangular manner through the paper. The time to flow through a specified distance from r_1 to r_2 is called the capillary suction time. Simplified theory for calculating CST is complicated by variable permeability parallel and perpendicular to the grain of the filter paper. Ellipses rather than circles result. In addition, sedimentation affects the rate of cake formation and the CST (Tiller and Li 2001b). For industrial applications, a commercially available capillary suction time apparatus is useful (Figure 22.62a).

22.7.2 Problems in Laboratory Tests

22.7.2.1 Samples

Representatives of samples and aging of samples are two big problems in lab tests. Special care should be paid to the sampling procedure. Due to aging of the sample slurry, and changing characteristics of slurry during shipping and storing, in-plant testing on fresh samples is strongly recommended.

22.7.2.2 Adverse Effect of Sedimentation on Filtration Experiments

All filtrations suffer from the difficulty of simultaneous sedimentation (Tiller et al. 1995). The relative rates of sedimentation and filtration or centrifugation underlie an assessment of the effect of sedimentation. Gravity filtration invariably requires agitation or recirculation. Sedimentation effects on a horizontal surface facing upward can be minimized by decreasing the slurry holding volume above the cake and providing adequate mixing in the reservoir. Particles with a wide size range in dilute slurries are almost impossible to filter satisfactorily in gravity filtration because of differential sedimentation. Large or dense particulates settle rapidly and form a cake that initially has an abnormally low resistance.

22.7.2.3 Wall Friction in C-P Cell and Small-Scale Cells

Percolation through compacted beds in compression-permeability (C-P) cells can be severely affected by sidewall friction which produces substantial cake nonuniformity (Tiller et al. 1972). It has been found that a large fraction of the applied load is absorbed by the wall. Risbud (1974) showed that thin cakes do not necessarily lead to uniform pressure distribution. For very thin cakes, the pressure just below the piston at the cake interface was distinctly nonuniform. The pressure at the centerline was higher than the applied pressure by as much as 10% to 15%. Radial movement of the solids involving friction on the piston as well as the walls accounts for this apparently strange behavior. For cakes of 20 to 75 mm in thickness in steel cells with diameters of 50 to 100 mm, as much as 50% of the load at the surface may be absorbed by the walls. The authors do not believe it is possible to produce a uniform cake in a compression-permeability cell or consolidometer. While the equipment can yield valuable information, it is complex, requires much time, and represents a relatively large capital investment if appropriately instrumented. It does not lend itself to routine testing.

22.7.2.4 Test Numbers

Determination of the effect of pressure drop and g-forces on flow rate and liquid content is the chief objective of tests involving compactible cakes. Accurate calculation of parameters in constitutive equations [Equation (22.29)] generally requires that a relatively wide range of

pressures be utilized. Ideally, a very low pressure in the neighborhood of 300 mm of water (0.5 psi) should be used. Capillary suction apparatus employing Whatman #17 has a suction pressure of approximately 14.85 kPa (2.15 psi). Determination of compactibility necessitates the use of gravity, vacuum, or pressure. Due to the limited data obtained, errors from wall friction, or sedimentation during tests, most compressibility coefficients reported in the literature are of questionable quality.

22.8 SLS SYSTEM DESIGN

For a particulate application involving SLS, how to choose the best equipment, to use batch or continuous operation, which filter medium to select, and what is the optimum operating conditions are concerns of engineers. Although theories are available for some SLS operations, solutions for equipment selection, process design, and optimization are still very much dependent on test and experience, and are frequently qualitative or semi-qualitative. In this section, strategy and decision networks for selection of SLS equipment, introduction of filter media, centrifugal pumps for filtration operation, and selection of filter aids by cycle analysis will be discussed.

22.8.1 Selection of SLS Equipment

22.8.1.1 Specifications of a SLS System

In approaching the initial selection of equipment, questions include what are the product (liquid or solid), the feed and production rates of the system, the required filtrate clarity, and the liquid and solute contents in the cake. The product may be solids, liquid, or both. For example, in the liquefied coal manufacturing process, the dissolved carbon in the liquid represents the main product. At the same time, minerals in the original coal end up as cake along with unconverted carbon, which is also a valuable component and can be used for the production of hydrogen. As far as the SLS operation is concerned, both cake solids and filtrate are of value in liquefied coal processes.

Purchas (1977) provided a conceptual model for initial specifications of a SLS system as illustrated in Figure 22.63.

22.8.1.2 Selection of Equipment and Process

The selection depends to a great extent on the rate of growth of the cake. This rate has a major effect on the following choices: batch versus continuous process; pressure or vacuum; gravity filters; and separation technique (filters, centrifuges, etc.). Table 22.8 (features of slurry), Table 22.9 (selection of filters), and Table 22.10 (comparison of separation processes) aid in this effort.

The basic strategy for equipment selection relating to cake buildup rate in Table 22.8 can be summarized as follows:

1. Continuous filtration is suitable for material of rapid cake buildup.
2. Medium-speed filtering materials are suited to vacuum equipment and filtering centrifuges like peeler or vertical basket centrifuges.
3. Slow filtering materials require pressure equipment or sedimenting centrifuges.
4. Dilute materials that result in high-resistance cakes are generally best handled in batch pressure filters and filter aids can be considered. If the solid concentration is less than 100 ppm, deep-bed filters become options.
5. Rapid settling slurries lend themselves to gravity separation or filtering centrifuges with wedge wire screen (like pusher or screen bowl centrifuges).

Flood, Porter, and Rennie (1977) developed Table 22.9 as an expanded version 5 to Table 22.8.

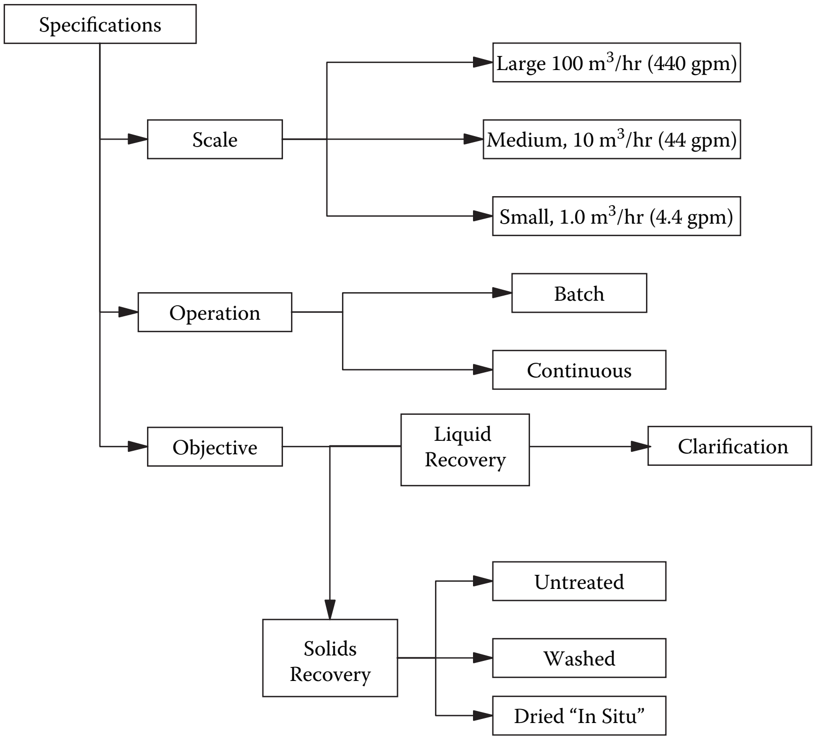

FIGURE 22.63 Specification of scale, type of operation, and objective.

TABLE 22.8
Slurry Characteristics

Type	Buildup	Characteristics
Rapid filtering	cm/sec	High concentration, fast settling, hard to suspend
Medium filtering	cm/min	Medium concentration forms, cake easily can be suspended
Slow filtering	cm/hr	Low concentration, high resistance, may blind media
Clarification	Little cake	Less than 1000 ppm, very high resistance

TABLE 22.9
Guide to Filter Selection

Slurry Settling Characteristics	Fast	Medium	Slow	Dilute	Very Dilute

22.8.1.3 Comparison of SLS Equipment

Fitch (1974) discussed the general problem of matching process specifications to SLS equipment and the necessity of considering trade-offs involving such items as filtrate clarity, cake dryness, reliability, maintenance, versatility, and cost. In Table 22.10, a comparative profile of all major types of SLS equipment is given. It should be emphasized that a wide range of performance occurs because of the endless variation in slurries, and the descriptive terms would undoubtedly vary some if another author were to prepare the same table.

22.8.2 Decision Network for Design for Cake Filtration Systems

A series of decisions must be made concerning the following factors in designing new or improving existing cake filtration systems:

1. Rate of cake buildup
2. Filtrate clarity
3. Solubles in cake
4. Liquid content of cake

In Figure 22.64, a framework for making decisions at different junctures is provided. At the first step, a decision must be made as to whether or not pretreatment may increase the rate of filtration and what type of filtration to use. Once a particular filter has been chosen, attention then focuses on the filtrate and wet cake. If the clarity is not satisfactory, a second-stage filtration (cartridge or granular bed) may be utilized. Alternatively, a tighter medium or a change in filter aid quality or quantity might provide a solution.

To remove mother liquor (or solubles in the mother liquor) in the cake, displacement or reslurrying washing, pressing, vacuum drainage, and blowing are employed in filters. Drainage or blowing can be employed separately or in combination with washing. At the start of displacement washing, pure mother liquor flows from the cake; and the washing efficiency is 100%. However, after approximately half of the liquid has been displaced, pure wash liquor breaks through the cake; and the displacement mechanism rapidly loses its effectiveness. Solubles may be trapped in "blind pores" where the wash does not effectively penetrate, and diffusion becomes the predominate mechanism of solute removal. Washing is inefficient in the diffusional stage, and reslurrying and refiltering may be the best path to follow.

Removal of residue liquid in the cake can be accomplished hydraulically or mechanically. The simplest procedure consists of increasing pressure at the end of filtration. If a centrifugal pump is employed, it may not be feasible to increase pressure, whereas a positive displacement pump provides a simple means for adjusting the final pressure. Highly compactible cakes do not generally lend themselves to reduction of average porosity by simple pressure increases. As demonstrated in Section 22.4.6, cakes that are highly compactible act differently under mechan-

TABLE 22.11
Classification of Filter Media

Type	Construction	Example
Flexible media	Woven fabric or woven wire	Including the wide variety of metallic, natural, and synthetic fabrics
	Nonwoven preformed	Including felt, melt blown, and similar materials
	Nonwoven, non-preformed	Cellulose pulp, asbestos
	Membranes	Organic or inorganic
Rigid media	Fixed	Including sintered metal, porous carbon, porous ceramic, formed plastics
	Loose	In packed beds of sand, carbon, and other loose materials

ical and hydraulic compression. A highly compactible material has very little reduction in porosity except in a layer close to the medium. There is little frictional drag in the first part of the cake, which results in a lack of consolidation except in the skin close to the medium. Comparatively, mechanical pressure directly applied on the cake can be quite effective. However, as the porosity decreases, cake permeability also decreases; and the rate of expression may drop substantially.

22.8.3 Selection of Filter Media

22.8.3.1 Introduction

The filter medium is the part of a filter that retains the solids while allowing passage of the fluid through its pore structure. It is one of the essential components of the filtration process, and is sometimes called "heart of filter." In practical operations, the suspension is normally composed of particles with a wide range of particle sizes and shapes, therefore, there are several mechanisms for particle capture.

Appropriate selection of filter media is one of the most important factors to ensure efficient performance of filtration equipment. The filtration performance requirements are application specific and may include (Cheremisinoff et al. 1983):

- Retention of particles
- Sufficient flow rate
- Easy cake release
- Gasket action
- Chemical and biological stability
- Abrasion resistance
- Dimensional stability with respect to stretching and shrinking
- Strength
- Fray or unraveling stability
- Washability for reuse or low price for disposability

According to materials and construction, filter media can be grouped as flexible and rigid media. The flexible media include woven (fabric or wire), nonwoven preformed, and nonwoven nonpreformed filter media. The rigid media can be classified as fixed or loose media as shown in Table 22.11. Among the various types of filter media, the woven flexible media is most commonly used for cake filters.

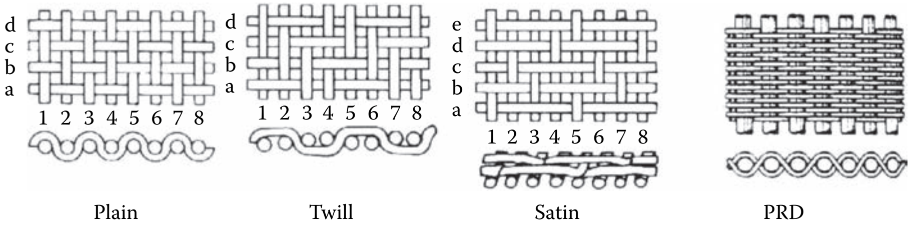

FIGURE 22.66 Four basic types of woven fabrics.

22.8.3.2 Woven Filter Media

Woven media are flexible and comprise metallic or nonmetallic materials formed by weaving. Metallic woven media are called woven wire, and nonmetallic woven media are called woven cloth or woven fabric. Woven wires are generally made with stainless steel, but can also be monel, nickel, inconel, or nichrome. They are stronger, better wear resistant, and more durable, but are more expensive compared with woven fabric. Selection of woven wire is sometimes solely on the basis of severe operating conditions.

Woven fabrics are usually made with natural or synthetic fibers from three different types of yarns: monofilament, multifilament, and spun staple, as shown in Figure 22.65. Performances of these three types of yarns are shown in Table 22.12.

There are many types of weaving patterns for woven fabrics and the four basic types are plain weave, twill weave, satin weave, and plain reverse Dutch weave (Svarovsky 1990) as shown in Figure 22.66. The filtration performances of the four types of weaves are shown in Table 22.13.

22.8.3.3 Selection of Filter Media

Selection of filter media is based mainly on testing results on the material performance and filtration performance. In addition to retention of variable particles and appropriate flow rate, special require-

ments on physical and filtration performance of filter media for different filters are summarized in Table 22.14.

22.8.4 Selection of Pumps in Filtration Operation

Pumps employed for slurries can be classified as (1) centrifugal, (2) progressive cavity or screw, (3) diaphragm, (4) piston pump, and (5) compressed gas either alone or combined with a pump. Pressure versus flow rate for various types of pumping mechanisms is illustrated in Figure 22.67. Arrows point in the direction of increasing time. Although constant pressure operation has dominated the literature and laboratory practice, generally diaphragm and single-screw rotary pumps are the best choices. Centrifugal pumps are widely employed in filtration in spite of their tendency to degrade aggregates because of large shear forces resulting from high-velocity impellers. Progressive cavity or screw pumps are capable of pumping high viscosity and high solid content slurries without particle breakup. The cost is high and maintenance may be a problem if the stator wears or seals leak. Piston pumps operate at constant rates that can be easily adjusted. There is a minimum breakup of particles. Abrasion can cause wear if particles invade the clearance between piston and cylinder. Severe pulsation is possible unless adequate damping devices are incorporated in the piping. Diaphragm pumps have some of the characteristics of piston pumps. However, with air driven pumps, the rate drops as pressure builds up. Progressive cavity, piston, and diaphragm pumps are also called positive displacement pumps. Gas driven filtration is only applicable in a

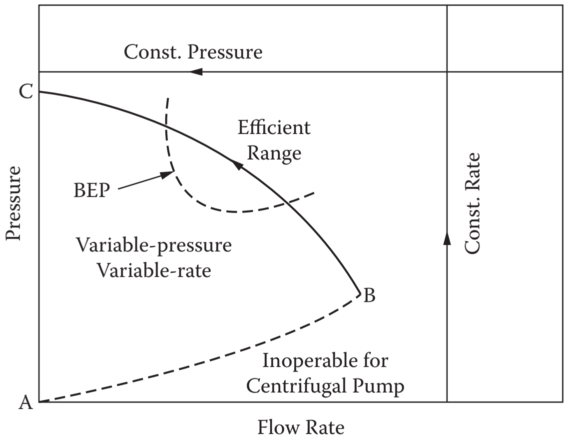

FIGURE 22.67 Characteristic curves for constant pressure and variable pressure operations.

few cases. Pumping of slurries frequently leads to erosion. Settling in feed tanks and piping sometimes is a problem.

With centrifugal pumps, pressure should be close to the best efficiency point (BEP), i.e., at intermediate pressures. Sometimes at low pressures, part of the liquid may vaporize, forming bubbles of gas. Such an occurrence may cause damage to the pump and surges and vibration coupled with low-energy efficiency. At low-flow rates, particles are retained for longer periods in the casing with increased possibility of particle degradation. Low pump speeds are best for fragile particles like flocs resulting from pretreatment operations. In general, it is advisable to test slurry characteristics before and after passing through a centrifugal pump to determine the possible degradation of aggregates resulting in increased specific resistance of cakes and decreased settling velocities in clarifiers.

A throttle valve is sometimes needed with a centrifugal pump or filtration is started at a pressure considerably above that at point B. The curve *AB* generally is essentially a parabola. The pressure drop across the cake is essentially the vertical difference between curves *CB* and *AB*. If the centrifugal pump is too large, overheating, particle breakup, and considerable maintenance problems are possible at startup.

22.8.5 Cycle Analysis in Selection of Filter Aids (Tiller and Li 2003)

Filter aids (diatomaceous earth, perlite, cellulose, etc.) are used to increase the porosity and decrease the flow resistance of cakes. Although the fundamentals are the same, design of a new filter and determination of the effect of adding filter aids to an existing filter (where the available cake thickness is fixed) lead to different conclusions concerning the optimum quantity. Determination of the optimum quantity of filter aid has generally rested on finding the amount that yields the maximum filtrate in a given time interval. Sometimes, this procedure can lead to gross errors if the final cake is saturated with liquid (such as no air blowing after filtration). It is essential to determine the average cake solidosity as a function of the fraction of filter aid and the cycle rate for the product solids. In a laboratory test, adding filter aid can substantially increase cake thickness. By contrast, cake thickness is fixed in an existing full-scale filter; and addition of filter aid replaces a portion of the product solid.

A typical relationship of the average solidosity of a cake as a function of the fraction of filter aid is shown in Figure 22.68a. The active solid product without filter aid has an average solidosity $\varepsilon_{sav} = 0.5$ as indicated by point *P*. With 50% filter aid, the mixture has a value of $\varepsilon_{sav} = 0.25$, point *R*. We first consider a filtration in which no filter aid is present. In Figure 22.68b, a cake with 50% solid product and 50% liquid is illustrated corresponding with point P in Figure 22.68a. In Figure 22.58c, the filtration is repeated with the addition of a volume of filter aid equal to the volume of

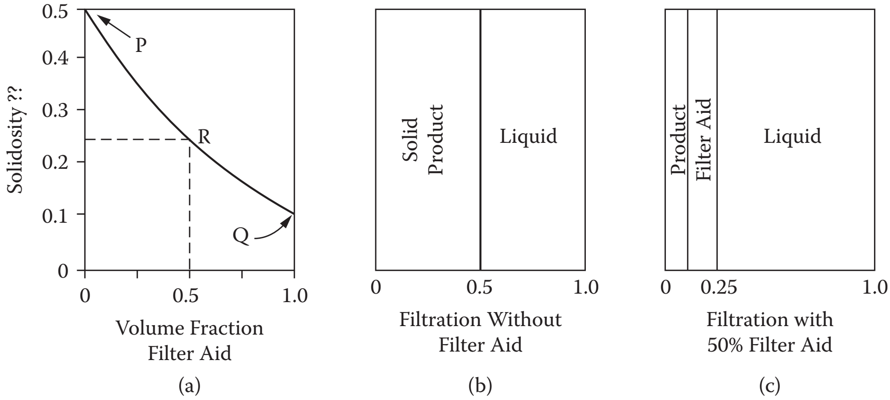

FIGURE 22.68

product solids corresponding with point *R* in Figure 22.68a. With the increase of the filter aid, the cake has 75% liquid, 25% solids, and the amount of product is reduced to one fourth of the quantity present in Figure 22.68b. As the active solid component in the filter has been reduced to 25% of the original amount in Figure 22.68b, four cycles will be necessary to yield the same quantity of active solids. It can easily be shown that after the addition of filter aids, overall cycle rates will be reduced and more cycles are required to produce the same amount of solids.

An example involving the addition of a perlite filter aid to a clay suspension with a volumetric concentration of $\varphi_s = 0.058$ will be discussed. Constant rate filtration (Camacho 1975) with different fractions of perlite was used to obtain cake resistance α_{av} and cake solidosity ε_{sav} as functions of Δp_c. The specific problem to be analyzed is a constant pressure filtration at 200 kPa (29 psi) of this clay suspension. For constant pressure and constant rate filtration with minimal medium resistance, maximum cycle flux is reached when the filtration time equals the time required to dump the cake, clean the filter, and start the next cycle (Rushton et al. 1996). In this example, it is assumed that the dead time between cycles is 15 minutes. With t (filtration) = 15 minutes, a cake thickness of L = 0.014 m results when the cycle rate is maximized for this highly resistant, moderately compactible clay.

Calculations involved in the analysis include (1) concentration of slurry after addition of perlite φ_{sF}; (2) time required to produce a cake of 0.014 m t; (3) number of cycles with filter aid addition f (volume fraction of filter aids in the total cake solids) to get the same amount of product solids without filter aid addition when $f = 0$; (4) volume/unit area of filtrate produced in 15 min; (5) the cycle rate based on liquid; and (6) cycle rate based on product clay solids. The calculated results are shown in Table 22.15.

TABLE 22.15
Cycle Rate Calculation Involving Filter Aids

1	2	3	4	5	6	7	8	9
							Cycle Rates (m^3m^2/hr)	
f	α_{av}(m^{-2})	ε_{sav}	φ_{sF}	t, sec for L = 0.014 m	v, m^3/m^2 t = 15 min	Number of Cycles	Liquid	Solid
0	2.21E(15)	0.47	0.058	3615	0.0496	1	0.0496	0.00328
0.1	2.22E(15)	0.45	0.064	2951	0.0466	1.04	0.0464	0.00312
0.2	7.27E(13)	0.33	0.071	43	0.233	1.42	0.0501	0.00365
0.333	4.09E(13)	0.26	0.085	11	0.265	1.81	0.029	0.00242
0.667	2.32E(13)	0.18	0.156	0.314	0.115	2.61	0.0021	0.00084

Starting with the fraction of perlite f in the first column, columns 2 and 3 contain the experimental values of α_{av} and ε_{sav} for a pressure filtration of 200 kPa. In column 4, values of the suspension concentration are shown as they reflect the addition of perlite. The time required to produce a cake with $L = 0.014$ m is tabulated in column 5. The short time of <1 sec for $f = 0.667$ results from the high slurry concentration of $\varphi_{sF} = 0.156$ compared with an average cake solidosity of $\varepsilon_{sav} = 0.18$. A more detailed analysis of the cake would provide the variation of ε_s with the distance x in the cake. An experiment with $f = 0.333$ indicated that ε_s at the cake surface had an approximate value of $\varepsilon_{so} = 0.1$; and at the medium, it reached a value in the range of 0.3 to 0.4. With $f = 0.333$, the concentration of $\varphi_{sF} = 0.085$ indicates the suspension is close to $\varepsilon_{so} = 0.10$ and when $f = 0.667$, the value of $\varphi_{sF} = 0.156$ is probably larger than ε_{so} indicates that the suspension is actually a cake. Calculations in the table for $f = 0.333$ and 0.667 cannot be taken seriously as the equations are only valid for true slurries. However, they indicate that concentrations in excess of $f = 0.333$ are impractical.

Column 6 contains the filtrate volume for time of 15 min. These values are frequently used to obtain the "optimum" amount of filter aid. They indicate that the maximum flow rate results from adding perlite when $f = 0.33$. However, the cycle rates in columns 8 and 9 show that the optimum dose of filter aid is $f = 0.2$. The example clearly shows that the choice of a filter aid and the value of f should be based on a cycle analysis and not on v versus t data.

22.8.6 Scale Up

SLS system design and scale up are frequently dependent on settling velocity of suspended particles, flow rate, specific cake resistance, cake % solids, medium resistance, clarity of filtrate, or overflow, which are obtained from tests. In-plant testing is suggested. If replacement equipment is to be considered for processes in operation, in-plant testing should be performed; and if a new product is involved, pilot-plant and bench-scale tests of separability should be conducted so that the maximum design information is available.

Truly satisfactory methods for scale up are not available. Purchas (1977) indicates that scale up has two meanings. While the obvious meaning refers to the prediction of the size of process equipment from small-scale tests, choice of suitable equipment is an equally important part of scale up. Purchas (1977) states "none of the test or scale up procedures presented merits being called a 'standard procedure'. The virtual total absence either of existing standards or of serious attempts to involve or develop standards in an area of such major importance can only be regarded as remarkable in the current era."

Included in *Solid/liquid Separation Equipment Scale Up* (1977) are methods advocated by different equipment manufacturers in the areas as shown in Table 22.16. Much useful information

23.1 INTRODUCTION

The solid/liquid separation operation of drying converts a solid, semi-solid, or liquid feedstock into a solid product by evaporation of the liquid via application of heat. In the special case of freeze drying, which takes place below the triple point of the liquid being removed, drying occurs by sublimation of the solid phase directly into the vapor phase. This definition thus excludes conversion of a liquid phase into a concentrated liquid phase (evaporation); mechanical dewatering operations such as filtration, centrifugation, sedimentation, etc.; supercritical extraction of water from gels to produce extremely high porosity aerogels (extraction); or so-called drying of liquids and gases by use of molecular sieves (adsorption), etc. Phase change and production of a solid phase as an end product are essential features of the drying process. Drying is an essential operation in the chemical, agricultural, biotechnology, food, polymer, ceramics, pharmaceutical, pulp and paper, mineral processing, and wood processing industries.

Drying is perhaps the oldest, most common, and most diverse of chemical engineering unit operations. Over 500 types of dryers have been reported in the literature, while over 100 distinct types are commonly available. It competes with distillation as the most energy-intensive unit operation due to the high latent heat of vaporization and the inherent inefficiency of using hot air as the (most common) drying medium. Various studies report national energy consumption for industrial thermal drying operations ranging from 10% to 15% for the United States, Canada, France, the U.K., etc., to 20% to 25% for Denmark and Germany. The latter figures have been obtained recently based on mandatory energy audit data supplied by industry and hence are more reliable.

Energy consumption in drying ranges from a low value of under 5% for the chemical manufacturing industries to 35% for papermaking operations. Capital expenditures for dryers are estimated to be in the order of only $800 million per annum for the United States. Thus, the major costs for dryers are in their operation rather than in their initial investment costs.

Drying of various feedstocks is needed for one or several of the following reasons: need for easy-to-handle free-flowing solids, preservation and storage, reduction in cost of transportation, achieving desired quality of product, etc. In many processes, improper drying may lead to irreversible damage to product quality and hence a nonsalable product.

Unique features of drying make it fascinating and challenging:

- Product size may range from microns to tens of centimeters (in thickness or depth)
- Product porosity may range from zero to 99.9%
- Drying times range from 0.25 sec (drying of tissue paper) to 5 months (for certain hardwood species)
- Production capacities may range from 0.10 kg/hr to 100 t/hr
- Product speeds range from zero (stationary) to 2000 m/sec (tissue paper)
- Drying temperatures range from below the triple point to above the critical point of the liquid
- Operating pressure may range from a fraction of a millibar to 25 atmospheres
- Heat may be transferred continuously or intermittently by convection, conduction, radiation, or electromagnetic fields

Clearly, no single design procedure applies to all or even several of the dryer variants. It is therefore essential to revert to the fundamentals of heat, mass, and momentum transfer coupled with knowledge of the material properties (quality) when attempting a design of a dryer or analysis of an existing dryer. Mathematically speaking, all processes involved, even in the simplest dryer, are highly nonlinear and hence scale-up of dryers is generally very difficult. Experimentation at laboratory and pilot scales coupled with field experience and know-how is essential to the development of a new dryer application. Dryer vendors are necessarily specialized and normally offer only a narrow range of drying equipment. The buyer must therefore be reasonably conversant with

the basic knowledge of the wide assortment of dryers and be able to come up with an informal preliminary selection before going to the vendors. In general, several different dryers may be able to handle a given application.

23.2 BASIC PRINCIPLES AND TERMINOLOGY

Drying is a complex operation involving transient heat and mass transfer along with several rate processes, such as physical or chemical transformations, which may cause changes in product quality as well as the mechanisms of heat and mass transfer. Physical changes that may occur include: shrinkage, puffing, crystallization, glass transitions, etc. In some cases, desirable or undesirable chemical or biochemical reactions may occur leading to changes in color, texture, odor, or other properties of the solid product. In the manufacture of catalysts, for example, drying conditions can yield significant differences in the activity of the catalyst by changing the internal surface area.

Thermal drying caused by the vaporization of the liquid results as heat is supplied to the wet feedstock. As noted earlier, heat may be supplied by convection (direct dryers), conduction (contact or indirect), radiation, or volumetrically by placing the wet material in a microwave or radio frequency (RF) electromagnetic field. Over 85% of industrial dryers are of the convection type, with hot air or direct combustion gases as the drying medium. Over 99% of the application involves removal of water. All modes except the dielectric (microwave and radio frequency) supply heat at the boundaries of the drying object so that the heat must then diffuse into the solid primarily by conduction. The liquid must travel to the boundary of the material before it is transported away by the carrier gas (or by application of vacuum for nonconvective dryers).

Internal transport of moisture within the solid may occur by any one or more of the following mechanisms of mass transfer:

- Liquid diffusion, if the wet solid is at a temperature below the boiling point of the liquid
- Vapor diffusion, if the liquid vaporizes within material
- Knudsen diffusion, at very low temperatures and pressures, e.g., in freeze drying
- Surface diffusion (possible although not proven)
- Hydrostatic pressure differences created by internal vaporization rates exceeding the rate of vapor transport through the solid to the surroundings
- Combinations of the above mechanisms

Since the physical structure of the drying solid is subject to change during drying, the mechanisms of moisture transfer may also change with elapsed time of drying.

23.2.1 Thermodynamic Properties of Air-Water Mixtures and Moist Solids

23.2.1.1 Psychrometry

As noted earlier, a majority of dryers are of the direct (or convective) type. In other words, hot air is used both to supply the heat for evaporation and to carry away the evaporated moisture from the product. Notable exceptions are freeze and vacuum dryers, which are used almost exclusively for drying heat-sensitive products, tend to be significantly more expensive than dryers operated near atmospheric pressure. Another exception is the emerging technology of superheated steam drying (Mujumdar 1995a). In certain cases, such as the drum drying of pasty foods, some or all of the heat is supplied indirectly by conduction.

Drying with heated air implies humidification and cooling of the air in a well-insulated (adiabatic) dryer. Thus, hygrothermal properties of humid air are required for the design calculations of such dryers. Pakowski et al. (1991) have presented a comprehensive summary of the engineering

TABLE 23.1
Thermodynamic and Transport Properties of Air-Water System

Property	Expression
P_v	$P_v = 100 \exp[27.0214 - (6887/T_{abs}) - 5.32 \ 1n(T_{abs}/273.16)]$
Y	$Y = 0.622RHP_v/(RHP_v)$
c_{pg}	c_{pg}=$100926 \times 10^3 - 4.0403 \times 10^{-2} + 6.1759 \times 10^{-4}T^2 - 4.097 \times 10^{-7}T^3$
k_g	$k_g = 2.425 \times 10^{-2} - 7.889 \times 10^{-5}T - 1.790 \times 10^{-8}T^2 - 8.570 \times 10^{-12}T^3$
ρ_g	$\rho_g = PM_g/(RT_{abs})$
μ_g	$\mu_g = 1.691 \times 10^{-5} + 4.984 \times 10^{-8}T - 3.187 \times 10^{-11}T^2 + 1.319 \times 10^{-14}T^3$
c_{pv}	$c_{pv} = 1.883 - 1.6737 \times 10^{-4}T + 8.4386 \times 10^{-7}T^2 - 2.6966 \times 10^{-10}T^3$
c_{pw}	$c_{pw} = 2.8223 + 1.1828 \times 10^{-2}T - 3.5043 \times 10^{-5}T^2 + 30601 \times 10^{-8}T^3$

Source: Mujumdar (1995b) and Pakowski et al. (1991).

properties of humid air. Table 23.1 summarizes the essential thermodynamic and transport properties of the air-water system. In Table 23.2, a listing of brief definitions of various terms encountered in drying and psychrometry is given. It also includes several terms not explicitly discussed in the text.

Figure 23.1 is a psychrometric chart for the air-water system. It shows the relationship between the temperature (abscissa) and absolute humidity (ordinale, in g water per kg dry air) of humid air from 0°C to 130°C at one atmosphere absolute pressure. Line as representing percent humidity and adiabatic saturation are drawn according to the thermodynamic definitions of these terms. Equations for the adiabatic saturation and wet-bulb temperature lines on the chart are as follows (Geankoplis 1983):

$$\frac{Y - Y_{as}}{T - T_{as}} = -\frac{c_s}{\lambda_{as}} = -\frac{1.005 + 1.88Y}{\lambda_{as}} \tag{23.1}$$

and

$$\frac{Y - Y_{wb}}{T - T_{wb}} = -\frac{h / M_{air} k_y}{\lambda_{wb}} \tag{23.2}$$

The ratio ($h/M_{air}k_y$), termed the psychrometric ratio, lies between 0.96 and 1.005 for air-water vapor mixtures; thus it is nearly equal to the value of humid heat c_s. If the effect of humidity is neglected, the adiabatic saturation and wet-bulb temperatures (T_{as} and T_{wb}, respectively) are almost equal for the air-water system. Note, however, that T_{as} and T_w are conceptually quite different. The adiabatic saturation temperature is a gas temperature and a thermodynamic entity while the wet-bulb temperature is a heat and mass transfer rate-based entity and refers to the temperature of the liquid phase. Under constant drying conditions, the surface of the drying material attains the wet-bulb temperature if the heat transfer is by pure convection. The wet-bulb temperature is independent of surface geometry as a result of the analogy between heat and mass transfer.

Most handbooks of engineering provide more detailed psychrometric charts including additional information and extended temperature ranges. Mujumdar (1995aORb) includes numerous psychrometric charts for several gas-organic vapor systems as well.

TABLE 23.2
Definitions of Commonly Encountered Terms in Psychrometry and Drying

Term (Symbol)	Meaning
Adiabatic saturation temperature (T_{as})	Equilibrium gas temperature reached by unsaturated gas and vaporizing liquid under adiabatic conditions. (Note: For air-water system only, it is equal to the wet bulb temperature T_{wb}.)
Bound moisture	Liquid physically and/or chemically bound to a solid matrix so as to exert a vapor pressure lower than that of pure liquid at the same temperature.
Constant rate drying period	Under constant drying conditions, the drying period when the evaporation rate per unit drying area is constant (when surface moisture is removed).
Dew point	Temperature at which a given unsaturated air-vapor mixture becomes saturated.
Dry bulb temperature	Temperature measured by a (dry) thermometer immersed in vapor-gas mixture.
Equilibrium moisture content (X^*)	At a given temperature and pressure, the moisture content of a moist solid in equilibrium with the gas-vapor mixture (zero for nonhygroscopic solids).
Critical moisture content (X_c)	Moisture content at which the constant drying rate first begins to drop (under constant drying conditions).
Falling rate period	Drying period (under constant drying conditions) during which the rate falls continuously in time.
Free moisture (X_f) ($X_f = X = X^*$)	Moisture content in excess of the equilibrium moisture content (hence free to be removed) at given air humidity and temperature.
Humid heat	Heat required to raise the temperature of unit mass of dry air and its associated vapor through one degree (kJ kg^{-1} K^{-1} or Btu $1b^{-10}$ F^{-1}).
Humidity, absolute	Mass of water vapor per unit mass of dry gas (kg kg^{-1} or lb lb^{-1}).
Humidity, relative	Ratio of partial pressure of water vapor in a gas-vapor mixture to equilibrium vapor pressure at the same temperature.
Unbound moisture	Moisture in solid that exerts vapor pressure equal to that of pure liquid at the same temperature.
Water activity (a_w)	Ratio of vapor pressure exerted by water in solid to that of pure water at the same temperature.
Wet-bulb temperature (T_{wb})	Liquid temperature attained when large amounts of air-vapor mixture are contacted with the surface. In purely convective drying, drying surface reaches T_{wb} during the constant rate period.

23.2.1.2 Equilibrium Moisture Content

The moisture content of a wet solid in equilibrium with air of given humidity and temperature is termed the equilibrium moisture content (EMC). A plot of the EMC at a given temperature versus dry-basis moisture content of the solid is termed the sorption isotherm. An isotherm obtained by exposing the wet solid to air of increasing humidity gives the adsorption isotherm. That obtained by exposing the solid to air of decreasing humidity is known as the desorption isotherm. Clearly, the latter is of interest in drying as the moisture content of the solids progressively decreases. Most drying materials display "hysteresis" in that the two isotherms are not identical.

Figure 23.2 shows the general shape of the typical sorption isotherms. They are characterized by three distinct zones, *A*, *B*, and *C*, which are indicative of different water binding mechanisms at individual sites on the solid matrix. In region *A*, water is tightly bound to the sites and is unavailable for reaction. In this region, there is essentially monolayer adsorption of water vapor and no distinction exists between the adsorption and desorption isotherms. In region *B*, the water is more loosely bound. The vapor pressure depression below the equilibrium vapor pressure of water at the same temperature is due to its confinement in the smaller capillaries. Water in region *C* is even more loosely held in larger capillaries. It is available for reactions and as a solvent.

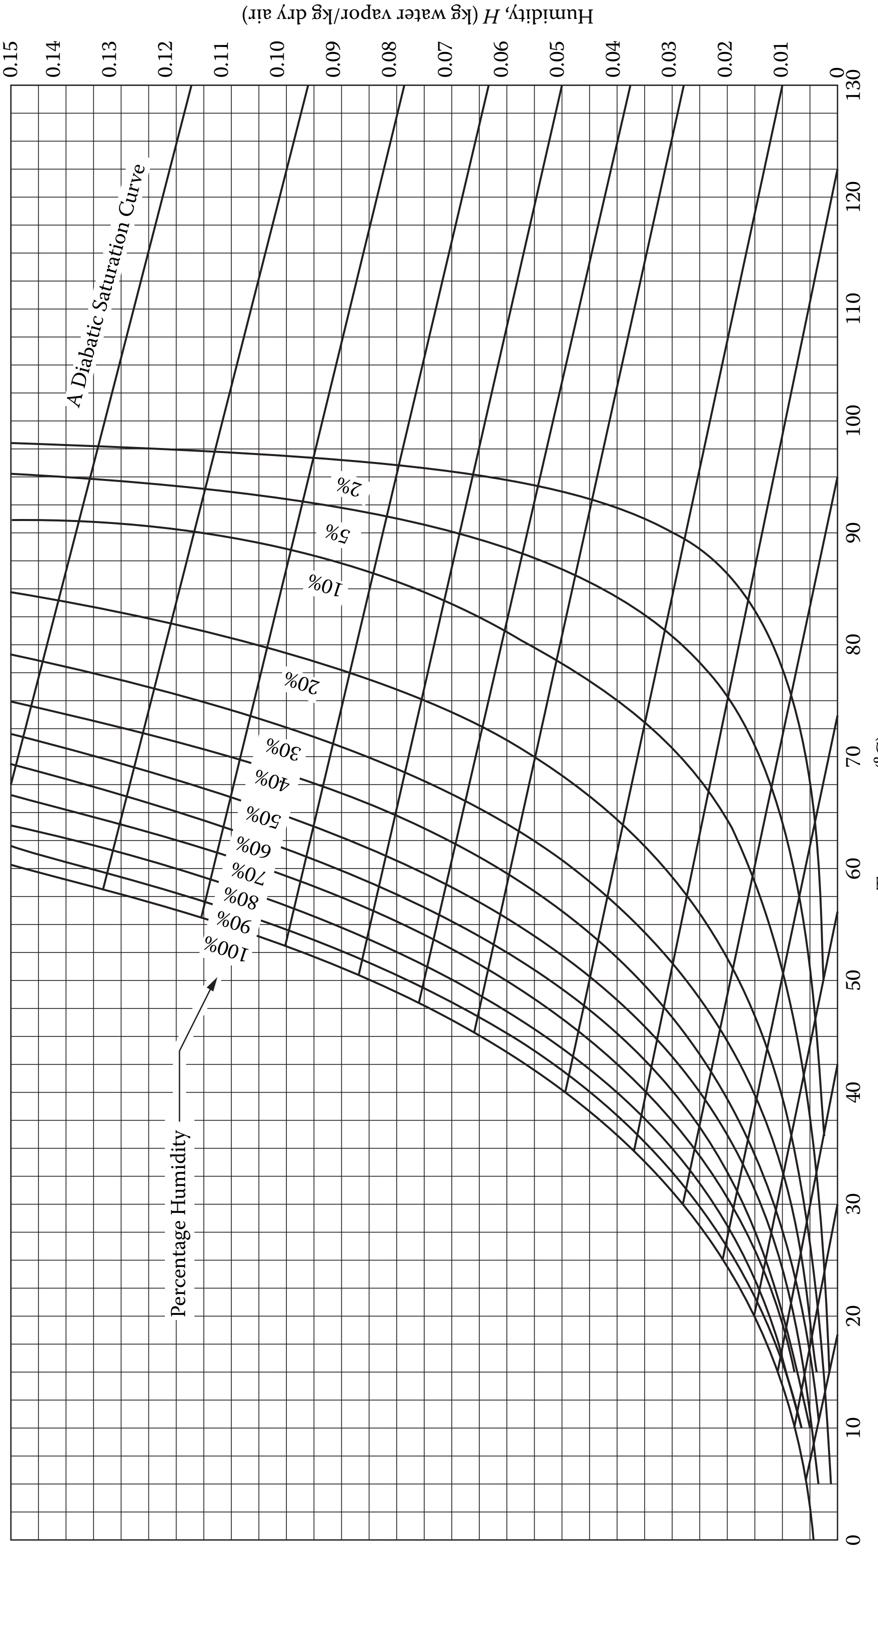

FIGURE 23.1 Humidity chart for mixtures of air and water (pressure of 101.325 kPa).

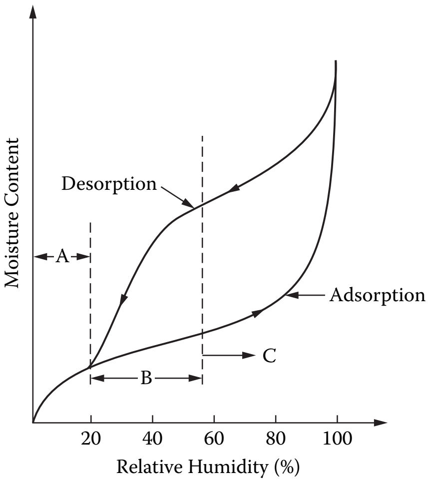

FIGURE 23.2 Typical sorption isotherms showing hysteresis.

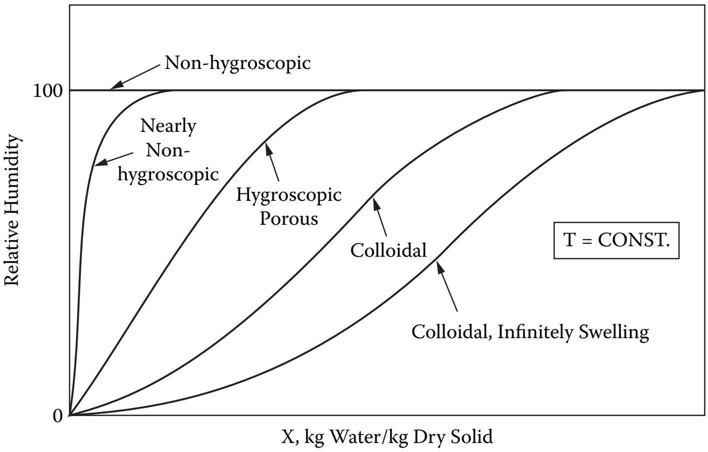

FIGURE 23.3 Equilibrium moisture curves for different types of solids.

Numerous hypotheses have been proposed to explain the hysteresis. Bruin and Luyben (1980), Fortes and Okos (1980), and Bruin (1988) provide more information on the topic.

Figure 23.3 shows schematically the shapes of the equilibrium moisture curves for various types of solids. Figure 23.4 shows the various types of moisture defined in Table 23.2. The desorption isotherms are also dependent on external pressure. However, in all practical cases of interest, this effect may be neglected.

According to Keey (1978), the temperature dependence of the equilibrium moisture content on temperature can be correlated by

$$\left[\frac{\Delta X^*}{\Delta T}\right]_{\psi=constant} = -\alpha X^* \tag{23.3}$$

where X^* is the dry-basis equilibrium moisture content T is the temperature, and Ψ is the relative humidity of air. The parameter α ranges from 0.005 to 0.01 K^{-1}. This correlation may be used to estimate the temperature dependence of X^* if no data are available.

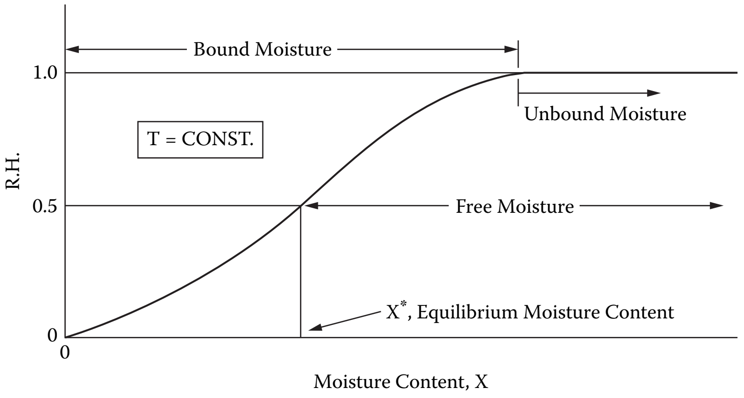

FIGURE 23.4 Various types of moisture.

For hygroscopic solids, the enthalpy of the attached moisture is less than that of pure liquid by an amount equal to this binding energy, which is also termed the enthalpy of wetting, ΔH_w (Keey 1978). It includes the heat of sorption, hydration, and solution and may be estimated from the following equation:

$$\left.\frac{d(\ln \psi)}{d(1/T)}\right|_{X=constant} = -\frac{\Delta H_w}{R_g T} \tag{23.4}$$

A plot of ln(Ψ) against $1/T$ is linear with a slope of $\Delta H_W/R_g$, where R_g is the universal gas constant ($R_g = 8.314 \times 10^3$ kg kgmol^{-1} K^{-1}). Note that the total heat required to evaporate bound water is the sum of the latent heat of vaporization and the heat of wetting; the latter is a function of the moisture content X. The heat of wetting is zero for unbound water and increases with decreasing X. Since ΔH_W is responsible for lowering the vapor pressure of bound water, at the same relative humidity, ΔH_W is almost the same for all materials (Keey 1978). For most materials, the moisture binding energy is positive; generally it is a monotonically decreasing function of the moisture content, with a value of zero for unbound moisture.

In general, water sorption data must be determined experimentally. Some 80 correlations, ranging from those based on theory to those that are purely empirical, have appeared in the literature. Two of the most extensive compilations are due to Wolf et al. (1985) and Iglesias and Chirife (1982). Aside from temperature, water sorption is also affected by the physical structure as well as the composition of the material. The pore structure and size, as well as the physical and/or chemical transformations during processing can cause significant variations in the moisture binding ability of the solid.

23.2.1.3 Water Activity

In drying of some materials, which requires careful hygienic attention, e.g., food, availability of water for growth of microorganisms, germination of spores, and participation in several types of chemical reactions becomes an important issue. This availability, which depends on relative pressure or water activity a_w, is defined as the ratio of the partial pressure p of water over the wet solid system to the equilibrium vapor pressure p_w of water at the same temperature. Thus, a_w, which is also equal to the relative humidity of the surrounding humid air, is defined as

$$a_w = \frac{p}{p_w} \tag{23.5}$$

TABLE 23.3
Minimum Water Activity for Microbial Growth and Spore Germination

Microorganism	Water Activity (a_w)
Organisms producing slime on meat	0.98
Pseudomonas, Bacillus cereus spores	0.97
B. subtilis, C. botulinum spores	0.95
C. botulinum, Salmonella	0.93
Most bacteria	0.91
Most yeast	0.88
Aspergillus niger	0.85
Most molds	0.80
Halophilic bacteria	0.75
Xerophilic fungi	0.65
Osmophilic yeast	0.62

Different shapes for the X versus a_w curves are observed, depending on the type of material (e.g., high, medium, or low hygroscopicity solids).

Table 23.3 lists the measured minimum a_w values for microbial growth or spore germination. If a_w is reduced below this value by dehydration or by adding water-binding agents like sugars, glycerol, or salt, microbial growth is inhibited. Such additives should not affect the flavor, taste, or other quality criteria, however. Since the amounts of soluble additives needed to depress a_w even by 0.1 are quite large, dehydration becomes particularly attractive for high moisture foods as a way to reduce a_w. Figure 23.5 shows schematically the water activity versus moisture content curve for different types of food. Rockland and Benchat (1987) provide an extensive compilation of results on water activity and its applications.

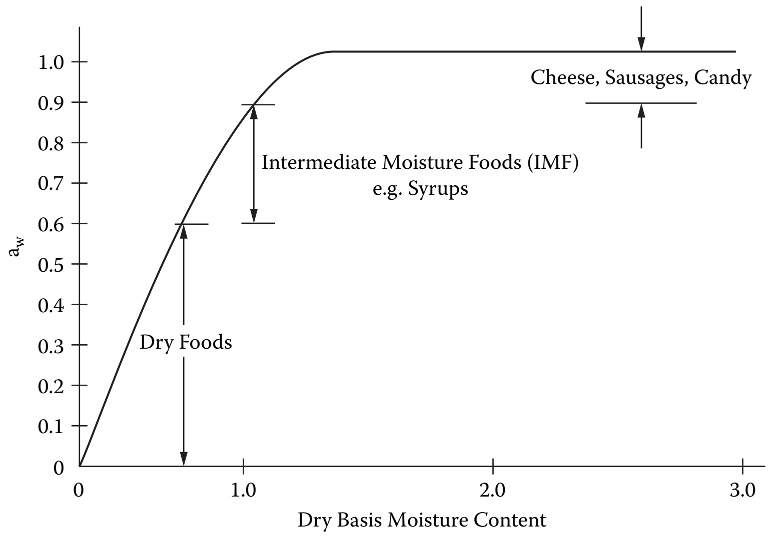

FIGURE 23.5 Water activity vs. moisture content curve.

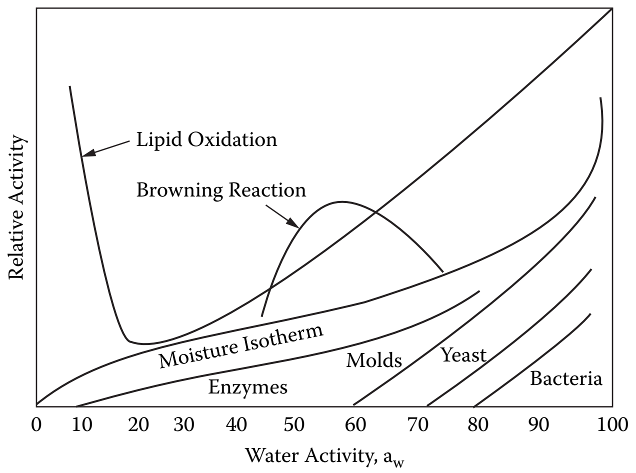

FIGURE 23.6 Deterioration rates as a function of water activity for food systems.

Figure 23.6 shows the general nature of the deterioration reaction rates as a function of a_w for food systems. Aside from microbial damage, which typically occurs for $a_w > 0.70$, oxidation, nonenzymatic browning (Maillard reactions), and enzymatic reactions can occur even at very low a_w levels during drying. Laboratory or pilot testing is essential to ascertain that no damage occurs in the selected drying process since this cannot in general be predicted.

23.2.2 Drying Kinetics

Consider the drying of a wet solid under fixed drying conditions. In the most general cases, after an initial period of adjustment, the dry-basis moisture content X decreases linearly with time t following the start of the evaporation. This is followed by a nonlinear decrease in X with t until, after a very long time, the solid reaches its equilibrium moisture content X^* and drying stops. In terms of free moisture content, defined as

$$X_f = \left(X - X^*\right) \tag{23.6}$$

the drying rate drops to zero at $X_f = 0$.

By convention, the drying rate N is defined as

$$N = -\frac{M_s}{A}\frac{dX}{dt} or -\frac{M_s}{A}\frac{dX_f}{dt} \tag{23.7}$$

under constant drying conditions. Here (kg m^{-2} h^{-1}) is the rate of water evaporation, A is the evaporation area (may be different from heat transfer area), and M_s is the mass of bone dry solid. If A is not known, then the drying rate may be expressed in kg water evaporated per hour.

A plot of N versus X (or X_f) is the so-called drying rate curve. This curve must always be obtained under constant drying conditions. Note that, in actual dryers, the drying material is generally exposed to varying drying conditions (e.g., different relative gas-solid velocities, different gas temperatures and humidities, different flow orientations). Thus, it is necessary to develop a methodology in order to interpolate or extrapolate limited drying rate data over a range of operating conditions.

Figure 23.7 shows a typical "textbook" drying rate curve displaying an initial constant rate period, where $N = N_c$ = constant. The constant rate period is governed fully by the rates of external

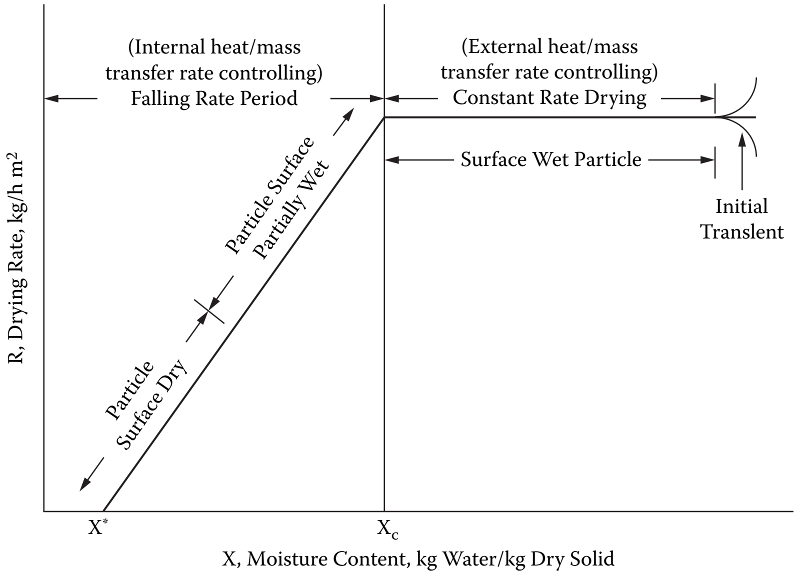

FIGURE 23.7 Typical textbook batch drying rate curve under constant drying conditions.

heat and mass transfer since a film of free water is always available at the evaporating surface. This drying period is nearly independent of the material being dried. Many foods and agricultural products, however, do not display the constant rate period at all since internal heat and mass transfer rates determine the rate at which water becomes available at the exposed evaporating surface.

At the so-called critical moisture content X_c, N begins to fall with further decreases in X since water cannot migrate at the rate N_c to the surface due to internal transport limitations. The mechanism underlying this phenomenon depends on both the material and drying conditions. The drying surface becomes first partially unsaturated and then fully unsaturated until it reaches the equilibrium moisture content X^*. Detailed discussions of drying rate curves are given by Keey (1992) and Mujumdar and Menon (1995). Approximate critical moisture content values for some selected materials are given in Table 23.4.

Note that a material may display more than one critical moisture content value at which the drying rate curve shows a sharp change of shape. This is generally associated with changes in the underlying mechanisms of drying due to structural or chemical changes. It is also important to note that X_c is not a material property. It depends on the drying rate under otherwise similar conditions. It must be determined experimentally.

TABLE 23.4
Approximate Critical Moisture Contents for Various Materials

Material	Critical Moisture Content (kg water/kg dry solid)
Salt crystals, rock salt, sand, wool	0.05–0.10
Brick clay, kaolin, crushed sand	0.10–0.20
Pigments, paper, soil, worsted wool fabric	0.20–0.40
Several foods, copper carbonate, sludges	0.40–0.80
Chrome leather, vegetables, fruits, gelatin, gels	>0.80

It is easy to see that N_c can be calculated quite easily using empirical or analytical techniques to estimate the external heat/mass transfer rates (Keey 1978; Geankoplis 1993). Thus,

$$N_c = \frac{\Sigma_q}{\lambda_s} \tag{23.8}$$

where Σ_q represents the sum of heat fluxes due to convection, conduction, and/or radiation, and λ_s, is the latent heat of vaporization at the solid temperature. In the case of purely convective drying, the drying surface is always saturated with water in the constant rate period and thus the liquid film attains the wet-bulb temperature. The wet-bulb temperature is independent of the geometry of the drying object due to the analogy between heat and mass transfer.

The drying rate in the falling rate period(s) is a function of X (or X_f) and must be determined experimentally for a given material being dried in a given type of dryer.

If the drying rate curve (N versus X) is known, the total drying time required to reduce the solid moisture content from X_1 to X_2 can be simply calculated by

$$t_d = -\int_{x_1}^{x_2} \frac{M_s}{A}\frac{dX}{N} \tag{23.9}$$

Table 23.5 lists expressions for the drying times for constant rate, linear falling rates, and a falling rate controlled by liquid diffusion of water in a thin slab. The subscripts c and f refer to the constant and falling rate periods, respectively. The total drying time is, of course, a sum of drying times in two succeeding periods. Different analytical expressions are obtained for the drying times t_f, depending on the functional form of N or the model used to describe the falling rate, e.g., liquid diffusion, capillarity, evaporation-condensation. For some solids, a receding front model (wherein the evaporating surface recedes into the drying solid) yields a good agreement with experimental observations. The principal goal of all falling rate drying models is to allow reliable extrapolation of drying kinetic data over various operating conditions and product geometries.

The expression for t_f in Table 23.5 using the liquid diffusion model (Fick's second law of diffusion form applied to diffusion in solids with no real fundamental basis) is obtained by solving analytically the following partial differential equation:

$$\frac{\partial X_f}{\partial t} = D_L \frac{\partial^2 X_f}{\partial x^2} \tag{23.10}$$

subject to the following initial and boundary conditions:

$X_f = X_{i,}$ everywhere in the slab at $t = 0$

$X_f = 0$, at $x = a$ (top, evaporating surface), and (23.11)

$\frac{\partial X_f}{\partial x} = 0$ at $x = 0$ (bottom, non-evaporating surface)

The model assumes one-dimensional liquid diffusion with constant effective diffusivity D_L, and no heat effects. X_2 is the average free moisture content at $t = t_f$ obtained by integrating the analytical

TABLE 23.5
Drying Times for Various Drying Rate Models

Model	Drying Time
Kinetic model $N = -\frac{M_S}{A}\frac{dX}{dt}$	t_d = Drying time to reach final moisture content X_2 from initial moisture content X_1.
$N = N(X)$ (General)	$t_d = \frac{M_s}{A}\int_{X_2}^{X_1}\frac{dX}{N}$
$N = N_c$ (Constant rate period)	$t_c = -\frac{M_s}{A}\frac{(X_2 - X_1)}{N_c}$
$N = aX + b$ (Falling rate period)	$t_f = \frac{M_s}{A}\frac{(X_1 - X_2)}{(N_1 - N_2)}\ln\frac{N_1}{N_2}$
$N = aX$ $X^* \le X_2 \le X_c$	$t_f = \frac{M_s X_c}{AN_c}\ln\frac{X_c}{X_2}$
Liquid diffusion model D_L = constant, $X_2 = X_c$ Slab; one-dimensional diffusion, evaporating surface at X^*	$t_f = \frac{4a^2}{\pi D_L}\ln\frac{8X_1}{\pi^2 X_2}$ X, average free moisture content a, half-thickness of slab

solution $X_f(x,t_f)$ over the thickness of the slab a. The expression in Table 23.5 is applicable only for long drying times since it is obtained by retaining only the first term in the infinite series solution of the partial differential equation.

The diffusivity of moisture in solids is a function of both temperature and moisture content. For strongly shrinking materials, the mathematical model used to define D_L must account for the changes in diffusion path as well. The temperature dependence of diffusivity is adequately described by the Arrhenius equation as follows:

$$D_L = D_{L0}\exp\left[-E_a / R_g T\right] \tag{23.12}$$

where D_L is the diffusivity, E_a is the activation energy, and T is the absolute temperature. Okos et al. (1992) have given an extensive compilation of D_L and E_a values for various food materials. Zogzas et al. (1996) provide methods of moisture diffusivity measurement and an extensive bibliography on the topic. Approximate ranges of effective moisture diffusivity for some selected materials are given in Table 23.6.

It should be noted that D_L is not a true material property, and care should be taken in applying effective diffusivity correlations obtained with simple geometric shapes (e.g., slab, cylinder, or sphere) to the more complex shapes actually encountered in practice as this may lead to incorrect calculated results (Gong et al. 1997).

In addition to being dependent on geometric shapes, diffusivity depends as well on the drying conditions. Figure 23.8 compares the diffusivity values for air-dried, freeze-dried, and puff-dried potatoes as a function of water activity. At very high activity levels, no differences might be

TABLE 23.6
Approximate Ranges of Effective Moisture Diffusivity in Some Materials

Material	Moisture Content (kg/kg, DB)	Temperature (°C)	Diffusivity (m^2/sec)
Alfalfa stems	3.70	26	2.6×10^{-10}–2.6×10^{-9}
Animal feed	0.01–0.15	25	1.8×10^{-11}–2.8×10^{-9}
Apple	0.10–1.50	30–70	1.0×10^{-11}–3.3×10^{-9}
Asbestos cement	0.10–0.60	20	2.0×10^{-9}–5.0×10^{-9}
Banana	0.01–3.50	20–40	3.0×10^{-13}–2.1×10^{-10}
Biscuit	0.10–0.60	20–100	8.6×10^{-10}–9.4×10^{-8}
Carrot	0.01–5.00	30–70	1.2×10^{-9}–5.9×10^{-9}
Clay brick	0.20	25	1.3×10^{-8}–1.4×10^{-8}
Egg liquid	—	85–105	1.0×10^{-11}–1.5×10^{-11}
Fish muscles	0.05–0.30	30	8.1×10^{-11}–3.4×10^{-10}
Glass wool	0.10–1.80	20	2.0×10^{-9}–1.5×10^{-8}
Glucose	0.08–1.50	30–70	4.5×10^{-12}–6.5×10^{-10}
Kaolin clay	<0.50	45	1.5×10^{-8}–1.5×10^{-7}
Muffin	0.10–0.95	20–100	8.5×10^{-10}–1.6×10^{-7}
Paper, thickness direction	~0.50	20	5×10^{-11}
Paper, in-plane direction	~0.50	20	1×10^{-6}
Pepperoni	0.16	12	4.7×10^{-11}–5.7×10^{-11}
Raisins	0.15–2.40	60	5.0×10^{-11}–2.5×10^{-11}
Rice	0.10–0.25	30–50	3.8×10^{-8}–2.5×10^{-6}
Sea sand	0.07–0.13	60	2.5×10^{-8}–2.5×10^{-6}
Soybeans	0.07	30	7.5×10^{-13}–5.4×10^{-12}
Silica gel	—	25	3.0×10^{-6}–5.6×10^{-6}
Starch gel	0.20–3.00	30–50	1.0×10^{-10}–1.2×10^{-9}
Tobacco leaf	—	30–50	3.2×10^{-11}–8.1×10^{-11}
Wheat	0.12–0.30	21–80	6.9×10^{-12}–2.8×10^{-10}
Wood, soft	—	40–90	5.0×10^{-10}–2.5×10^{-9}
Wood, yellow poplar	1.00	100–150	1.0×10^{-8}–2.5×10^{-8}

observed, but at lower activity levels, the diffusivities may differ by an order-of-magnitude due to the inherently different physical structure of the dried product. Thus, the effective diffusivity is regarded as a lumped property that does not really distinguish between the transport of water by liquid or vapor diffusion, capillary or hydrodynamic flow due to pressure gradients set up in the material during drying. Further, the diffusivity values will show marked variations if the material undergoes glass transition during the drying process.

Keey (1978) and Geankopolis (1993), among others, have provided analytical expressions for liquid diffusion and capillarity models of falling rate drying. Table 23.7 gives solutions of the one-dimensional transient partial differential equations for cartesian, cylindrical, and spherical coordinate systems. These results can be utilized to estimate the diffusivity from the falling rate drying data or to estimate the drying rate and drying time if the diffusivity value is known.

The diffusivity D_L is a strong function of X_f as well as temperature and must be determined experimentally. Thus, the liquid diffusion model should be regarded purely as an empirical representation of the falling rate drying. More advanced models are, of course, available, but their widespread use in design of dryers is hampered by the need for extensive empirical information required to solve the governing equations. Turner and Mujumdar (1997) provide a wide assortment of mathematical models of drying and dryers, and also discuss the application of various techniques for the numerical solution of the complex governing equations.

One simple approach to interpolating a given falling rate curve over a relatively narrow range of operating conditions is that first proposed by van Meel (1958). He found that the plot of the normalized drying rate $v = N/N_c$ versus the normalized free moisture content $\eta = (X - X^*)/(X_c - X^*)$ was nearly independent of the drying conditions. This plot, called the characteristic drying rate curve, is illustrated in Figure 23.9. Thus, if the constant drying rate N_c can be estimated and the equilibrium moisture content data are available, then the falling rate curve can be estimated using this highly simplified approach. Extrapolation over wide ranges is not recommended, however.

Waananen et al. (1993) have provided an extensive bibliography of over 200 references dealing with models of drying for porous solids. Basically, such models are useful to describe

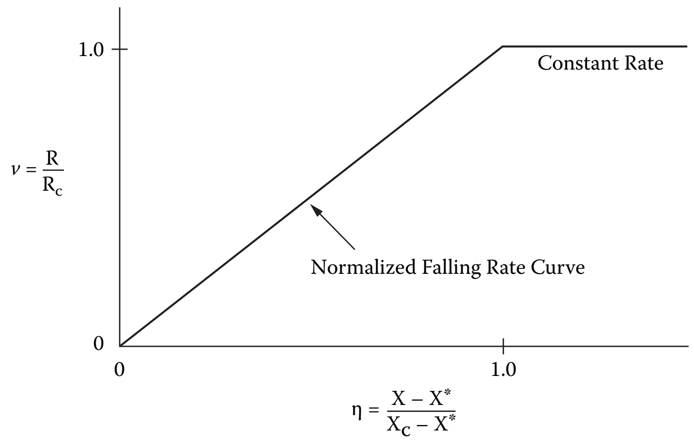

FIGURE 23.9 Characteristic drying rate curve.

drying processes for the purposes of engineering design, analysis, and optimization. A mathematical description of the process is based on the physical mechanisms of internal heat and mass transfer that control the process resistances, as well as the structural and thermodynamic assumptions made to formulate the model. In the constant rate period, the overall drying rate is determined solely by the heat and mass transfer conditions external to the material being dried, such as the temperature, gas velocity, total pressure, and partial pressure of the vapor. In the falling rate period, the rates of internal heat and mass transfer determine the drying rate. Modeling of drying is complicated by the fact that more than one mechanism may contribute to the total mass transfer rate and the contributions from different mechanisms may change during the drying process.

Diffusional mass transfer in the liquid phase, as discussed earlier, is the most commonly assumed mechanism of moisture transfer used in modeling drying that takes place at temperatures below the boiling point of the liquid under locally applied pressure. At higher temperatures, the pore pressure may rise substantially and cause a hydrodynamically driven flow of vapor, which, in turn, may cause a pressure driven flow of liquid in the porous material.

For solids with continuous pores, a surface tension driven flow (capillary flow) may occur as a result of capillary forces caused by the interfacial tension between the water and the solid particles. In the simplest model, a modified form of the Poiseuille flow can be used in conjunction with the capillary forces equation to estimate the rate of drying. Geankoplis (1993) has shown that such a model predicts the drying rate in the falling rate period to be proportional to the free moisture content in the solid. At low solid moisture contents, however, the diffusion model may be more appropriate.

The moisture flux due to capillarity can be expressed in terms of the product of a liquid conductivity parameter and moisture gradient. In this case, the governing equation has, in fact, the same form as the diffusion equation.

For certain materials and under conditions such as those encountered in freeze drying, a "receding-front" model involving a moving boundary between "dry" and "wet" zones often describes the mechanism of drying much more realistically than does the simple liquid diffusion or capillarity model. Examination of the freeze drying of a thin slab of frozen material indicates that the rate of drying is dependent on the rate of heat transfer to the "dry-wet" interface, and the mass transfer resistance offered by the porous dry layer to permeation of the vapor that sublimes from the interface. Because of the low pressures encountered in freeze drying, Knudsen diffusion effects may be significant. Liapis and Marchello (1984) have discussed models of freeze drying involving both unbound and bound moisture.

23.3 CLASSIFICATION AND SELECTION OF DRYERS

In this section, we will examine the key classification criteria for industrial dryers and then proceed to selection criteria with the explicit understanding that the latter is a complex process and is not entirely scientific, but also involves subjective judgment as well as considerable empiricism. It should also be noted that the pre-drying as well as post-drying stages have important bearing on the selection of appropriate dryer types for a given application. Indeed, for optimal selection of solid/liquid separation processes, one must examine the overall flowsheet as well as the "drying system." This section will be confined, however, only to the classification and selection of dryers.

Another important point to note is that several dryer types (or drying systems) may be equally suited (technically and economically) for a given application. A careful evaluation of as many of the possible factors affecting the selection will help reduce the number of options. For a new application (new product or new process), it is important to follow a careful procedure leading to the choice of the dryers. Characteristics of different dryer types should be recognized when selecting dryers. Changes in operating conditions of the same dryer can affect the quality of the dried product. So, aside from the dryer type, it is also important to choose the right operating conditions for optimal quality and cost of dehydration.

Baker (1997) has presented a "structural approach" for dryer selection that is iterative. It includes the following steps:

1. List all key process specifications.
2. Conduct preliminary selection.
3. Perform bench-scale tests, including quality test.
4. Make economic evaluation of alternates.
5. Conduct pilot-scale trials.
6. Select most appropriate dryer types.

Often, for same materials, a specific dryer type is indicated from the outset. If selection is based exclusively on past experience, it has three limitations:

1. If the original selection is not optimal (although it works satisfactorily), the new choice will also be less-than-optimal.
2. No new drying technologies are considered by default.
3. It is implicitly assumed the "old" choice was arrived at logically, which is often not the case.

23.3.1 Classification of Dryers

There are numerous schemes used to classify dryers (Mujumdar 1995b; van't Land 1991). Table 23.8 lists the criteria and typical dryer types. Types marked with an asterisk (*) are among the most common in practice. Such classification is rather coarse. Just the fluidized bed dryer can be subclassified into over 30 types.

Each type of dryer has specific characteristics, which make it suitable or unsuitable for specific applications. Details can be found in Mujumdar (1995). Certain types are inherently expensive (e.g., freeze dryers) while others are inherently more efficient (e.g., indirect or conduction dryers). Thus, it is necessary to be aware of the wide variety of dryers available in the market and their special advantages and limitations. Furthermore, note that the aforementioned classification does not include most of the novel drying technologies, which are applicable for very specific applications. The reader is referred to Kudra and Mujumdar (1995) for details on novel drying technologies.

Following is a general scheme proposed by Baker (1997) for classification of batch and continuous dryers. Note that there is a more limited choice of batch dryers—only a few types can be operated in both batch and continuous modes.

TABLE 23.8
Classification of Dryers

Criterion	Types
Mode of operation	Batch
	Continuous*
Heat input-type	Convection,* conduction, radiation, electromagnetic fields, combination of heat transfer modes
	Intermittent or continuous*
	Adiabatic or nonadiabatic
State of material in dryer	Stationary, moving, agitated, dispersed, etc.
Operating pressure	Vacuum*
	Atmospheric
Drying medium (convection)	Air*
	Superheated steam
	Flue gases
Drying temperature	Below boiling temperature*
	Above boiling temperature
	Below freezing point
Relative motion between drying medium and drying solids	Concurrent
	Countercurrent
	Mixed flow
Number of stages	Single*
	Multi-stage
Residence time	Short (<1 min)
	Medium (1–60 min)
	Long (>60 min)

* Most common dryer type in industry.

23.3.1.1 Batch Dryers: Classification (Baker 1997)

Particulate Solids: Major Classes—Layer (Packed Bed); Dispersion Type

1. Layer type
   a. Contact (conduction or indirect type), e.g., vacuum tray, agitated bed, rotary batch
   b. Convection (atmospheric tray)
   c. Special types (e.g., microwave, freeze, solar)
2. Dispersion type
   a. Fluidized bed/spouted bed
   b. Vibrated bed dryer

23.3.1.2 Continuous Dryers: Classification

Major Classes—Layer; Dispersion Type

1. Layer type
   a. Contact (conduction or indirect type), e.g. drum, plate, vacuum based, agitated bed; indirect rotary, etc.
   b. Convection, e.g., tunnel, spin-flush, throughflow, conveyor, etc.
   c. Special, e.g., microwave, radio frequency, freeze, solar, etc.

2. Dispersion type
   a. Fluid bed, vibrated bed, direct rotary, ring, spray, jet-zone

Classification of dryers on the basis of the mode of thermal energy input is perhaps the most useful since it allows one to identify some key features of each class of dryers.

23.3.1.3 Direct Dryers

Direct dryers, also known as convective dryers, are by far the most common. About 85% of industrial dryers are estimated to be of this type despite their relatively low thermal efficiency caused by the difficulty in recovering the latent heat of vaporization contained in the dryer exhaust in a cost-effective manner. Hot air produced by indirect heating or direct firing is the most common drying medium, although for some special applications superheated steam has recently been shown to yield higher efficiency and often a higher quality product. Superheated steam at near atmospheric pressure can be used only for materials that are stable at higher temperatures. For heat-sensitive materials it is possible to operate a superheated steam dryer at lower pressures where the saturation temperature is lower. Flue gases may be used when the product is not heat sensitive or affected by the presence of products of combustion. In direct dryers, the drying medium contacts the material to be dried directly and supplies the heat required for drying by convection; the evaporated moisture is carried away by the same drying medium.

Drying gas temperatures may range from 50°C to 400°C, depending on the material. Dehumidified air may be needed when drying highly heat-sensitive materials. An inert gas such as nitrogen may be needed when the product is susceptible to oxidation, when drying explosive or flammable solids, or when an organic solvent is to be removed. Solvents must be recovered from the exhaust by condensation so that the inert (with some solvent vapor) can be reheated and returned to the dryer.

Because of the need to handle large volumes of gas, gas cleaning and product recovery (for particulate solids) becomes a major part of the drying plant. Higher gas temperatures yield better thermal efficiencies subject to product quality constraints.

23.3.1.4 Indirect Dryers

Indirect dryers involve a supply of heat to the drying material without direct contact with the heat transfer medium, i.e., heat is transferred from the heat transfer medium (steam, hot gas, thermal fluids, etc.) to the wet solid by conduction. Since no gas flow is presented on the wet solid side, it is necessary to either apply vacuum or use gentle gas flow to remove the evaporated moisture so that the dryer chamber is not saturated with vapor. Heat transfer surfaces may range in temperature from –40°C (as in freeze drying) to ~300°C in the case of indirect dryers heated by direct combustion products such as waste sludges. In vacuum operation, there is no danger of fire or explosion. Vacuum operation also eases the recovery of solvents by direct condensation, thus alleviating serious pollution problems. Dust recovery is obviously simpler so that such dryers are especially suited for drying of toxic, dusty products that must not be entrained in gases. Furthermore, vacuum operation lowers the boiling point of the liquid being removed; this allows drying of heat-sensitive solids at relatively fast rates.

Heat may be supplied by radiation (using electric or natural gas-fired radiators) or volumetrically by placing the wet solid in dielectric fields in the microwave or radio frequency range. Since radiant heat flux can be adjusted locally over a wide range, it is possible to obtain high drying rates for surface-wet materials. Convection (gas flow) or vacuum operation is needed to remove the evaporated moisture. Radiant dryers have found important applications in some niche markets, e.g., drying of coated papers or printed sheets. However, the most popular applications involve the use of combined convection and radiation. It is often useful to boost the drying capacity of an existing convection dryer for sheets such as paper.

Microwave dryers are expensive in terms of both the capital and operating (energy) costs. They have found limited applications to date. However, they do have special advantages in terms of product quality when handling heat-sensitive materials. They are worth considering as devices to speed up drying in the tail end of the falling rate period. Similarly, RF dryers have limited industrial applicability. They have found some niche markets, e.g., drying of thick lumber and coated papers. Both microwave and RF dryers must be used in conjunction with convection or under vacuum to remove the evaporated moisture. Standalone dielectric dryers are unlikely to be cost-effective except for high-value products. See Schiffmann (1995) for a detailed discussion of dielectric dryers.

It is possible, indeed desirable in some cases, to use combined heat transfer modes, e.g., convection and conduction, convection and radiation, convection and dielectric fields, etc., to reduce the need for increased gas flow that results in lower thermal efficiencies. Use of such combinations increases the capital costs, but these may be offset by reduced energy costs and enhanced product quality. No generalization can be made a priori without tests and economic evaluation. Finally, the heat input may be steady (continuous) or time-varying; also, different heat transfer modes may be deployed simultaneously or consecutively depending on the individual application. In view of the significant increase in the number of design and operational parameters resulting from such complex operations, it is desirable to select the optimal conditions via a mathematical model.

23.3.2 Selection of Dryers

In view of the enormous choices of dryer types one could possibly deploy for most products, selection of the best type is a challenging task that should not be taken lightly, nor should it be left entirely to dryer vendors who typically specialize in only a few types. The user must take a proactive role and employ vendors' experiences and bench-scale or pilot-scale facilities to obtain data that can be assessed for a comparative evaluation of several options. A wrong dryer for a given application is still a poor dryer, regardless of how well it is designed. Note that minor changes in composition or physical properties of a given product can influence its drying characteristics, handling properties, etc., leading to a different dried product and, in some cases, severe blockages in the dryer itself. Thus, tests should be carried out with the "real" feed material and not a "simulated" one when feasible.

Although here we will focus only on the selection of the dryer alone, it is very important to note that in practice one must select and specify a drying system that includes pre-drying stages (e.g., mechanical dewatering, evaporation, pre-conditioning of feed by solids backmixing, dilution, or pelletization and feeding) as well as the post-drying stages of exhaust gas cleaning, product collection, partial recirculation of exhaust gas, cooling of product, coating of product, agglomeration, etc. The optimal cost-effective choice of a dryer will depend, in some cases, significantly on these stages. For example, a hard pasty feedstock can be diluted to a pumpable slurry, atomized, and dried in a spray dryer to produce a powder, or it may be pelletized and dried in a fluid bed or in a through circulation dryer, or dried as is in a rotary or fluid bed unit. Also, in some cases, it may be necessary to examine the entire flowsheet to see if the drying problem can be simplified or even eliminated. Typically, nonthermal dewatering is an order-of-magnitude less expensive than evaporation, which, in turn, is many-fold more energy efficient than thermal drying. Demands on product quality may not always permit one to select the least expensive option based solely on heat and mass transfer considerations. Often, product quality requirements have overriding influence on the selection process.

As a minimum, the following quantitative information is necessary to arrive at a suitable dryer:

- Dryer throughput; mode of feedstock production (batch/continuous)
- Physical and chemical properties of the wet feed as well as the product desired (specifications); expected variability in feed characteristics
- Upstream and downstream processing operations

- Moisture content of feed and product
- Drying kinetics data; moist-solid sorption isotherms
- Quality parameters
- Safety aspects, e.g., combustion and dust explosion, fire hazard, toxicity, etc.
- Value of the product
- Need for control
- Toxicological properties of the product
- Potential for fire or explosion hazards
- Turndown ratio, flexibility in capacity requirements
- Type and cost of fuel, cost of electricity
- Environmental regulations

For high-value products like pharmaceuticals, certain foods, and advanced materials, quality considerations override other considerations since the cost of drying is unimportant. Throughputs of such products are also relatively low.

In some cases, the feed may be conditioned (e.g., size reduction, flaking, pelletizing, extrusion, backmixing with dry product) prior to drying, which affects the choice of dryers.

As a rule, in the interest of energy savings and reduction of dryer size, it is desirable to reduce the feed liquid content by less expensive operations such as filtration, centrifugation, evaporation, etc. It is also desirable to avoid over-drying, which increases the energy consumption as well as the drying time, i.e., reduced throughput from a given dryer.

Drying of food and biotechnological products requires adherence to GMP (Good Manufacturing Practice of the Food and Drug Administration) and hygienic equipment design and operation. Such materials are subject to thermal as well as microbiological degradation during drying as well as in storage.

If the feed rate is low (<100 kg/hr), a batch-type dryer may be suitable. If the feed is produced in much larger quantities in batch mode (e.g., 2000 kg batches), one may consider a batch dryer. Note that there is a limited choice of dryers that can operate in the batch mode.

In <1% of cases of industrial drying, the liquid to be removed in dryers is a nonaqueous (organic) solvent or a mixture of water with a solvent. This is not uncommon in drying of pharmaceutical products. Special care is needed to recover the solvent and to avoid potential danger of fire and explosion.

Table 23.9 presents a typical checklist most vendors of dryers use to select and quote an industrial dryers.

Drying kinetics plays a significant role in the selection of dryers, aside from simply deciding the residence time required; it limits the types of suitable dryers. Location of the moisture (whether near the surface or distributed in the material), nature of moisture (free or strongly bound to solid), mechanisms of moisture transfer (rate limiting step), physical size of product, conditions of drying medium (e.g., temperature, humidity, flow rate of hot air for a convective dryer), pressure in dryer (low for heat-sensitive products), etc., have a bearing on the type of suitable dryer as well as the operating conditions. Most often, not more than one dryer type will likely meet the specified selection criteria.

Several attempts have been reported in the literature at development of automated expert systems that guide the selection process. This scheme has met with limited success because there are too many criteria and too many exceptions to rules encountered in practice. Slightly different rules result in different selection solutions. Some of the recommended dryers may not be available from local vendors or the delivery times may be unacceptably long. In some cases, none of the dryers may meet the specified criteria. For example, in drying a highly sticky liquid, none of the dryers may be appropriate unless the feed is backmixed, pelletized, dried in a through circulation tunnel dryer, and then milled to a desired specification. Local environmental regulations may dictate the choice of an indirectly heated rotating shelf vacuum dryer (plate dryer) if the material to be dried

TABLE 23.9
Typical Checklist for Selection of Industrial Dryers

Physical form of feed	Granular/particulate/sludge/crystalline/ liquid/pasty/suspension/solution/ continuous sheets, planks, odd-shapes (small large)
	Sticky, lumpy, other
Average throughput	kg/hr (dry/wet); continuous
	kg per batch (dry/wet)
Expected variation in throughput (turndown ratio)	
Fuel choice	Oil
	Gas
	Electricity
Pre- and post-drying operations (if any)	
For paniculate feed products	Mean particle size
	Size distribution
	Particle density
	Bulk density
	Rehydration properties

is fragile and toxic at the same time. If it were not toxic, a through circulated rotating shelf dryer (e.g., Turbo dryer) may be more economic.

In Table 23.10, Kemp (1998) gives results that were obtained from the proprietary dryer selection algorithm developed by Separation Processes Service (SPS) of AEA Technology, Harwell, United Kingdom. Although only one choice is reported here, it should be noted that, in most cases, alternate dryers can also be recommended with nearly equal performance. If local cost of equipment and energy are factored in along with the value of the dried product itself, the results may be different as well.

A further caution to be exercised when selecting dryers is not to be biased by the way the product is made in the laboratory. Drying as well as filtration, at extremely small scales, are very different from that at a scale that is several orders-of-magnitude larger. Some materials may start to form hard lumps under their own weight—this may not show in pilot tests if the product depth is under the critical depth needed to produce lumps. A double-cone vacuum dryer, for example, has a tendency to form snowballs on full-scale but not necessarily on pilot-scale equipment (Kemp 1998).

Table 23.11 lists some key recommendations on dryer selection based on specific properties of the material. It is not all-inclusive, nor does it cover all special physical and/or chemical

TABLE 23.10
Selection Results for a Variety of Industrial Case Studies

Material	Solids Flow Rate (kg/hr)	Highest-Ranked Dryer	Remarks
Inorganic powder	360	Cascading rotary	Wide range of choices
Salt	500	Plug flow fluid bed	Attrition prevention
Organic peroxide	40	Batch fluid bed	Explosible; inerted
Organo-tin comp	100	Conical vacuum	Toxic, form cuts
Crystals	1000	Plate dryer	Fragile agglomerates
Pharmaceutical	30	Batch freeze dryer	Volatile retention
Mineral industry	500	Spray dryer	Attrition of nozzle
Sewage sludge	1500	Well-mixed fluid bed	Many alternatives
Corn cereal	2000	Cascading rotary	Min. residence time
Polymer	5000	Plug flow fluid bed	Also two-stage options
Inorganic paste	1000	Perforated band	Feed modified to pellets

TABLE 23.11
Key Recommendations on Dryer Selection Based on Specific Properties of the Materials

Quality Parameter	Suggested Dryer/Remarks
Fragile, weak granules, agglomerates	Avoid agitation of material conveyor, tunnel, tray dryers
Flammable	Inert drying medium vacuum dryer, superheated steam dryer
Fire/explosion hazards	As above; lower oxygen concentration in drying; indirect drying
Very sticky feedstock	Pre-condition; solids backmixing, pelletization
High-heat sensitivity	Vacuum or freeze dryers
High-volatile content	Freeze dryers (to retain aroma)
Organic liquid present	Closed-system dryers, spray dryers, fluidized bed dryers
Gentle handling required	Batch or continuous tray, vibrated bed dryers
Excessive drying times	Use dielectric heating (microwave or radio frequency) over part of drying
No contamination permissible; filter cake	Dewater and dry in same unit, e.g., Nutsch filter/dryer

properties. Exceptions do exist, of course. Some other dryers can be modified to meet the specific requirements as well.

We do not focus on novel or special drying techniques here for lack of space. However, it is worth noting that many of the new techniques use superheated steam as the drying medium or are simply intelligent combinations of traditional drying techniques, e.g., combination of heat transfer modes, multistaging of different dryer types, etc. Superheated steam as the convective drying medium offers several advantages, e.g., higher drying rates under certain conditions, better quality for certain products, lower net energy consumption as the excess steam produced in the dryer is used elsewhere in the process, elimination of fire and explosion hazard, etc. Vacuum steam drying of timber, for example, can reduce drying times by a factor of up to four while enhancing wood quality and reducing net fuel and electricity consumption by up to 70%. The overall economics are also highly favorable. Some conventional and more recent drying techniques are listed in Table 23.11.

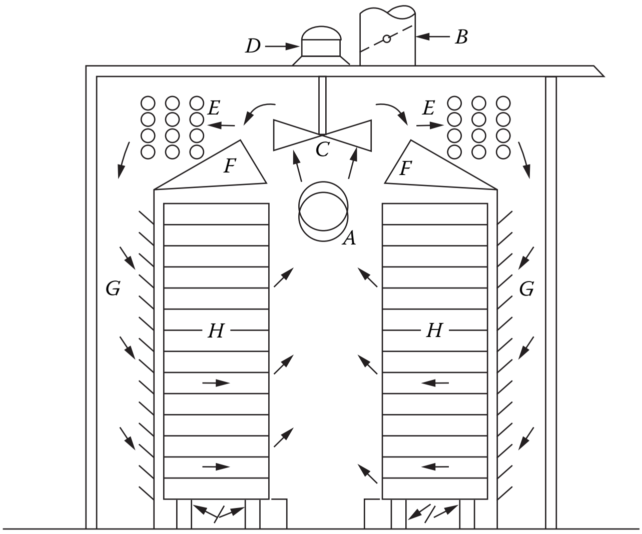

FIGURE 23.10 Schematic of a batch tray dryer.

23.4 DRYING EQUIPMENT

In this section, a number of dryer types commonly used in practice will be discussed based on their different capabilities of handling different types of feedstock, e.g., particulate/granular solids and slurries and suspensions. Some other selected dryers (e.g., infrared, microwave, radio-frequency dryers) will also be mentioned.

23.4.1 Dryers for Particulates and Granular Solids

23.4.1.1 Tray Dryers

By far the most common dryer for small tonnage products, a batch tray dryer (Figure 23.10) consists of a stack of trays or several stacks of trays placed in a large insulated chamber in which hot air is circulated with appropriately designed fans and guide vanes. Often, a part of the exhausted air is recirculated with a fan located within or outside the drying chamber. These dryers require a large amount of labor to load and unload the product. Typically, the drying times are long (10 to 60 hours). The key to successful operation is the uniform air flow distribution over the trays as the slowest drying tray decides the residence time required and hence dryer capacity. Warpage of trays can also cause poor distribution of drying air and hence poor dryer performance.

The batch tray dryer can often be converted into a continuous unit. Figure 23.11 shows the so-called Turbo dryer, which consists of a stack of coaxial circular trays mounted on a single vertical shaft. The product layer fed into the first shelf is leveled by a set of stationary blades that scratch a series of grooves into the surface layer of the solid particles. The blades are staggered to ensure mixing of the material. After one rotation, the material is wiped off the shelf by the last blade and falls onto the next lower shelf. Up to 30 trays or more can be accommodated.

Hot air is supplied to the drying chamber by turbine fans. In the design shown, the air is heated by internal heaters. The wet granular material is fed at the top and it falls under gravity to the next tray through radial slots in each circular shelf. A rotating rake mixes the solids and thus improves the drying performance. Such dryers can be operated under vacuum for heat-sensitive materials or when solvents must be recovered from the vapor. In a modified design, it is possible to heat the trays by conduction and apply vacuum to remove the moisture evaporated.

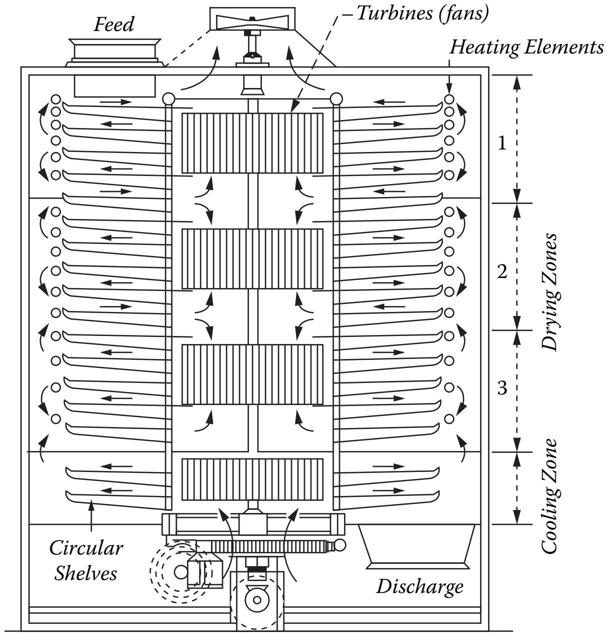

FIGURE 23.11 Schematic of a Turbo dryer.

23.4.1.2 Rotary Dryers

The cascading rotary dryer is a continuously operated direct contact dryer consisting of a slowly revolving cylindrical shell that is typically inclined to the horizontal a few degrees to aid in the transportation of the wet feedstock, which is introduced into the drum at the upper end and the dried product withdrawn at the lower end (Figure 23.12). To increase the retention time of very fine and light particles (e.g., cheese granules) in the dryer, in rare cases it may be advantageous to incline the cylinder with the product end at a higher elevation. The drying medium (hot air, combustion gases, flue gases, etc.) flows axially through the drum either concurrently with the feedstock or counter-currently. The latter mode is preferred when the material is not heat-sensitive and needs to be dried to very low moisture content levels. The concurrent mode is preferred for heat-sensitive materials and for higher drying rates in general.

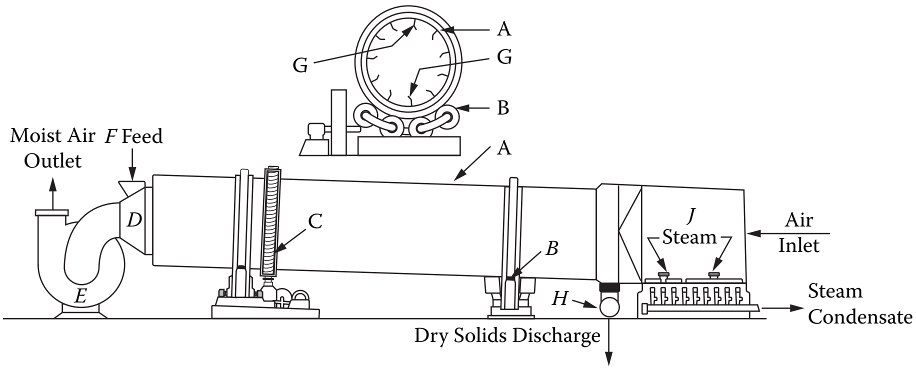

FIGURE 23.12 Countercurrent air-heated rotary dryer: (A) dryer shell; (B) shell-supporting rolls; (C) drive gear; (D) air-discharge hood; (E) discharge fan; (F) feed chute; (G) lifting flights; (H) product discharge; (J) air heater.

In this type of dryer, a wide assortment of granular products of diverse shapes, sizes, and size distributions can be processed by proper design of the internal flights and lifters. Special internals are needed for materials that tend to form large lumps, which must be broken to avoid major problems in the later stages of drying. The lifters lift the material to the top of the drum where it showers down in the form of cascades. Major heat and mass transfer steps occur during the flight of the particles from the top to the bottom of the drum by gravity. The drying medium is in cross-flow with respect to the cascading particles. Clearly, particles with terminal velocities below the cross-flow gas velocity will be entrained and collected in the gas cleaning equipment. The cascading action often causes severe attrition of fragile materials, especially when the drum diameter is large.

Although numerous attempts have been reported that permit calculation of the average particle residence times in rotary dryers, the design of commercial units is still based on pilot tests. Empirical rules (often proprietary) are generally based on prior experience with similar material and similar designs of rotary dryer hardware. The drying process is essentially intermittent. It is intense during the cascading motion under gravity when the particles contact the cross-flowing hot gas stream. When the particles settle on the drum wall as a bed carried upward by the revolving shell, there is a "soaking" or "tempering" period when the temperature and moisture content fields in the particles tend to equalize before the particles are exposed to the convective drying condition again.

Rotary dryers can be designed for drying times from 10 to 60 minutes. If a large retention time is needed for removing the internal moisture in the falling rate period, it is possible to use a smaller shell diameter at the wet end for surface moisture removal with low holdup of material in the drum and then increase the shell diameter at the dry end to allow a longer retention time with a larger holdup. In some designs, it is possible to use a pneumatic conveyor to carry the product out of the dryer.

Thermal efficiencies of rotary dryers vary widely in the range of 30% to 60%. For good efficiency, the product holdup (typically 10% to 15% of volume) should be such as to cover the flights or lifters fully. The lifters should be carefully designed to ensure good cascading action, avoiding large clusters of material falling from the flights. Length-to-diameter ratios of 4 to 10 are common in industrial practice.

Rotary dryers can be operated at very high temperatures to accomplish various reactions in addition to or instead of simple drying; these units are referred to as kilns. It is necessary to line the shell of rotary kilns with suitable refractory materials.

In order to enhance the drying rates in the rotary dryer without raising the gas temperature or gas flowrate excessively, it is possible to introduce steam heated tubes or coils within the shell. Aside from providing additional energy for drying, such internals can also help with redistribution or delumping of the material. Of course, it is possible to use internal heaters only if the material does not stick to the walls of the internals.

A new variant of the classical rotary dryer uses a central axial header for drying gas that is injected at discreet intervals along the length of the rotating shell directly into the "kilning" bed of particles. This type of flow distribution is more effective for heat and mass transfer and results in volumetric heat and mass transfer coefficients up to two times larger than those in the cascading dryer. However, this design is not suited for all types of materials.

Rotary dryers are very flexible, very versatile, and are especially suited for high production rate demands. On the negative side, they are typically less efficient, demand high capital costs, and significant maintenance costs, depending on the material being dried. They are not recommended for fragile materials and for low production rates.

Finally, it is useful to note that while most of the continuous rotary dryers are operated under near atmospheric pressure, the term vacuum-rotary dryer refers to an entirely different class of dryers. It is, in fact, an indirect-type batch dryer because of the difficulty of maintaining vacuum under continuous feeding and discharge conditions. Here, the horizontal cylindrical shell is stationary while a set of variously designed agitator blades revolves on a central shaft to agitate the material contained in the dryer shell. Heat is supplied by heating the shell jacket using condensing steam or a thermal fluid. In larger units, the central agitator shaft and the blades may also be heated.

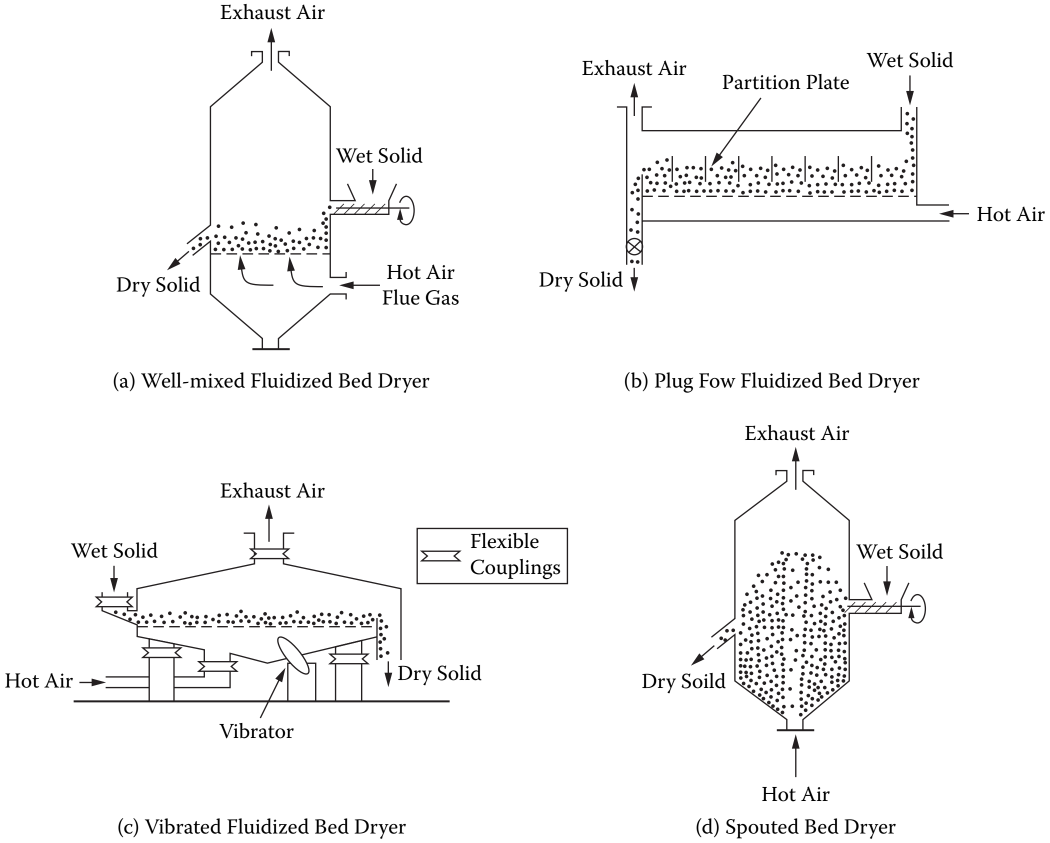

FIGURE 23.13 Fluidized and modified fluidized bed dryers.

The agitator may be a single- or double-spiral. The outer blades are set close to the wall and may have a scraper attached to keep the material from building up on the walls and deteriorating the thermal performance of the unit. This type of dryer is useful for handling heat-sensitive materials, which dry at lower temperatures because of the vacuum conditions.

23.4.1.3 Fluidized Bed Dryers

Fluidized bed dryers offer the advantages of high drying rates, high thermal efficiency, low floor area, ease of control, etc., for drying of particulate solids, sludges, and even slurries when inert particles are used as the bed media. Their limitations include high power consumption, attrition, and lower flexibility than competing dryers, e.g., rotary, conveyor dryers, etc. Mechanical agitation of vibration may be necessary to handle sticky or highly polydisperse particles.

Figure 23.13 shows the four common types of fluidized and modified fluidized bed dryers that may be operated in either the batch (lower capacities) or continuous mode. Numerous variants are possible and in use.

Figure 23.14 outlines a classification of fluidized bed dryers. For heat-sensitive materials, e.g., polymer pellets, use of immersed heat exchangers allows use of lower fluidizing air temperature without increasing drying time. Such exchangers can be used, however, only if the solids do not foul their surfaces.

Well-mixed continuous fluidized bed dryers are most commonly used if the final product moisture content distribution is permitted to vary somewhat due to the inherent residence time distribution in the dryer. Equilibration occurs during storage, resulting in uniform product moisture.

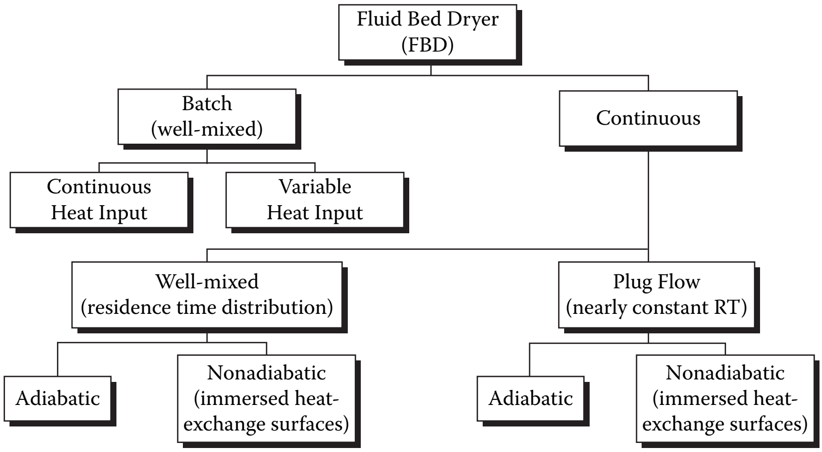

FIGURE 23.14 Coarse classification scheme for fluidized bed dryer.

Also, when handling fairly wet feedstocks, such as filter cakes, mixing of the wet feed into a highly agitated bed of drier particles allows smoother fluidization.

Plug-flow fluidized bed dryers are recommended when it is very important to ensure an almost uniform particles residence time in the dryer. Such dryers may be rectangular geometry trough with large aspect ratios. If floor space is a problem, the trough can be made into a spiral channel. In the straight trough configuration, it is possible to have gas temperature distribution along the length of the dryer. The inlet region can use higher air temperature to enhance the drying rate while toward the end, when the product has lower moisture content, the air temperature can be lowered; in many cases, ambient air is used to cool the product prior to storage or packaging.

When drying large particles, which are difficult to fluidize, a spouted bed or one of its many variants may be used instead of the conventional fluidized bed in which the air is distributed uniformly through a low open area–supporting grid. In a spouted bed, the air enters as a jet and causes a regular recirculatory motion of the particles within the vessel. Due to several limitations, the conventional spouted bed has not found significant commercial application as a dryer, however.

When handling difficult-to-fluidize granular products (because of large size, wide size distribution, or surface stickiness), mechanical assist may be needed to cause the particle bed to be dispersed. Mechanical agitation of the bed or application of vertical vibration at frequencies in the range of 5 to 20 Hz at half-amplitudes of 3 to 5 mm eases separation of the particles. In fact, very low velocities of the drying air are needed to cause pseudo-fluidization by vibration; the resulting drying rates are comparable to those obtained at higher velocities (and hence higher power consumption and particle attrition) in a conventional fluidized bed. The power required for vibration is rather small compared to that used for air handling in a fluidized bed. For fragile solids, e.g., crystals, weak agglomerates, tea leaves, etc., a vibrated fluidized bed may be preferable to conventional fluidized beds. It is used also for large, complex-shaped particles, e.g., chopped or cut fruits and vegetables.

23.4.1.4 Freeze Dryers

Highly heat-sensitive solids, such as some certain biotechnological materials, pharmaceuticals, foods with high flavor content, etc., may be freeze dried at a cost that is at least one order-of-magnitude higher than that of spray drying—itself not an inexpensive drying operation. Here, drying occurs well below the triple point of the liquid (often at temperatures in the vicinity of –40°C) by sublimation of the frozen moisture into vapor, which is then removed from the drying chamber by mechanical vacuum pumps or steam jet ejectors. Generally, freeze drying yields the highest quality

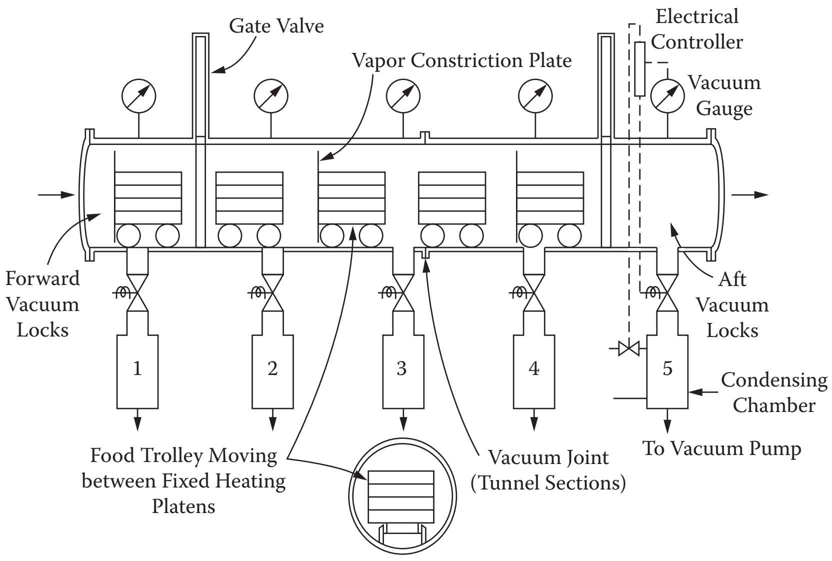

FIGURE 23.15 Schematic diagram of a typical tunnel freeze dryer.

product of any dehydration techniques. A porous, non-shrunken structure of the product allows rapid rehydration. Flavor retention is also high due to the low temperature operation. Living cells, e.g., bacteria, yeasts, and viruses, can be freeze dried and the viability on reconstitution can still be high. Mammalian cells, however, cannot be preserved by freeze drying. Because of its inherently high-cost nature, freeze drying is not common in the chemical industry.

Most freeze dryers are batch type with rather low capacities, although some continuous freeze drying units are in operation. Industrial freeze dryers can be of several types; simple tray freeze dryers are by far the most common. Heat for sublimation is supplied by conduction through the tray bottom. Vacuum pressure is typically under 25 Pa and the condenser operates at around –40°C. The heaters start at a higher temperature (say, 120°C) but the temperature drops with time, according to schedules determined empirically, to lower values, say –40°C over 8 to 10 hour runs. To minimize drying times, freeze dryers are program controlled. Multibatch freeze dryers are used to permit nearly equal loads on all systems throughout the drying cycle. A number of batch cabinets are programmed to operate with staggered, overlapping drying cycles.

A tunnel freeze dryer (Figure 23.15) is basically a large vacuum cabinet into which tray-carrying trolleys are loaded at intervals through a vacuum lock at one end of the tunnel. Figure 23.15 shows a unit with vacuum locks at each end, one for loading and the others for discharging. Low-pressure steam is used to heat the plates on which the trays sit. Liapis and Bruttini (1995) have provided a detailed analysis of the drying characteristics, costs, and details on various freeze-dried products. Recent developments in freeze drying (also called lyophilization) of pharmaceutical and biological products are discussed in Rey and May (1999).

23.4.1.5 Vacuum Dryers

For drying of granular solids or slurries, vacuum dryers of various mechanical designs are available commercially. They are more expensive than atmospheric pressure dryers but are suited for heat-sensitive materials or when solvent recovery is required or if there are risks of fire and/or explosion. Single-cone and double-cone mixers can be adapted to drying by heating the vessel jackets and applying vacuum to remove moisture. Figures 23.16 and 23.17 show two vacuum dryers available commercially. The paddle dryer is suited for sludge-like materials while the vacuum band dryer is

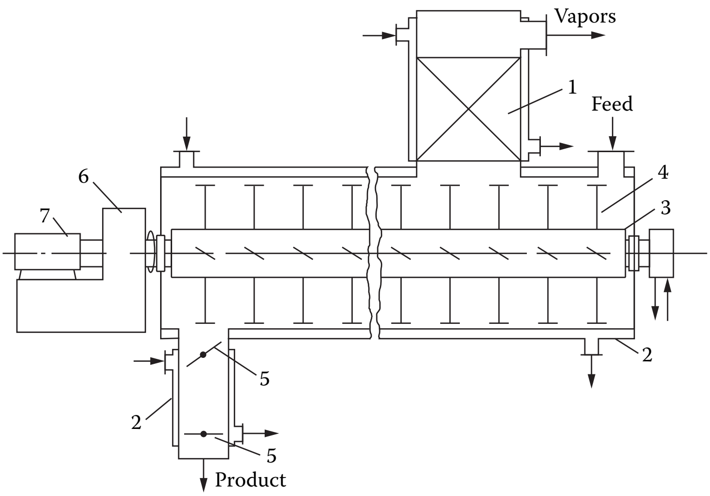

FIGURE 23.16 Continuous vacuum paddle dryer: (1) vapor filter; (2) steam jacket; (3) shaft with paddles; (4) paddles; (5) valves; (6) shaft drive; (7) shaft oscillator.

good for thin pastes or slurries. The material forms a film over the heated band; it may boil and form a highly foamy, porous structure of very low-bulk density.

23.4.2 Dryers for Slurries and Suspensions

23.4.2.1 Spray Dryers

Over 20,000 spray dryers are presently in use commercially to dry products from agro-chemicals, biotechnological products, fine and heavy chemicals, dairy products, dyestuffs, and mineral concentrates to pharmaceuticals in capacities ranging from a few to 50 tons/hr evaporation capacity. Liquid feedstocks, such as solutions, suspensions, or emulsions, can be converted into powder, granular, or agglomerate form in a one-step operation in spray dryer. Figure 23.18 gives a process schematic for a spray dryer plant. Atomized feedstock in the form of a spray is contacted with hot gas in a suitably designed drying chamber. Proper selection and design of the atomizer is vital to the operation of the spray dryer as it is affected by the type of feed (viscosity), abrasive property of the feed, feed rate, desired particle size, and size distribution as well as the design of the spray dryer chamber geometry and mode of flow, e.g., concurrent, countercurrent, or mixed flow (see Figure 23.19).

Masters (1991) and Filkova and Mujumdar (1995) provide further information on spray drying in a tabular form. The design of spray dryers depends heavily on pilot-scale testing. It is impossible to scale-up quality criteria for spray dryers. Fortunately, in most cases, the larger scale dryer provides a better quality product than the one obtained in smaller scale-pilot tests. Aside from the drying rate and quality tests, it is also important to check for potential deposits in the drying chamber as they may lead to fire and explosion hazards.

Essentially, three major types of atomizers are used in practice: (1) rotary wheel (or disk) atomizers, (2) pressure nozzle, and (3) two-fluid nozzle. Figure 23.20 shows some typical atomizer designs. Ultrasonic and electrostatic atomizers can also be used for special applications to produce monodisperse sprays, but they are very expensive and low capacity. Most spray dryers operate at slight negative pressure. New designs with low-pressure chambers enhance drying rates at lower temperatures to dry heat-sensitive products.

The design of the spray drying chamber depends on the needed residence time (Table 23.12) as well as the type of atomizers used (Table 23.13). The mode of flow, e.g., concurrent, countercurrent, mixed flow, etc., depends on the desired characteristics of the product, as summarized in Table 23.14. Finally, Table 23.15 gives suggested spray dryer system layouts depending on the feedstock characteristics, e.g., presence of organic solvents, danger of fire or explosion, etc.

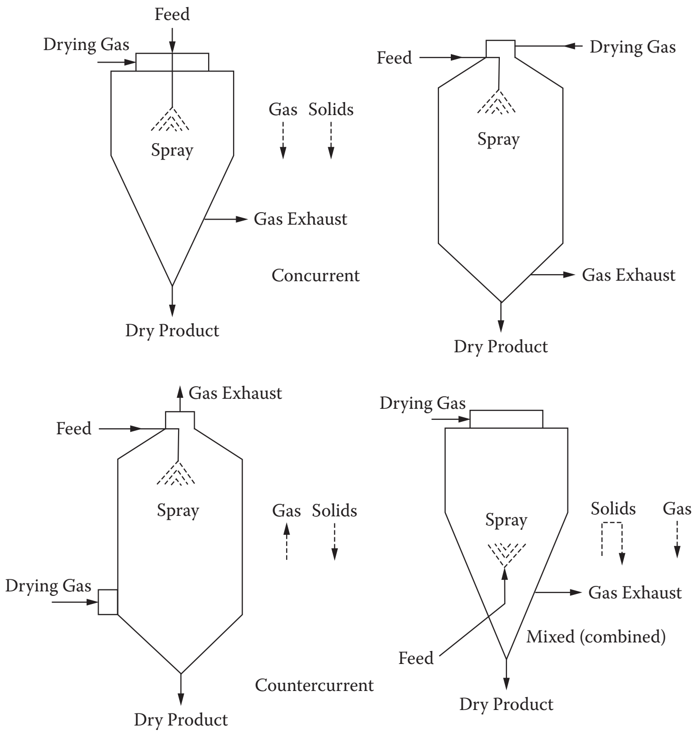

FIGURE 23.19 Schematic diagrams of co-current, countercurrent, and missed flow spray dryer configurations.

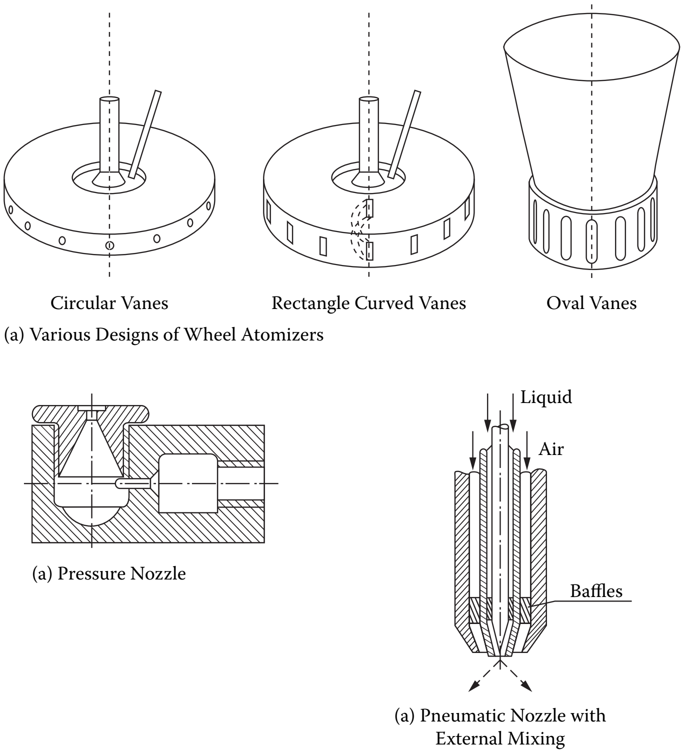

FIGURE 23.20 Atomizers.

TABLE 23.12
Residence Time Requirements for Spray Drying of Various Products

Residence Time in Chamber	Recommended for
Short (10–20 sec)	Fine, non-heat-sensitive products; surface moisture removal, nonhygroscopic
Medium (20–35 sec)	Fine-to-coarse sprays (d_{mean} = 180 μm)
	Drying to low final moisture
Long (>35 sec)	Large powder (200–300 μm)
	Low final moisture, low-temperature operation for heat-sensitive products

TABLE 23.14
Selection of Mode of Flow in Spray Drying Chamber Based on Desired Powder Characteristics

Dryer Design—Flow Type	Characteristics
Concurrent	Low product temperature
Mixed flow with integrated fluidized beds	To produce agglomerated powder
Mixed flow (fountain type)	For coarse sprays in small chambers; product not heat-sensitive
Countercurrent flow	Products that withstand high temperatures; coarse particles; high-bulk density powders

TABLE 23.15
Spray Dryer System Layout

System Layout	Characteristics
Open cycle	General; all aqueous feeds
Closed cycle	Recovery of solvents; prevention of vapor emissions; elimination of explosion or fire hazards
Semi-closed	Prevent powder explosion (keep O_2 content low), yet use higher inlet temperature
Self-inertizing	

TABLE 23.16
Selection of Dry Powder Collection System

Requirement	Recommended System
Low cost, efficient, easy to clean	Cyclones
Medium cost, very efficient, high running cost	Bag filter
Large air volumes	Electro-static precipitator
Product recovery; fines	Cyclone + wet scrubber

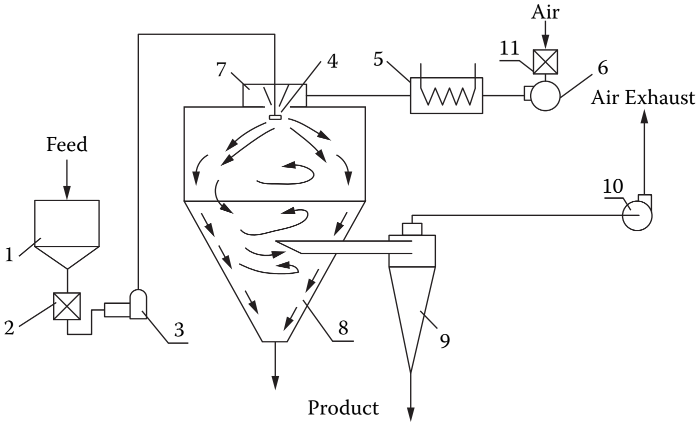
Collection of the dried powder from the spray dryer is also an important issue. Table 23.16 lists general recommendations for the selection of the dry powder collection system.

Since the choice of the atomizer is very crucial, it is important to note the key advantages and limitations of the wheel and pressure nozzles most common in practice. Although both types may be used for same feedstocks, the product properties (bulk density, porosity, size, etc.) will be different.

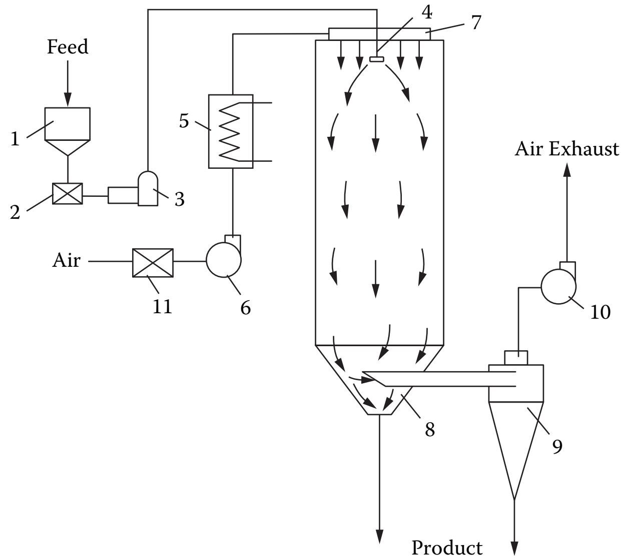
Rotary wheel (or disk) atomizers
- Advantages
  - Handle large feed rates with a single wheel
  - Suited for abrasive feeds with proper design
  - Negligible clogging tendency
  - Change of rpm controls particle size
  - More flexible capacity
- Limitations
  - Higher energy consumption compared to pressure nozzles
  - More expensive
  - Broad radial spray requires large drying chamber (cylindrical-conical type)

Pressure nozzles
- Advantages
  - Simple, compact, cheap
  - No moving parts
  - Low-energy consumption
- Limitations
  - Low capacity (flow rates)
  - High tendency to clog
  - Erosion can change spray characteristics

Figure 23.21 shows schematics of two spray dryers, one fitted with a wheel atomizer (cylindrical-conical) and the other with a nozzle atomizer (single or two-fluid), which is a cylindrical vessel.



(a) With Wheel Atomizer



(b) With Nozzle Atomizer

FIGURE 23.21 Spray dryer layout: (1) feed tank; (2) filter; (3) pump; (4) atomizer; (5) air heater; (6) fan; (7) air dispenser; (8) drying chamber; (9) cyclone; (10) exhaust fan; (11) filter.

These figures also show other components of the system (feed tank, filter, pump, air heater, fan cyclone, exhaust fan, etc.).

Figure 23.22 shows the layout of a spray dryer system, which is self-inertizing because the partial recycle from the combustion chamber decreases the oxygen level to a low enough value such that it does not sustain combustion of the product. Hence, it is used to handle materials with high risk of fire and explosion. Here, excess air entering the system passes through the burner flame and is used as combustion air, thus inactivating it.

When the product coming out of the spray dryer is too fine it does not wet readily and so is harder to reconstitute. To make the product more readily soluble, it is agglomerated in a small fluidized or vibrated fluidized bed, as shown in Figure 23.23. This two-stage arrangement is used in the production of instant coffee, milk powder, cocoa, etc. An extension of this basic concept is the so-called spray-fluidizer, which dries the material in two stages. In the first stage (spray dryer),

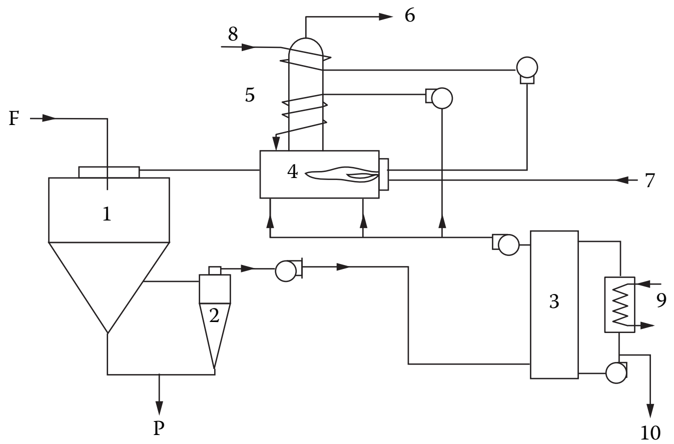


FIGURE 23.22 Self-inertizing spray drying system: (1) drying chamber with rotary atomizer; (2) cyclone; (3) scrubber condenser; (4) direct-fired heater; (5) heat exchanger for waste-heat recovery; (6) exhaust to atmosphere; (7) fuel; (8) combustion air; (9) cooler; (10) condensate; F, feed; P; product.

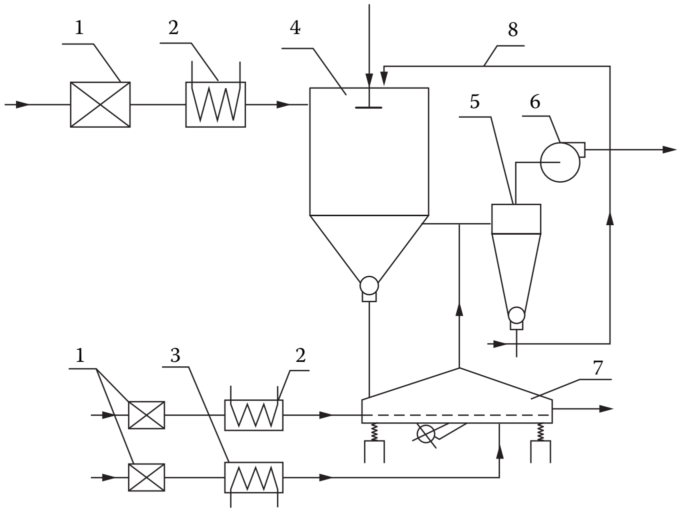

FIGURE 23.23 A two-stage spray drying process for milk: (1) air filter; (2) heater; (3) cooler; (4) spray dryer; (5) cyclone; (6) exhaust fan; (7) fluidized bed dryer; (8) return line of fine powder.

the surface moisture from droplets is removed fully, along with some internal moisture. The final moisture content is achieved in a fluidized bed located at the bottom of the spray chamber as an integral part of it. This two-stage drying process is very efficient and economic. The fluidized bed drying unit can be replaced with a through circulation band dryer at the bottom of the chamber; this concept is the basis of the so-called filtermat dryer used for sticky and sugar-rich materials, which are hard to dry. The bottom section of the spray chamber in this case is much wider, unlike the spray-fluidizer.

23.4.2.2 Drum Dryers

In drum dryers, slurries or pasty feedstocks are dried on the surface of a slowly rotating steam-heated drum. A thin film of the paste is applied on the surface in various ways. The dried film is removed (doctored off) once it is dry and is collected as flakes (rather than powder). Figure 23.24

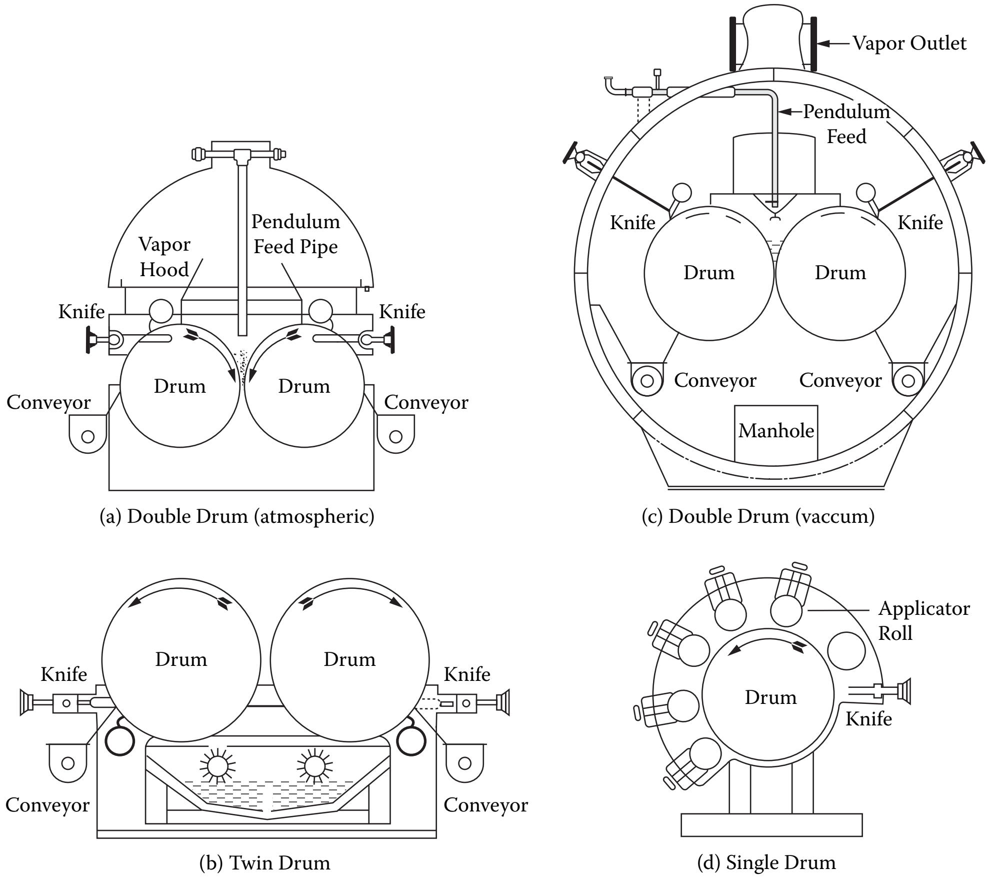

FIGURE 23.24 Types of drum dryers: (a) double drum (atmospheric); (b) twin drum; (c) double drum (vacuum); and (d) single drum.

shows four types of commonly used drum dryer arrangements, which are self-explanatory. The design of applicator rolls is important since the drying performance depends on the thickness and evenness of the film applied. The paste must stick to the surface of the drum for such a dryer to be applicable.

Five key variables influence the drum dryer performance. They are (1) steam pressure or heating medium temperature; (2) speed of rotation; (3) thickness of film; (4) feed properties (e.g., solids concentration, rheology, temperature, etc.); and (5) method of removing dust flakes by scraper or knife. Because they allow control of the temperature, drum dryers may be used to produce a precise hydrate of a chemical compound rather than a mixture of hydrates.

Vacuum operation of both single- and double-drum dryers enhances drying rates for heat-sensitive materials, such as pharmaceutical antibiotics. They are also used when a porous structure of product is desired. When recovery of solvents is an issue, vacuum operation is often recommended. When recovering high boiling point solvents such as ethylene glycol, lowering the pressure depresses the boiling point. For a detailed description and discussion of various drum dryers, the reader is referred to Moore (1995).

23.4.3 Selected Dryers and Drying Systems

Key features and applications of some specialized dryer types that are used in the chemical and ancillary industries but perhaps less commonly than the spray, rotary and fluidized bed types are

listed here: two-stage dryers, flash or pneumatic dryers, spin-flash dryers, Roto-Louvre dryer, tunnel dryers, band dryers, infrared, microwave, and radio frequency dryers.

Flash and spin-flash dryers can be used for the removal of surface moisture from a variety of feeds ranging from particulates to pastes in medium to high tonnages. The residence time in these dryers is very short (10 to 30 seconds), although, in some cases, it is enhanced by automatic aerodynamic recirculation of the heavier (larger or wetter) particles through the dryer tube. Band dryers are used for relatively free-flowing particulate materials for medium tonnages, and, in some cases, very large circulation conveyor dryers are used to replace rotary dryers. Most of the dryers mentioned here have several variants that make them more efficient or desirable for a given application; here we will cover only the most basic dryer concepts.

23.4.3.1 Two-Stage Dryers

When both surface and internal moistures must be removed from large quantities of feedstock, it is desirable to consider two-stage operation, where the two stages may be the same dryer type (e.g., fluidized bed) or may be different. The fundamental advantage of such a system is that one can then remove the surface moisture rapidly using dryers or conditions suitable for its rapid removal (e.g., using higher gas temperatures or velocities), and using a dryer allowing longer residence time or gentler drying conditions as the second stage. A plug-flow continuous fluidized bed dryer can be zoned along its length by lowering the gas temperature from inlet to outlet, for example.

Figure 23.25 shows a two-stage arrangement, where the top first stage is a well-mixed fluidized bed dryer for a filter cake, which is difficult to fluidize unless it is mixed with a fluidized bed of lower moisture content. In this figure, the first stage also uses internal heating panels to increase the drying rate since this stage receives drying air, which is the exit air from the lower second stage. The lower stage, which receives the output of the first stage by gravity through a centrally located discharge tube, is a spiral plug-flow fluidized bed dryer, which controls the particle residence time to yield a uniform product.

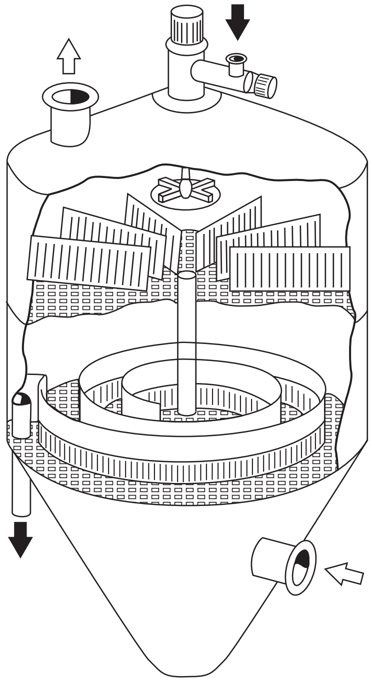

FIGURE 23.25 Schematic of a two-stage fluid bed.

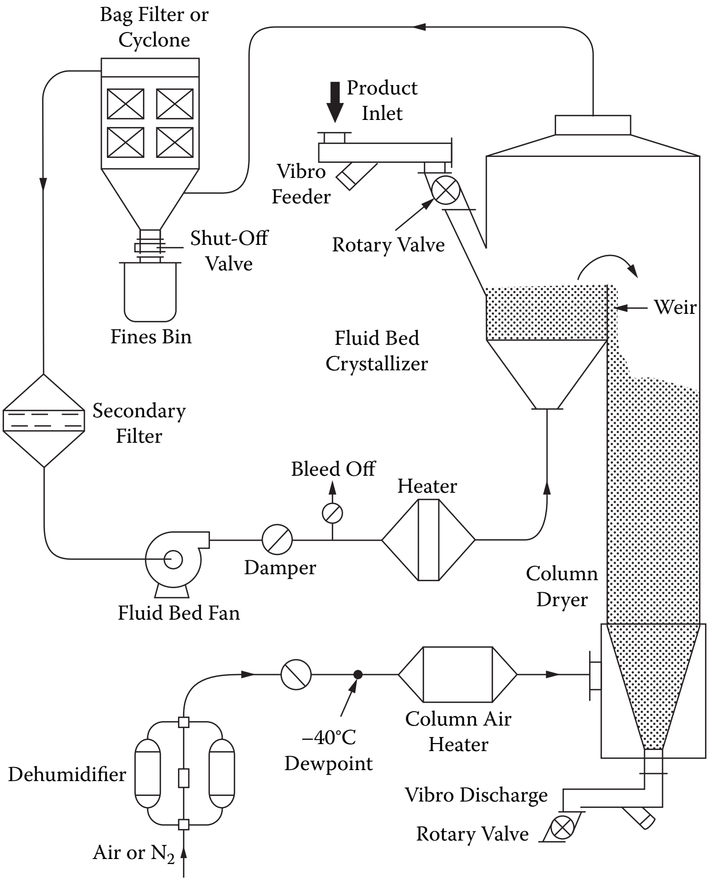

FIGURE 23.26 Continuous fluid bed crystallizer/column dryer for polyester.

Figure 23.26 is another example of a commercial two-stage dryer for crystallization/drying of polyester chips. A small fluidized bed, as the first stage, removes the readily removable liquid while the tall "column" dryer allows a very long residence time during which the material crystallizes and dries slowly.

Numerous examples of two-stage dryers are used commercially. They are viable options and perhaps need to be considered more often than they are today to reduce drying costs and even enhance product quality. Many examples can be found in Mujumdar (1995b).

23.4.3.2 Flash Dryers

Figure 23.27 shows a schematic of the simple flash (pneumatic) dryer system. Here, the wet feed is dispersed mechanically into a hot gas stream (commonly air or combustion gases) and conveyed for a long enough time to allow drying of the particulates in the size range 10 to 500 μm (microns) during their transport. Clearly, only the surface moisture of small particles can be removed economically in such a system of reasonable length of the insulated conveying tube. Most dryers are thus adiabatic and use a flash tube of circular and uniform cross-section. In some cases, the tube may diverge and converge, or have sudden expansions and contractions. The tube may be heated through the wall to maintain the temperature driving force, as the gas supplies heat to the particles as heat of vaporization and sensible heat. Noncircular cross-sections (e.g., rectangular with rounded corners) and tubes of nonrectilinear configurations (e.g., in the form of a ring) are also employed for special applications. For details, see Mujumdar (1995b).

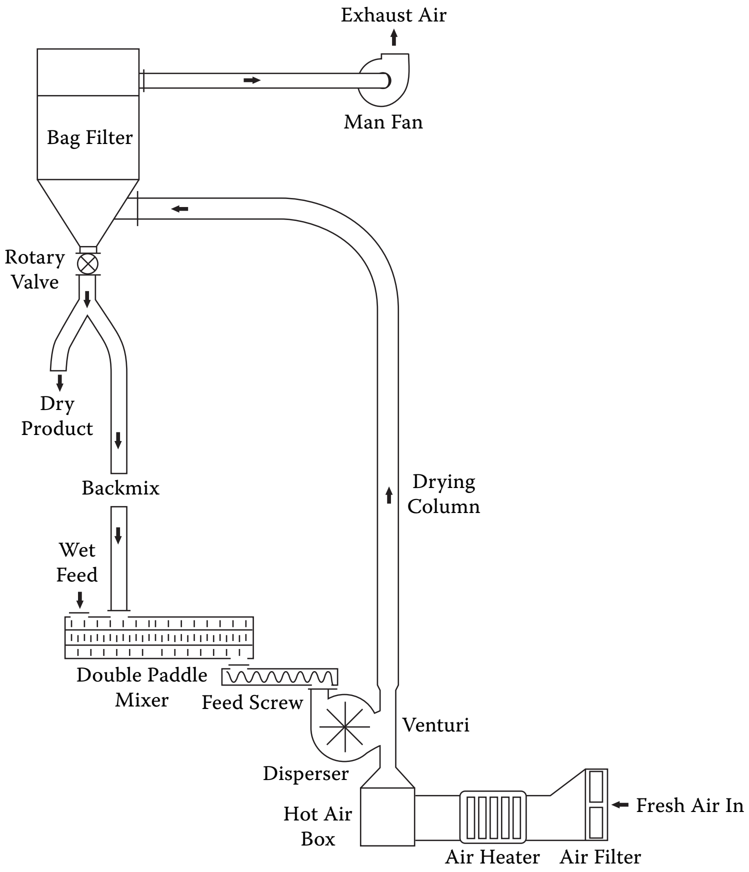

FIGURE 23.27 Flash dryer fitted with back mixer and bag filter.

Flash dryers may be used to dry heat-sensitive solids in view of the short exposure time to the drying medium. They have low capital cost, although, in some cases, the ancillary equipment (disperser, blender [if solids backmixing is needed prior to dispersion], heat exchangers, product collection devices, etc.) may cost much more than the basic flash dryer tube itself. Because of the risk of fire and explosion, care must be taken to avoid flammability limits in the dryer. The dryer must be designed with suitable rupture disks to minimize damage in the event of an explosion. The dryer has small "foot print" (e.g., small floor area) since the flash tube generally rises vertically so the flow of particulates against gravity increases the residence time in the tube of a given length. When it is feasible, a flash dryer should be considered. It does cause attrition, however. It can be used as the first stage of a two-stage dryer system to remove only the surface moisture rapidly and cheaply while a higher residence time dryer (e.g., fluidized bed) may be deployed as the second stage. Removal of the surface moisture also helps fluidize the material well, aside from reducing the size of the fluidized bed unit.

Design of the feed system is crucial for a flash dryer. For free-flowing powdery solids, a screw feeder or a rotary valve is effective. Pasty or sticky materials need to be pre-conditioned by blending them with dried product using a single- or twin-shaft paddle blender and then dispersing them mechanically using a kicker mill or one of several other designs of rotating disperser. The product may be collected in cyclones or baghouses and the very fine material removed prior to exhaust in wet scrubbers.

Flash dryers utilizing superheated steam as the drying medium often have unique quality and energy advantages over air drying systems. More recently, flash dryers consisting of inert media

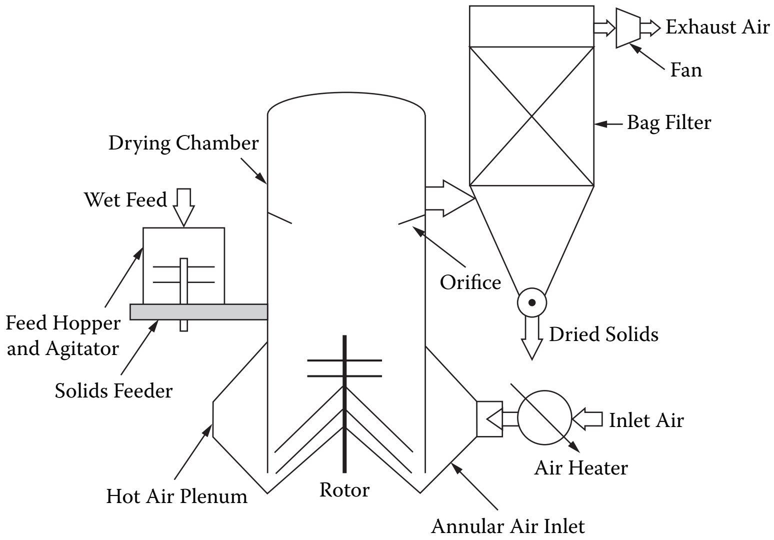

FIGURE 23.28 Spin-flash dryer.

have been employed at pilot scale to dry slurries and suspensions, which are sprayed on to them. The particles are coated thinly by the slurry and dried rapidly as a thin film. Attrition due to interparticle collisions and shrinkage-induced breakage of the dried film allow entrainment of the dry powder into the drying gas for collection in a cyclone or baghouse. This process is yet to be commercialized.

23.4.3.3 Spin-Flash Dryers

This dryer is basically a mechanically agitated fluidized bed designed for very short residence times, so it is suited for the removal of only the surface moisture. Sludges, pulps, pastes, filter cakes, high-viscosity liquids, etc., can be dried without the use of an atomizer. As shown in Figure 23.28, a rotor placed at the bottom of the dryer chamber serves to disperse the feed, which falls by gravity onto it; hot drying air enters the chamber tangentially and spirals upward, carrying and drying the dispersed particles. The exhaust containing the dried powder is cleaned and the powder recovered. Heavier wet particles remain within the chamber for a longer time and are broken up by the rotor—only the dried fine powder escapes to the gas cleaning system. This type of dryer can be a replacement for the more expensive spray dryer (which needs more thermal energy because the feed is wetter due to the pumpability requirements and also expensive because of the need for an atomizer). To date, numerous materials have been dried successfully in such units at capacities up to 10 tons/hr. They are more expensive than the conventional flash or fluidized bed dryers. Care must be taken to ensure in pilot tests that there is no danger of product sticking and accumulations on the walls.

23.4.3.4 Roto-Louvre Dryer

This dryer is a modification of the conventional rotary dryer, in which the drying gas contacts the wet particles rather inefficiently as the particles shower down from the flights and get exposed to the axial cross-flow of the gas. In a roto-louvre design (Figure 23.29), the slowly rotating horizontal drum (2 to 3 rpm) is fitted with longitudinal louvres, which make a tapered drum within the external drum. Diameters up to 3.5 m and lengths up to 12 m have been built commercially. The particles form a gently rolling fluidized bed at the bottom of the inner drum as the drying gas is introduced. The resulting heat and mass transfer rates are much greater than those achieved in a conventional

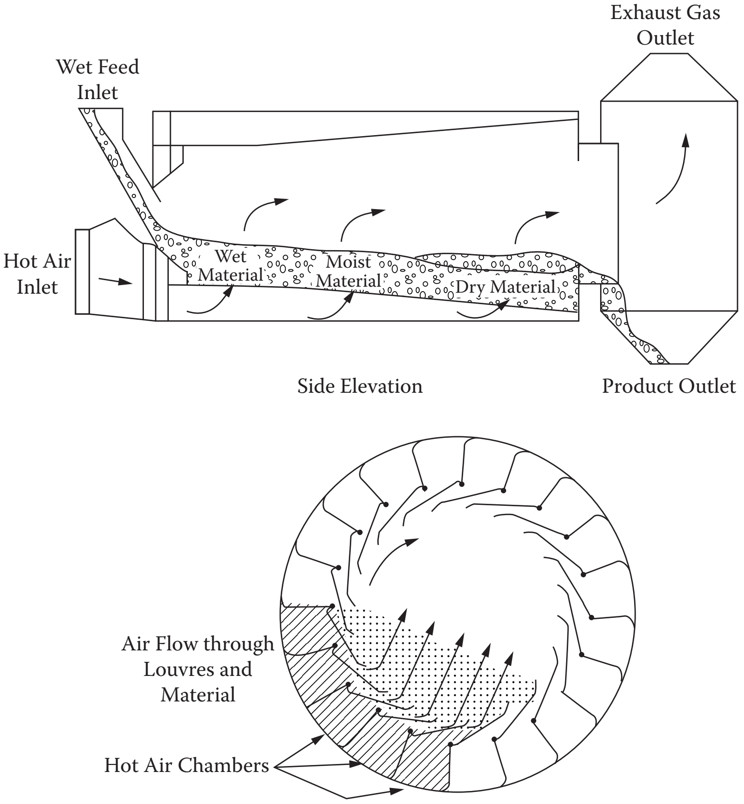

FIGURE 23.29 Roto-louvre dryer.

rotary dryer. Hence, the size of the dryer may be reduced by up to 50%. However, the additional complexity of the equipment increases the initial cost. Product handling is gentler and results in less attrition.

23.4.3.5 Tunnel Dryers

In this simple dryer concept, cabinets, trucks, or trolleys containing the material to be dried are transported at an appropriate velocity through a long insulated chamber (or tunnel). The hot drying gas flows in concurrent, countercurrent, cross-flow, or mixed-flow fashion (Figure 23.30). In the concurrent mode, the hottest and driest air meets the wetted product and hence results in high initial drying rates but with relatively low product temperature (wet-bulb temperature of surface moisture is present). Higher gas temperatures can be used in concurrent arrangements while in countercurrent dryers, the inlet drying gas must be at a lower temperature if the product is heat sensitive. If the material to be dried is not heat sensitive and low residual moisture content is a requirement, then one may employ higher gas temperatures in the countercurrent arrangement as well. Combination flow or cross-flow arrangements are used less commonly. The latter offer high drying rates, but the tunnels must be designed to fit the trolleys snugly so the drying gas flows through the material much like a through-circulation packed bed dryer. Total drying times often range from 30 minutes to 6 hours.

23.4.3.6 Band Dryers

For relatively free-flowing granules and extrudates, which may undergo mechanical damage if they are dispersed, band dryers (Figure 23.30) are a good option. It is essentially a conveyor dryer in which a perforated band supports the bed of drying solids. Drying air at rather low velocities flows

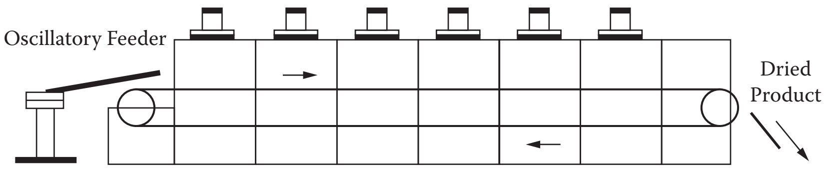

FIGURE 23.30 Band dryer.

upward through the band to accomplish drying. Clearly, this type of dryer is not a good choice for very wet or very fine solids. If the bed depth is large (>10 to 15 cm), a significant moisture profile may occur in the bed with the solids resting on the band overdried and overheated. One option to alleviate this problem is to reverse the gas flow direction alternately over the length of the dryer. This evens out the moisture profile while increasing the drying rate as well. Another option is to cause mixing of the bed at appropriate intervals of space. In some commercial designs, such as so-called multipass dryers, several bands are stacked one above the other and the material is made to drop under gravity from the higher to the next lower band, which causes some random mixing of the material before it undergoes further through-circulation drying. It is possible to use a temperature profile along the length of the conveyor so that the drier product can be exposed to lower gas temperatures if that is desired. Also, the final section may be a simple cooler so the product is ready for packaging or storage. Residence times from 10 to 60 minutes are economically feasible. These dryers are quite versatile and can handle relatively large and arbitrary-shaped particles, which may be heat sensitive and fragile at the same time. Gas cleaning requirements are minimal as low gas velocities are used. Also, power requirements for air handling are low due to the low pressure drops needed. In commercial designs of very large band dryers, it is important to ensure uniform distribution of the product on the band and also uniform distribution of the air flow within the chamber of the dryer to ensure uniform product moisture content.

23.4.3.7 Infrared Dryers

Infrared (IR) dryers may be gas-fired ceramic radiators or electrically heated panels. The IR wavelength range is from 0.1 to 100 μm, which generates heat in the exposed physical body. The wavelength ranges 0.75 to 3.0 μm, 3.0 to 25 μm, and 25 to 100 μm are referred to as near IR, middle IR, and far IR ranges, respectively. Industrial radiators are of two types: (1) light radiators (near IR), e.g., quartz glass with peak radiation intensity at 1.2 μm; and (2) dark radiators, e.g., ceramic (3.1 μm) or metal radiators (2.7 to 4.3 μm).

While convection can yield heat fluxes of the order of 1 to 2 kW m^{-2}, radiation can yield much higher levels of heat flux, e.g., 4 to 12 kW m^{-2} (light radiators) and 4 to 25 kW m^{-2} (dark radiators).

In many drying operations, the evaporation rates feasible are not high enough to require IR radiators, however. There are some niche applications for IR dryers in industry, e.g., drying of coated paper, booster drying of paper in paper machines, etc. They offer the advantages of compactness, simplicity, ease of local control, low equipment costs, etc. Also, in combination with convection, IR dryers offer the potential for significant energy savings and enhancement in drying rates with better product quality. On the negative side, the high heat flux may scorch the product and enhance fire and explosion hazards. Clearly, IR must be used in conjunction with convection or vacuum. Good control is essential for safe operation, i.e., the IR power source must be cut off if there is upset in the process, which may lead to overheating of the product.

23.4.3.8 Microwave (MW) and Radio Frequency (RF) Drying

Unlike conduction, convection, or radiation, dielectric heating heats a material containing a polar compound volumetrically, i.e., thermal energy supplied at the surface does not have to be conducted

TABLE 23.17
Basic Characteristics of Microwave and Radio Frequency Techniques

Characteristics	Microwave	Radio Frequency
Frequency/wavelength (free space)	896 MHz/30.0 cm 915 MHz/32.8 cm 2450 MHz/12.2 cm	13. 56 MHz/22.2 m 27.12 MHz/11.1 m 40.68 MHz/7.4 m
Power source	Magnetron (klystron)	Class C triode
Typical efficiency	~50%	~60%
Maximum power of a single unit	60 kW at 915 MHz 6 kW at 2450 MHz	600 kW
Principal mechanism of heat generation	Dipole oscillation	Ionic conduction
Loss factor	May be low	Must be relatively high
Penetration depth	Medium or low	High
Product shape	Any	More or less regular
Product size	Small and medium	May be large
Generator service life	2000–5000 hr	5000–10,000 hr
Generator-to-applicator capital cost ratio	0.5	2.3

into the interior, as limited by Fourier's law of heat conduction. This type of heating provides the following advantages:

- Enhanced diffusion of heat and mass
- Development of internal pressure gradients that enhance drying rates
- Increased drying rates without increasing surface temperatures
- Better product quality

When an alternating electromagnetic field is applied to a "lossy" dielectric material, heat is generated due to friction of the excited molecules with asymmetric charges, e.g., water. This is a result of ionic conduction or dipole oscillations (Kudra and Strumillo 1998). The radio frequency range extends from 1 to 300 MHz while the microwave range is from 300 to 3000 MHz. However, only specific frequency ranges are permitted for industrial heating applications, i.e., in RF, ranges 13.56, 27.12, and 40 MHz and for MW, 915 (896 in Europe) and 2450 MHz. Bound and free water have different loss factors. Because loss factors increase with temperature, there is a danger of runaway, i.e., an accelerated heating rate causing a thermal damage to the material.

Table 23.17 summarizes the basic characteristics of MW and RF techniques. The main limitation of MW and RF drying is that the technique is highly capital intensive. It also consumes high-grade energy, i.e., electricity, and the conversion efficiency to the dielectric field is only in the order of 50%. Thus, these techniques are suited only for special applications involving very high-value products, extremely long drying time to remove traces of moisture, or to obtain products of special characteristics not obtained otherwise. It is therefore not surprising that MW/RF drying is used only in special niche applications. Further, these techniques are used mainly to boost drying capacity (to remove free water rapidly without generation of large thermal gradients in the material) or to remove the last few percent of water that comes out very slowly. Generally, dielectric heating is combined with convection or vacuum to reduce the energy consumption. Microwave vacuum drying and microwave freeze drying have found to date only limited commercial applications. Microwave freeze drying is typically carried out at well below the triple point of water. Typical conditions are pressure in the range of 500 Pa and temperature of –40°C. Use of excessive power as well as maldistribution of power due to nonhomogeneities in the frozen

solids can cause problems in MW drying. The main hurdle to commercialization of MW freeze drying is the high cost.

Numerous laboratory- and pilot-scale studies have been reported on MW drying at atmospheric as well as vacuum conditions. It is also possible to "pipe" microwave energy in various dryer configurations, e.g., fluidized bed, spouted bed, vibrated bed, or tray dryers, to enhance convective drying rates. Unfortunately, while all these techniques do provide significant enhancement of the drying time required, the initial and operating costs are such that the enhancement obtained does not offset the added cost. Drying of treated grapes in combined microwave and convection dryers has been shown to be very rapid and energy efficient. However, the costs are prohibitively high. Recent research has shown that intermittent application of a microwave field results in the production of better quality dried product.

23.4.3.9 Superheated Steam Drying

Figure 23.31 classifies superheated steam dryers based on their operating pressures. The product temperature necessarily exceeds the saturation temperature of steam corresponding to the operating pressure. Thus, for products that may undergo undesirable physical transformations (e.g., melting) or chemical transformations (e.g., hydrolysis) at elevated temperatures with steam or with the small quantities of oxygen that necessarily leaks into any system, a low-pressure operation is desirable. The vapor evolving from the product may be withdrawn from the chamber, condensed, and the latent heat recovered. Alternatively, the vapor is reheated within the chamber by tubular or plate heat exchangers and recirculated as a convective drying medium to enhance the drying rate. Such a system is used commercially to dry timber with very attractive results; the net energy consumption is reduced several fold; the product quality is enhanced; and the environmental problem of emission of the volatile organic compound produced during drying is eliminated. The organic volatile components (boiling point ranging from room temperature to >200°C) are condensed out with the steam; since the two are immiscible, simple decantation allows recovery of the condensibles, which may be sold separately (e.g., terpenes, essential oils).

High-pressure superheated steam dryers need to be pressure vessels and hence are capital intensive. They are recommended only for special applications. For example, a pressurized, fluid-

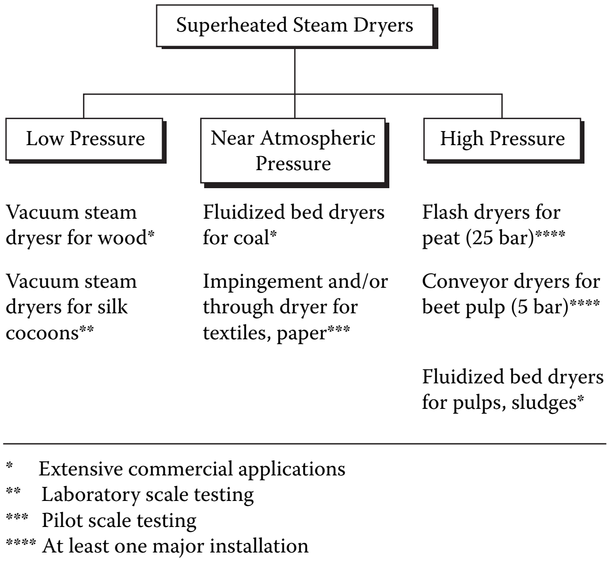

FIGURE 23.31 Classification of superheated steam dryers based on their operating pressures.

ized, bed superheated steam dryer is marketed commercially for drying of beat pulp. It yields a higher quality fiber that can be used for human consumption while the same product dried in hot air gives a lower quality fiber that is used for animal feedstocks. Higher pressures are typically not cost-effective, although the specific volume of superheated steam is reduced and its enthalpy per unit volume increased at higher pressures.

In general, superheated steam drying should be considered if one or more of the following conditions apply:

1. Energy cost is very high; product value is low or negligible (e.g., commodities like coal, peat, newsprint, tissue paper, and waste sludges that must be dried to meet regulatory requirements).
2. Product quality is much superior (e.g., newsprint, which yields superior strength properties in steam and permits use of lower chemical pulp content to attain same strength and runnability).
3. Risk of fire, explosion, or other oxidative damage is very high (e.g., coal, peat, pulps, etc.). Lower insurance premiums may partially offset added investment cost of a steam dryer.
4. Quantity of water to be removed as well as production capacity required are high. This affords economy of scale.

Such dryers are superior only for continuous operation because of the inherent problems associated with start-up and shut-down when water condensation on the product as well as presence of noncondensables (air) cause problems. See Mujumdar (1995a) for detailed information on superheated steam drying.

23.4.3.10 Drying of Boards and Sheets

Drying of sheet-form materials or materials in the form of large and small pieces often occurs for paper, textile, coated or impregnated fabrics, wood processing, food processing, polymer and photographic film production as well as in the graphic arts industries. Figure 23.32 outlines several possible dryers when the feedstock is other than particulate or liquid-like. The main dryer types suited for such materials will now be reviewed very briefly.

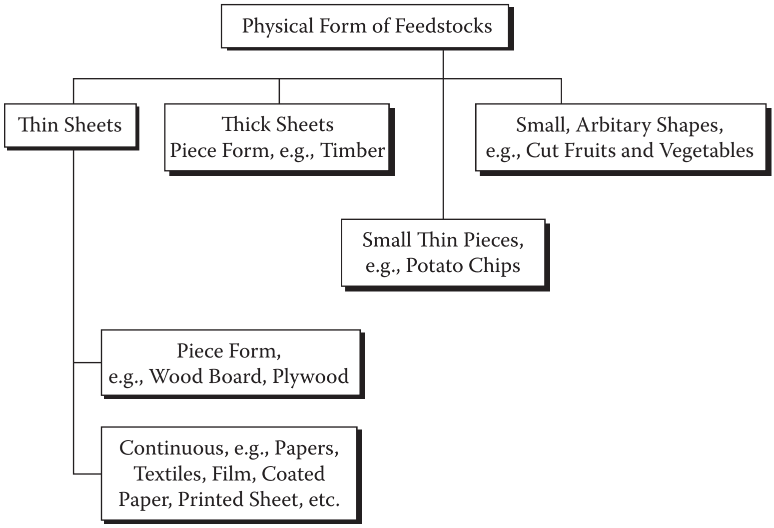

FIGURE 23.32 Classification of feedstock by physical form.

23.4.3.10.1 Dryers for Continuous Sheets

Convection, conduction, as well as infrared dryers can be used for such materials, although combined mode dryers often are more efficient. Paper, coated webs, or textiles are dried on steam-heated cylinders (conduction heating) or jets of hot air may be impinged on the sheet for concurrent convective heating as well. In some cases, it may be desirable to use infrared heating to augment the drying rate if the material is not very heat-sensitive. For drying of thin permeable sheets, drying air through the sheet highly enhances drying rates. Combined through and impingement drying is a particularly attractive option for drying of tissue or newsprint. For thin sheets, the total drying time may be in the order of seconds (e.g., tissue paper) to several minutes (e.g., textiles).

23.4.3.10.2 Dryers for Piece-Form Sheets

Materials like plywood or chip board require long residence times to dry. Impinging jets may be used initially to remove surface moisture; internal moisture removal can be achieved in a tunnel dryer with modest parallel flow of drying medium.

23.4.3.10.3 Dryers for Very Thick Sheets (or Odd Shapes)

The drying times may range from days to months. Wood, for example, is dried in hot air kilns from weeks to months, depending on the size of the pieces to be dried and the type of wood species. Superheated steam drying under vacuum conditions enhances drying rates as well as product quality. Only batch dryers are suited for these long drying time requirements.

23.4.3.10.4 Drying of Materials in the Form of Thin Wafers

Continuous conveyor, through-circulation, or impinging jet-fluidized bed dryers (sometimes called jet-zone dryers) are often used in the wood processing (e.g., wafer board) and food processing (e.g., potato chips, etc.) industries. In the jet-zone process, hot air jets impinge on a thin layer of wet chips, which are conveyed mechanically; the high-velocity jets "pseudo-fluidize" the material to accomplish uniform drying. Wood chips, for example, may be dried in a rotary or a conveyor dryer.

23.4.3.10.5 Drying of Arbitrary-Shaped, Non-Fluidizable Pieces

Vibrated beds, impinging jet-fluidized beds, mechanically fluidized beds, rotary, or conveyor dryers may be used. Each type of dryer has its own advantages and limitations, so a careful evaluation of all the key criteria noted earlier in this chapter must be made before the final selection.

23.5 CLOSING REMARKS

A general introduction has been provided to the basic principles and terminology of drying and drying equipment commonly used in practice as well as classification and selection criteria for industrial dryers for various forms of materials. For more detailed and current information, the interested reader may visit the Web site http://www.geocities.com/drying_guru. This site provides hot links to numerous other sites for literature, conferences, and other resources pertaining to all aspects of drying on a global scale. The recently published book edited by Devahastin (2000) is recommended for a concise yet in-depth discussion on industrial drying technologies. For information on ancillary equipment required for a drying system, Mujumdar (1995b) covers control of dryers, explosion and fire hazards, control of emissions, as well as new drying technologies not covered in this chapter. Also, research and development personnel may find the latest developments in drying technology by referring to *Drying Technology—An International Journal* as well as the proceedings of the biennial International Drying Symposium series and regional conferences devoted to drying.

NOMENCLATURE

A	Evaporation area, m^2
a_w	Water activity
c_P	Specific heat, J kg^{-1} K^{-1}
c_s	Humid heat, J kg^{-1} K^{-1}
D_L	Effective diffusivity, m^2 s^{-1}
D_{L0}	Effective diffusivity at reference temperature, m^2 s^{-1}
E_a	Activation energy, J
ΔH_W	Enthalpy of wetting, J kg^{-1}
h	Convective heat transfer coefficient, W m^{-2} K^{-1}
k_g	Thermal conductivity, W m^{-1} K^{-1}
k_y	Convective mass transfer coefficient, kgmol s^{-1} m^{-2} mol $frac^{-1}$
M_{air}	Molar mass of air, $kgmol^{-1}$
M_s	Mass of bone dry solid, kg
N	Drying rate, kg m^{-2} h^{-1}
P_v	Vapor pressure of pure water, Pa
p	Partial pressure, Pa
p_w	Equilibrium vapor pressure of water, Pa
R_g	Universal gas constant, 8.314 J mol^{-1} K^{-1}
	Temperature, °C
T_{abs}	Absolute temperature, K
T_{wb}	Wet-bulb temperature, °C
t	Time, sec (or hr)
X	Total moisture content, kg water/kg dry solid
X_c	Critical moisture content, kg water/kg dry solid
X_f	Free moisture content, kg water/kg dry solid
X^*	Equilibrium moisture content, kg water/kg dry solid
Y	Absolute air humidity, kg water vapor/kg dry air

GREEK LETTERS

η	Normalized moisture content
λ	Latent heat of vaporization, J kg^{-1}
μ_g	Dynamic viscosity, kg m^{-1} s^{-1}
ν	Normalized drying rate
ρ_g	Density, kg m^{-3}
Ψ	Relative humidity of air

SUBSCRIPTS

24.6 Screening Machine Operations and Maintenance 1727

24.1 FUNDAMENTALS OF SCREENING

Screening is a process that uses a media, such as mesh or a perforated plate, to separate a material based on particle size. Other techniques are used to separate particles based on characteristics such as density or shape. While screening is often the most accurate, economical, and common separation technique, size separation can also be achieved using other processes such as air classification or flotation. These latter techniques exploit differences in aerodynamic or hydrodynamic characteristics of different particle sizes to effect a separation. They are good choices for separating very fine materials (<40 microns) that present problems (e.g., screen blinding, high screen area requirements) for conventional mechanical screening. They cannot, however, provide a sharp separation, so serious compromises on product quality and separation efficiency must be made. Hence conventional dry screening is often the preferred method of separation.

In general, screening is used for separations in the particle size range of 40 microns (μm) to 50 mm. Table 24.1 lists the most common industrial applications for which screening is an important part of the process. There are three basic types of screening operations: scalping, fines removal, and grading. In scalping, a small percentage (<5%) of oversize material, considerably larger than the average particle size, is removed. An example is the removal of large lumps from fertilizer to improve its spreading characteristics. In fines removal, the opposite of scalping, a small percentage (<10%) of fine material, which is considerably smaller than the average particle size, is removed. An example is the removal of objectionable dust from a consumer product such as laundry detergent. In grading, material is separated into one or more grades or products, each having distinct particle size distributions and size limits. An example is the separation of activated carbon filter media into distinct granule size ranges.

24.2 FACTORS AFFECTING SCREENING PERFORMANCE

Screening performance is affected by many factors, the most important of which are material characteristics. Because screening is a separation based on particle size, the most important material characteristic is particle size distribution. This distribution is determined by taking a small repre-

sentative sample and determining the weight of particles within size ranges. This is most commonly accomplished by sieve analysis. In this technique, standardized test sieves with precise apertures defined by standards organizations such as ASTM, ISO, TYLER, DIN, and others, are used (Table 24.2). Sieves used in North America are defined by the ASTM E11 specification.

These test sieves are arranged in a stack from coarsest to finest with a collection pan below the finest sieve. The sample of material to be analyzed is introduced to the top sieve, and the stack is exposed to a combination of motions that cause the material to stratify through the sieves. After a set period of time, the stack is disassembled, and the weight of material retained on each sieve is measured and recorded as a percent of the total sample (Table 24.3).

While mechanical sieve analysis is the most common method for characterizing particle size distribution, other measurement techniques such as laser diffraction and video imaging are often utilized. Laser diffraction has the advantage of being able to measure small particles that cannot be effectively measured by sieves. It is particularly useful for fine powders. Video imaging systems have the advantage of being able to characterize not only particle size, but also particle shape. While their use may expand in the future, to date, neither laser diffraction nor video analysis has been embraced by many processors of granular materials, who continue to rely on mechanical sieve analysis techniques. Regardless of the measurement technique used, particle size distribution generally resembles a bell-shaped curve (Figure 24.1). Figure 24.1 also indicates the portion of the solids that might be separated in fines removal or scalping.

Performance, specifically screening machine capacity, is greatly influenced by the location, the desired separation point on the distribution curve. A typical capacity curve is shown in Figure 24.1. For scalping operations at the coarse end of the particle distribution (right side of curve), very high screening capacities are achievable. This is because most of the particles are much smaller than the screen opening and pass through quite easily, with multiple particles passing simultaneously. The capacities are also quite high for fines removal (left side of curve) because, again, the fine particles that should pass through the screen are much smaller than the screen opening. The capacities, in this case, are not quite as high as with scalping because the fine particles must first work their way through the bed of material that is traveling across the screen surface.

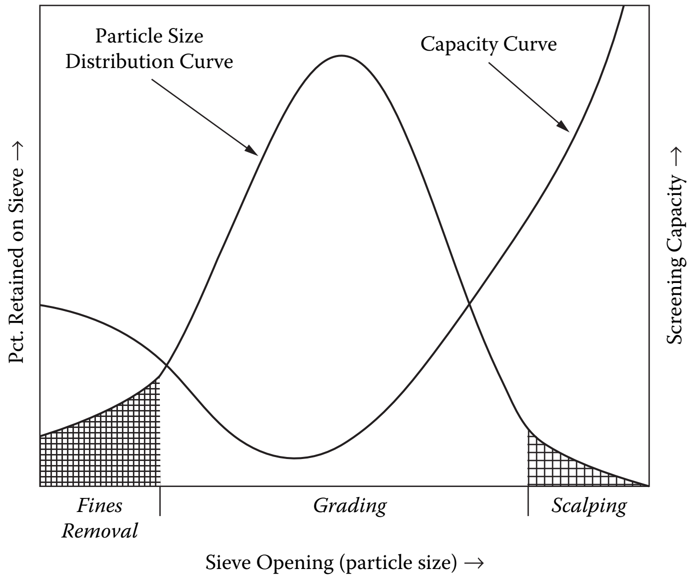

FIGURE 24.1 Particle size distribution curve.

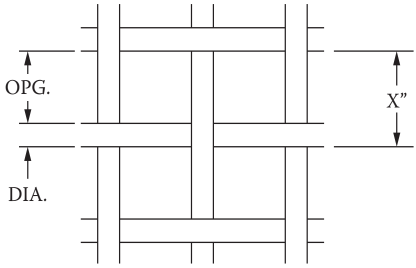
Capacities are lowest when grading. This is because the required separations use screen openings that are near the peak of the particle size distribution curve, where there are numerous particles approximately the same size as the screen opening. These near-size particles that are smaller than the screen opening and should pass through the screen often require multiple exposures to the opening to pass through. In addition, the near-sizes that are slightly larger than the screen opening temporarily block openings, thus limiting the number of screen openings available for the smaller particles. Accurate gradations require relatively low feed rates and highly effective screening motions.

Particle shape affects screening performance. Particles can be various shapes: granular, spherical, cylindrical, etc. Regular shapes such as spherical often allow for relatively sharp separations. Screening of irregular shapes (e.g., elongated, sliver-like, plate-like) generally produce inaccurate separations since the particles enter the screen openings at many different angles. Particle shape can also cause screen blinding, in which particles slightly larger than the screen openings plug the openings. Crystalline particles and spherical particles are particularly prone to blinding.

Another material characteristic that affects screening performance is bulk density. In general, the higher the bulk density, the higher the screen capacity. There are two reasons for this. One is that the force that causes a particle to pass through an opening is proportional to the particle's mass. Consequently, heavy materials like metal powder screen quite readily. However, lightweight materials like sawdust are generally screened at very low-mass flow rates. The second reason is that screening is essentially a volumetric process, as volume defines the depth of material on the screen surface. So, for a given volumetric flow through a screener, the material with the higher bulk density will result in the higher screening rate for a given bed depth, i.e., mass flow.

Flowability of a material, indicated by its angle of repose, affects screening performance since materials that do not flow well do not spread out on the screen surface and properly present themselves to the screen openings. Materials with poor flow characteristics do not convey well along the screen surface. This leads to deeper bed depths and lower screening efficiency. While a material's angle of repose gives some indication of flowability, it is best to evaluate flowability by measuring the material's conveying rate under actual screening conditions.

Surface moisture generally has a significant negative impact on screening performance. Moisture level is measured directly using specialized laboratory equipment in which the solid granular sample is weighed before and after drying. Moisture can cause particles to agglomerate, thus



$$\text{Mesh Count} = \frac{1}{X}$$

$$\text{Opening} = \frac{1}{\text{Mesh Count}} - \text{DIA.}$$

$$\text{Percent Open Area} = (\text{Opening} \times \text{Mesh Count})^2 \times 100$$

FIGURE 24.2 Wire cloth openings.

preventing them from passing through the screen opening. Moisture can also cause particles to bridge across a screen opening, effectively blinding the screen media. Hence, many materials must be dried before they can be screened. While the allowable moisture level varies depending on the material, a good rule of thumb is that if the material can be agglomerated by hand (i.e., making a "snowball"), it is probably too moist to be screened.

The bridging of an opening can also be caused by static charge, which is most likely to occur in materials that have been excessively dried or have very fine particle sizes. For such particles, the force of static attraction (which is proportional to the particle's surface area) overcomes the gravitational screening force (which is proportional to the particle's mass). In addition, a static charge can result in a dust or solid particle explosion. While numerous accessories have been proposed for reducing static charges in screening equipment, none are completely effective. The use of additives such as aluminum oxide or the introduction of limited moisture in the form of steam is often quite successful.

The screen media selected has a significant impact on screening performance. Most production screens are specified by identification of at least two of the following four parameters: mesh counts, wire diameter, opening, and percentage open area. The mesh count is the number of wires (or openings) per linear inch. Subtracting the wire diameter from the inverse of the mesh count gives the actual opening in inches. Percentage open area is the ratio of the area of the openings to the total surface area of the screen multiplied by 100. The relationship of these wire cloth specifications is shown in Figure 24.2.

Wire cloth is produced to varying degrees of accuracy and in several commercial grades. It is important to avoid confusion between the sieve numbers used to identify test sieves and the mesh counts used to specify production screen clothing. Typically, multiple wire diameters are available for a given mesh count. This will result in several different available openings, and therefore screening characteristics. As shown in Table 24.4, there are five commercial grades of 10 mesh screen clothing available, yet none has the same opening as a No. 10 test sieve. This is not the problem it may appear to be, because in production screening one typically uses a screen opening slightly larger than the desired nominal separation point. Because of the confusion that can arise when screen media are described by "mesh," it is always best to define the screen opening in "inches" or "microns."

Selection of a screen goes beyond simply choosing a screen opening and wires material. Often, several commercial grades of screens are available with the same opening. In general, screens with a relatively heavy wire for a given opening will be the most durable; however, they are more likely to blind and will have lower capacities due to a lower open area percentage. Screens woven with a finer wire will be more flexible and therefore less prone to blinding, but may have a low service life. While square mesh screens are by far the most common, screens can be woven with a rectangular opening. This can be particularly effective in increasing screen capacity or making

TABLE 24.4

length separations. Screen clothing for chemical applications is commonly constructed of Type 304 stainless steel.

Screens can be woven of synthetic material such as nylon and polyester. These alternatives offer performance advantages in certain screening applications. Another alternative is perforated steel plate. Weld profile and finish should also be consistent with the materials being screened. These plates are also effective and are quite durable. However, they have a low percentage of open area and therefore have lower capacity for a given screen area.

24.3 SCREEN MOTION AND CONFIGURATION

Screening machines are available in various shapes, sizes, and types of motion (Figure 24.3).

The two most common screen motions used in screening machines are vibratory and gyratory. Vibratory is characterized by a short stroke, high-frequency motion commonly used for coarse separations and for screening applications where a high degree of separation accuracy is not required. For finer separations, or when separation accuracy is a priority, gyratory motion is preferred due to its longer stroke and lower speed. Other types of screen motion such as drum screens or centrifugal screens are used for specialized applications.

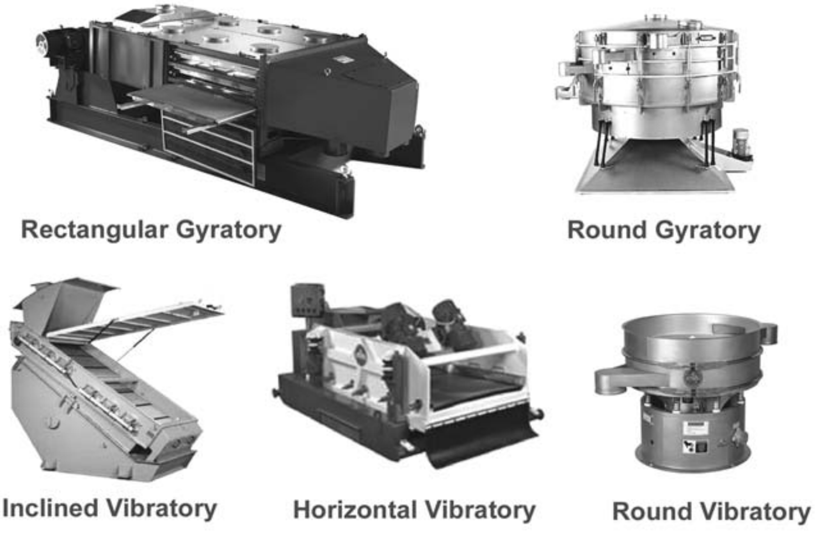

FIGURE 24.3 Screener types.

The performance of a screening machine is determined by its combination of stroke, frequency, plane of action, and screen shape. The stroke is the peak-to-peak distance traveled by the screen in one cycle. For vibrating screeners, the stroke is typically 3 to 6 mm, while for gyratory machines it is 50 to 90 mm. Frequency of a screening machine is the number of cycles of motion completed by the screen in a given time period, typically one minute. Vibrating screeners generally operate at 1000 to 3600 rpm, while gyratory screeners operate at 200 to 300 rpm.

The plane of action or slope of the screen deck affects performance. Increasing the slope of the screen surface often increases the conveying rate of the material and therefore increases the amount of material that can pass through the screener. However, this has a negative impact on screening accuracy. Horizontal screen decks typically provide better separation accuracy. Because the deck is horizontal, gravity has very little effect on the conveying of the material. To achieve reasonable capacities, the screening motion must be capable of effectively conveying the material across the horizontal screen deck.

Screen shape also affects performance. Relatively small screening machines that handle lower capacities use round horizontal screens. These machines are typically fed at the center of the screen, and the material moves toward the edges. The resulting short effective screen length limits their application when accurate grading is required. Rectangular screen decks are used for higher capacity applications and when greater separation accuracy is needed. These rectangular decks can be inclined to improve conveying and increase capacity. By feeding the material to one end of a rectangular screen, accurate separations can be achieved because the material must travel the full length of the screen, thereby maximizing exposure to the screen openings.

Because of their low equipment cost, vibrating screening machines are perhaps the most commonly used, and can be quite effective, particularly in scalping applications. For grading and fines removal, gyratory screening machines have significant advantages. Vibrating screeners often do not have sufficient stroke to properly spread and stratify the material as it is fed onto the screen deck. This prevents the finer particles from achieving maximum exposure to the screen openings. The long stroke of gyratory machines spreads the material across the full width of the machine and stratifies the bed of material, causing the finer particles to settle down to the screen surface. Because vibrating screeners have a large vertical component of motion, the material becomes suspended above the screen surface, reducing the probability that a particle will pass through a screen opening. Gyratory machines use a sifting motion to keep the material in contact with the screen surface, maximizing opportunities for fine particles to pass.

The performance of a screening machine can be significantly affected by the rate material fed to it. A screener has an ultimate volumetric capacity, which is a function of internal construction and material handling capabilities. However, because capacity is defined by acceptable separation performance, the operating capacity will be lower than the maximum volumetric capacity. This balance between volumetric capacity and screening performance must be evaluated when selecting screening equipment.

Blinding causes reduction in available screen area and therefore reduces screening accuracy and screener capacity. Blinding generally occurs when near-size particles, slightly larger than the screen opening, lodge in the opening. Blinding can also be caused by bridging, which occurs when groups of particles, all much smaller than the screen opening, bind together and block the screen openings. Surface moisture or electrostatic charge can also cause blinding. Fibrous materials can cause blinding when particles wrap themselves around screen wires. In screening applications where blinding is a concern, control measures must be employed to prevent the cumulative effects of this blinding. The most common method is to trap bouncing balls in pockets below the screen clothing. The motion of the screening machine itself causes the balls to bounce randomly within their pockets and cleans the screen clothing. Other measures such as vibrating rings, compressed air, rotating brushes, and ultrasonic vibrations have also been used.

24.4 SPECIFYING SCREENER PERFORMANCE

Screening machines are evaluated on their ability to maximize both product quality and screening efficiency. One or more of the fractions, or flows, produced is considered to be "product." This product has imposed on it a quality specification defining the acceptable particle size distribution. Often, this specification consists simply of particle size limits. For example, in a scalping application, the product quality specification may be stated as "0% + 10 U.S. allowable," i.e., a sample of material that passes through the screen should contain no material coarser than a No. 10 U.S. test sieve. Similar specifications can also be applied to define acceptable results of a fines removal operation. For example, a fines specification of 3% maximum allowable –60 U.S. means that the analysis of a sample taken from the material that passed over the screen would contain no more than 3% by weight passing the No. 60 U.S. test sieve.

Limits and tolerances can also be applied to define product quality in grading applications. Certain industries have arrived at other particle size quality measurements to be applied to their products. The fertilizer industry commonly uses SGN (size guide number) to define the desired mean particle size and UI (uniformity index) to define the allowable variation from that mean particle size. Industrial sands are characterized by the GFN (grain fineness number) that approximates the theoretical sieve opening that would equate to the mean grain size. Abrasives, such as shot and grit, have exacting specifications that set limits and tolerances on the product. Filter media, such as activated carbon, are specified in terms of ES (effective size) and UC (uniformity coefficient), which are analogous to the SGN and UI used in the fertilizer industry. Regardless of the product specification, the key factor affecting product quality is the screen opening selected. So, if a screener is not producing adequate product quality, typically a screen with a different opening must be used.

Although product quality is important, it is not the sole criteria for evaluating screening performance. The other key measure of screening performance is screening efficiency. Screening efficiency is generally measured in one of two ways. The most common of these is referred to as "yield." Yield is the amount of material separated as product as a percentage of that product fraction which is available in the feed. Thus yield measures the efficiency by which the screener produces the desired, on-specification product.

A more exacting measure of screening efficiency is referred to as product recovery efficiency. It is expressed as a percentage based on the amount of on-size product in the product fraction separated by the screener, divided by the amount of on-size material available in the feed to the screener. Product recovery is calculated as follows:

$$\text{Efficiency (Product Recovery)} = \frac{\text{percent on-spec material in product} \times \text{percent product production rate}}{\text{percent on-size material available in feed}}$$

The product production rate is defined as the percent of material separated by the screener as product times the feed rate to the screener. Production rates are meaningful only if the quality of the product meets the product specifications.

The example shown in Figure 24.4 is a typical screening application in which a screener is used to extract on-size product from a process flow. The example illustrates the relationship between product quality, product yield, and product recovery efficiency.

Product quality is always a factor in system design, but it is screening efficiency that determines production rates and overall system efficiencies. For systems that include recycle loops, screening efficiency can have a compound effect on overall system performance. Clearly, the more efficiently a screener extracts on-size product, the higher the production rate. Often, the reject streams from the screener are recycled and reintroduced to the screener. In such cases, on-size material that was mistakenly rejected by the screener will be needlessly reprocessed, resulting in higher energy costs

Product Recovery Efficiency: $\dfrac{95.3\%\text{ on-specification} \times 63.5\%\text{ product yield}}{67.1\%\text{ available product}} = 90.2\%$

FIGURE 24.4 Typical screening application.

and lower overall system efficiency. This is particularly important in granulation systems and compaction circuits that typically produce material with a broad particle size range, in which only a relatively small percentage of the material produced is actually on-size product. In such cases, it is critical that the screening machine be as efficient as possible at extracting this on-size material.

While screen-opening selection has the greatest effect on product quality, it is the screening machine motion that has the greatest effect on screening efficiency. Certainly, changing the screen opening can increase screening efficiency. For example, in an oversize removal application, using a screen opening larger than the desired separation point can increase screening efficiency. However, this will have a negative impact on product quality, as the larger opening will allow oversize particles to pass through the screen and contaminate the product. By using an efficient screening motion, appropriate screen openings can be selected to ensure product quality without the penalty of inefficiently rejecting on-size material.

24.5 SCREENING EQUIPMENT SELECTION CRITERIA

To properly evaluate the performance of a screening machine, it is necessary to define the feed rates, and mass flow rates for each separated fraction, and particle size analyses for the feed material

and all fractions. As this is often impractical in a production unit, it is preferable to record and analyze these data in a pilot production or laboratory setting. Because of the wide variety of applications and types of screening equipment, no reliable formulas are available to predict performance based solely on process conditions. For this reason, most manufacturers of screening equipment have test laboratories where empirical methods are used to predict screener performance. These tests are used to formulate reliable estimates of product quality, product yield, screening efficiency, and screener capacity. A screener's capacity should always be specified by the feed rate to the machine rather than the product rate produced from the machine.

Sometimes, a manufacturer will define a screening machine's capacity in terms of a screen loading per screen area, for example, 5000 kg/hr/m^2. This loading is specific for a granular solid mixture and for specific equipment. Loadings vary considerably with application requirements, and even when handling the same application, screeners of different types can have very different loading capacities. Continuing the example, a screener with a screen area of 10 m^2 would have a capacity of about 50,000 kg/hr (5000 × 10). Or, for a feed rate of 30,000 kg/hr, a screen area of about 6 m^2 (30,000 ÷ 5000) is needed.

If the required feed rate for a system is relatively high, two possible alternatives occur: one large screener or multiple smaller screeners. While the latter approach typically involves higher installed cost, it offers several advantages. First, smaller screeners tend to be easier to operate because the components to be serviced are more manageable. Second, a dual-machine system allows the entire flow to be diverted to one machine while the other is being serviced. Of course, operating in such condition will necessitate a reduction in overall system processing rate or compromised screening performance.

Beyond screening performance, an evaluation of screening equipment should include various features affecting performance, durability, and maintainability. For example, the method of screen attachment must be appropriate for the application. Specifically, screen clothing must be tensioned at the proper force level to ensure the screen deck remains taut under the material load. While coarse screens (>10 mm) can be tensioned by hand and fixed with mechanical fasteners, finer screen clothing should be tensioned by spring loaded devices or factory set pre-tensioning and attachment. If several screen decks are required to make the necessary separations, it is often desirable to use a single-screening machine with multiple decks installed. This is typically the most cost-effective approach if the amount of screen area required on each deck is approximately the same. If the number of decks required exceed three, it is often more cost-effective to use two separate screening machines arranged in series. This eliminates the complexity involved with a four- or five-deck screener and also allows for tailoring the screener sizes to the amount of screen area required for each separation.

A key element of any screening machine is the drive system. Two types of drive systems are generally used. Drives used on screeners (typically of the vibrating type) in which the screen box are mounted on springs or cables allow the box to move freely in a cyclical motion. The drive consists of a rotating eccentric weight and is attached to the screen box. This intentionally out-of-balance system produces a motion in the screen box that is synchronous with the drive speed and proportional to the ratio of the drive weight to the sprung weight of the screen box. Screen box stroke can therefore be increased or decreased by adjusting the drive weight. One drawback is that screener motion is dampened when a large amount of material is introduced to the screen box, resulting in a significant loss of screening performance.

The other type of screening machine drive system is the positive displacement or crank drive. In this system (typically used for gyratory screen motion), an eccentric crank produces the motion. The advantage is that screen motion is fixed at the designed stroke regardless of material load. The positive displacement drives must employ rotating weights, for counterbalancing the moving assembly. Gyratory screeners are more expensive than vibratory screeners.

When installing a screening machine, the surrounding structure should be properly designed to withstand the forces generated by the screening equipment. In addition to the static load of the

screener and the material in it, the screening machine will generate dynamic loads, which may be produced at a frequency close to the resonant frequency of the surrounding structure. A thorough structural analysis is required when considering any screener installation. Also, consideration must be given to the accessibility of screener components requiring service or maintenance. For example, removal of screen decks for screen clothing replacement can necessitate an area of floor space equal to that of the machine itself. Accessibility must also be provided for servicing of the screener drive and material flow connections.

The proper selection of screening equipment must include a complete analysis of both installed (capital) and operating costs. For example, the cost advantage of an inclined screener over a horizontal screener could be outweighed by the additional cost of the building necessary to accommodate the taller inclined machine. Similarly, a rectangular vibrating screener typically costs less than a rectangular gyratory machine. However, because the vibrating screener may not spread the incoming material sufficiently, a separate, full width-vibrating feeder may be required. In such a case, the total cost for the vibrating feeder and screener could exceed that of the gyratory screener. When evaluating operating costs, the single most important factor is often screening efficiency. A more efficient screener will produce more product from a given feed rate, resulting in increased overall system efficiency and lower overall system operating costs.

The selection criteria described in this section are summarized in Table 24.5.

24.6 SCREENING MACHINE OPERATIONS AND MAINTENANCE

Most screening machines are designed to be configured for a specific set of application conditions and require no further adjustment during operation. However, it is necessary to monitor performance of the screener to ensure that it is operating properly. The frequency of this monitoring is driven by the cost impact of screened product that is out of specification. The cost impact may be a rejected shipment or an overloaded recycle loop. The best method of monitoring screener operation is to perform particle size analyses of samples of the input and output streams. Unfortunately, provisions for this kind of sampling are often not taken into account in the original design of the system. The

results can identify various problems that may have developed since the last sampling. For example, if an analysis of material passing through a screen reveals the presence of particles larger than the installed screen opening, then one can infer that the screen has a tear in it or one of the seals in the machine has failed. Conversely, if an analysis of material passing over a screen reveals an unusually high percentage of fine material, then one can infer that the screen is blinded or the machine is overloaded, either of which would lead to poor fines removal performance.

Screener maintenance involves both preventive and corrective maintenance. Preventive maintenance includes lubrication, cleaning, and routine inspection of all critical components per the manufacturer's instructions. Corrective maintenance most commonly involves repair or replacement of the screen media. Screen media life is a function of many process variables. Some factors that lead to short screen media life are operating with high screen loadings, using very fine screen wire, and screening of abrasive materials. For example, a relatively coarse 5 mm opening screen with a large diameter wire might last several years, while a fine screen with a 100 micron opening might last only a few days or weeks. When designing processes that are expected to have low screen media life, consideration must be given to frequent servicing of the screen media. If the effects of a torn screen are intolerable, it may be necessary to establish a mean time to failure value for the screen media and make preemptive replacements before failures are expected.

Because most screening machines have relatively massive moving or rotating components, it is imperative that appropriate safety precautions be taken when working on or around the equipment. The manufacturers' manuals and labeling detail the safety considerations. Extra precaution must be taken when processing materials that present explosion hazards. Manufacturers of screening machines will often include special provisions for grounding the various subassemblies and components of the machine to ensure that an electrostatic charge differential does not develop between such components and result in a spark that could trigger an explosion. Machine maintenance can necessitate the removal of these grounding provisions, and care must be taken that they be properly replaced and secured before the machine is returned to operation.

Most screening machines are designed and fabricated such that their useful service lives are measured in decades rather than years in most applications. However, some applications can dramatically shorten service life. Abrasive materials can cause premature wear, particularly when process rates are high. Some materials attack the screener's metal components. Salts, such as sodium chloride, calcium chloride, and ammonium sulfate, are particularly aggressive. In such cases, selection of the materials of construction is critical to maximizing screener service life. In this matter, it is best to work closely with the manufacturer, sharing all pertinent process parameters so recommendations can be made based on their experience with similar systems.

25.1 CONVEYING OF BULK SOLIDS

Conveyors *transport* solid material streams. With appropriate geometry and speed control, they regulate the volumetric flow of the material and are called *volumetric feeders*. With the further mass sensing and control modules, they regulate the mass flow of material and are called *gravimetric feeders*.

25.2 CHARACTERIZING THE MATERIALS TO BE HANDLED

Before selecting a conveyor for a specific application, the properties and handling characteristics of the bulk material must be determined. Conveyor manufacturers often use empirical bench-top tests and observations of actual systems to measure bulk density, particle size, stickiness, abrasiveness, etc. Helpful information is often published by manufacturers' engineering associations in the various countries. Typical are the publications by the Conveyor Equipment Manufacturers Association (CEMA) in the United States. Used primarily for mechanical conveying, the CEMA provides terminology, definitions, and test procedures for describing 37 bulk materials. Each measured characteristic is assigned an alpha-numeric classification code designation. It is widely used and appears in many equipment catalogs as an aid in selecting a conveyor. The CEMA publication also includes an extensive list of handling characteristics for common bulk materials.

Although the characteristics of a solid are useful information, they are not a substitute for experience because only the user knows plant process conditions and potential process changes or

upsets. Changes in moisture, particle size and size distribution, particle attrition, and even changes in raw material supplier, for example, affect the performance of mechanical and pneumatic conveyors. Actual operation must be considered before making a final choice of a conveyor. Often, material samples are tested or are sent to conveyor manufacturers for tests. Testing "similar" materials often helps.

Flow theories plus laboratory tests often permit the design of storage silos and hoppers. The following can be determined: power consumption for withdrawing solids and granules from hoppers and bins, prediction of frictional wear of conveyor and silo surfaces during handling of bulk materials, and attrition of particles during storage and handling. The American Society for Testing Materials (ASTM), Subcommittee D18.24, is currently developing improved Standard Testing Methods for Bulk Solids.

25.3 BELT CONVEYORS

A belt conveyor is made up of an endless belt that traverses between two or more pulleys and is supported at intermediate points by idler rolls. These conveyors can handle a wide range of materials, from fine powders to large lumpy stone or coal, at rates varying from several tons per hour to over 5000 ton/hr. Belt speeds vary from 35 to 300 m/min with belts extending over considerable distances. Such belts are widely used. Figure 25.1 shows a typical belt. It can be arranged horizontally and with inclined or declined sections combined with convex and concave curves in the belt. The desired path of travel is limited only by the strength of the belt and the permissible angle of incline or decline for the particular situation.

Bulk materials are sometimes conveyed on flat belts supported on horizontal idlers on the carrying and return runs. However, in most industrial systems, in order to increase the handling capacity, the belt is formed into a trough shape after it has been loaded with material and it is supported along the carrying run by troughing idlers. The most common troughing idler consists of three rolls. The belt is realigned to a flat position over the head pulley to discharge the material and returns supported on horizontal rolls. The viscoelastic properties of the conveyor belt and the distribution of stresses during start-up and shut-down must be considered when designing long conveyor belts and belts with horizontal curves.

Solids being transferred vary in size of particles; dusty material sometimes results in dust explosions. The materials can also vary in abrasiveness, be free-flowing, or cohesive, or friable. Wet or sticky materials, however, are often a problem if they are not continuously cleaned from the belt surface.

Material characteristics are typically used to determine the required belt width, the carrying capacity of a particular belt, and the maximum inclination at which the belt can be operated.

The angle of repose and angle of surcharge: The angle of repose is the angle a freely formed heap of bulk material makes with the horizontal. The measured value of this angle, when taken together with observations of particle shape and size, moisture, and flowability, determines the angle of surcharge. This is defined as the angle (to the horizontal) that a material assumes while the material is on a moving conveyor belt. For most materials, the angle of surcharge is 5° to 15° less than the angle of repose, but with some very free flowing materials it may be 20° less to avoid spillage from the edge of the belt. Because the cross-section area of the heap is defined by the belt trough geometry and the angle of surcharge, the belt speed required for a desired transport rate of a material with a known density can be easily determined.

The size and proportion of lumps: The larger the lump, and the greater the number, the wider the belt must be to prevent lumps from spilling from a horizontal conveyor; they are more likely to fall off of inclined conveyors.

Fluidizing or air retention properties: Materials that are easily aerated and have long air retention time limit belt inclination and speed.

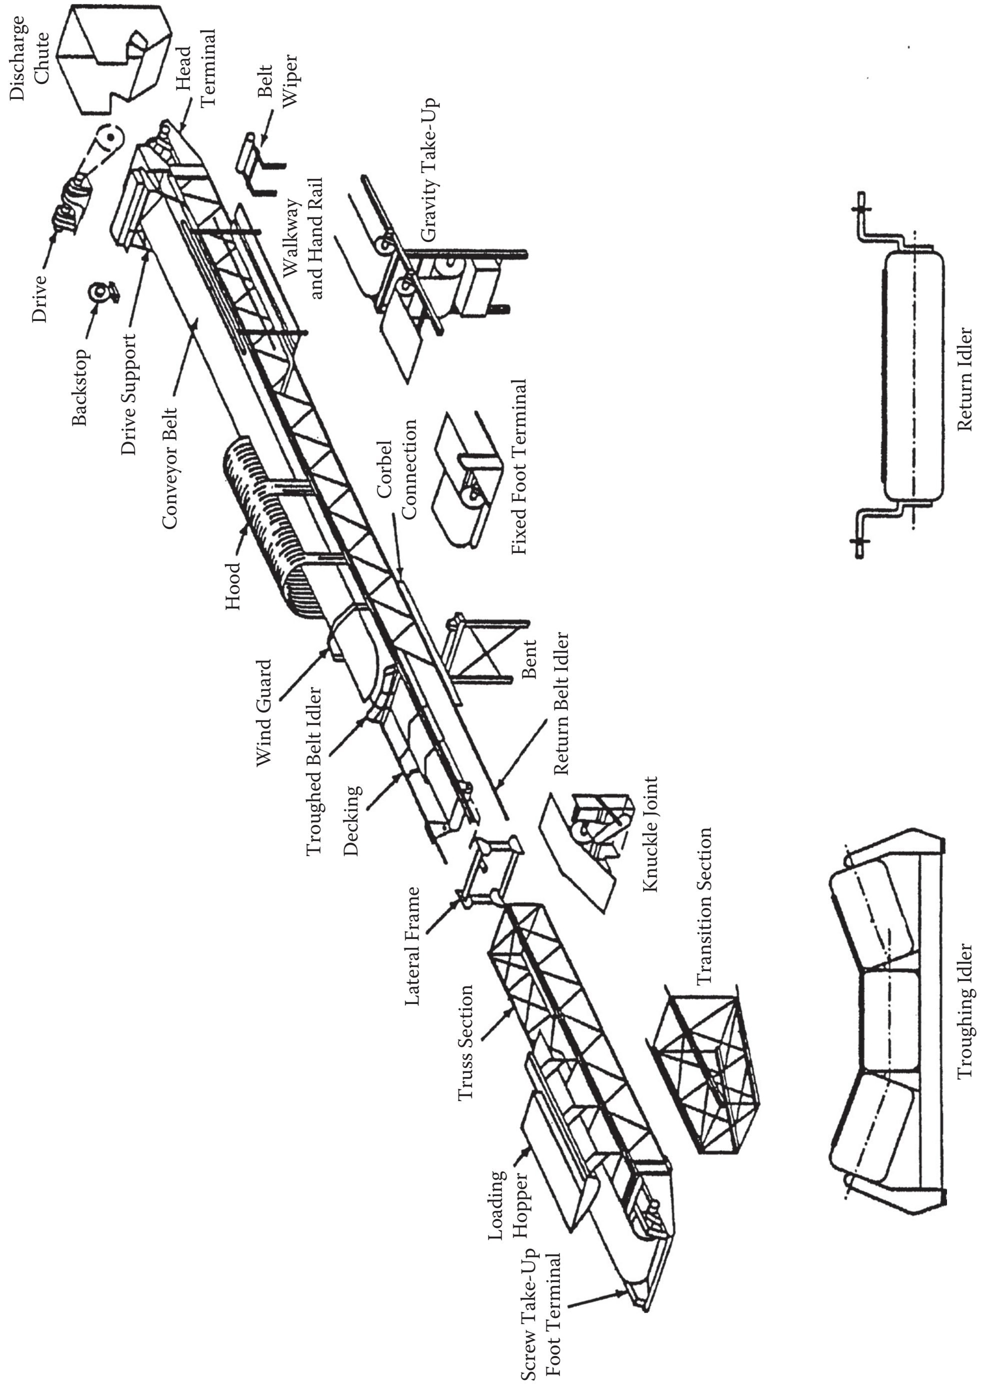

FIGURE 25.1 Troughing belt and support assembly.

25.3.1 Carrying Idlers

The most commonly used troughed carrying idler consist of three rolls with two outer rolls inclined at 20°, 35°, or 45° from the horizontal. Carrying capacity increases with the troughing angle. In the past, the multi-ply belts in use were stiffer and did not conform well to idlers having troughing angles over 20°. The newer belts, having carcasses of synthetic fiber blends, are more flexible and can be designed for higher angles. Idlers of 35° to 45° are gaining in popularity. It is important that the belt is centered on the idlers.

The mechanical design of the idler rolls is a function of the particular service under which the conveyor operates. Minimum industrial standards for roll dimensions, bearings, and application criteria for different service conditions have often been established. Idler life is determined by a combination of factors such as bearings, seals, shell thickness, load density, and operating environment.

Bearing rating and life are the only variables for which laboratory tests can provide standard values. CEMA therefore uses bearings as a guide for establishing idler ratings. In rating the idler bearing life, CEMA uses the term "useful life" (BU) representing the statistical point in hours where a minimum of 90% of the bearings will still be functional with no increase in torque or noise. The minimum required load ratings for equal-length roll idlers for service conditions ranging from light duty to heavy duty based on 90,000 hours minimum bearing life at 500 rpm have been determined for belt widths ranging from 18 to 96 inches, for 20°, 35°, and 45° troughing angles and for flat return idlers. These ratings form the basis for the minimum design requirements for CEMA-rated idlers. Actual figures for idlers are obtained from the idler manufacturer. Whereas bearing life is useful as an indicator of idler life, other factors such as bearing seal effectiveness may be more important in determining idler life.

Specialized idlers are available for certain applications. Examples are plastic disc catenary idlers for wet corrosive materials; two-roll idlers, where the rolls are oriented in a "V" for a lighter duty conveying system; and suspended idler supports for severe service.

25.3.2 Belts

Conveyor belts are manufactured in widths up to 2500 mm. Belts are susceptible to damage and are often the most expensive portion of the total system. The belt consists of two principal elements: the covers (top and bottom) and the carcass. The covers protect the carcass against environmental effects, wear, and cutting. Covers are generally natural or synthetic rubber, thermosetting elastometers, and thermoplastic materials. The carcass provides the tensile strength required to start and move the loaded belt, the traverse flexibility and longitudinal flexibility to allow the belt to both support the load and conform to the shape of the idlers when running empty and to properly wrap around pulleys, and the strength to absorb the impact forces at the loading point. Carcasses have one or more plies of a woven fabric bonded together with an elastomeric compound. Woven materials include cotton, rayon, nylon, polyester, polyamides (nylon), and glass, in the pure form or in blends. The fabrics are constructed with warp yarns that run lengthwise along the belt and filling (weft) yarns that run crosswise. There are a variety of weaves available for specific applications. New high-tenacity synthetic fibers and improvements in belt construction have led to belts with load capacities equal to or exceeding those of the previous belts with fewer plies. A more recent development in belt technology has been the solid-woven carcass belts impregnated and covered with poly-vinyl-chloride (PVC) or urethane plastisol. Steel cable belts made with a single layer of parallel steel cables completely imbedded in rubber and enclosed between one or more fabric plies are available for even higher tensile loadings. A more recent development in high-tensile strength belts has been the use of Kevlar (DuPont) high-strength (aromatic polyamides) fibers in woven, cord, solid woven, and cable construction. Careful cost analyses are needed in selecting the type of belt to be used.

25.3.2.1 Take-Up

A take-up is required on a belt conveyor to ensure the proper belt tension at the drive pulley and along the conveyor and to ensure the proper troughing contour between idlers. Belts stretch during start-up and as they age.

25.3.2.2 Backstops

A backstop is a device that permits rotation of the pulley in the forward direction but automatically prevents rotation in the opposite direction. A backstop should be mounted at the head shaft of an inclined belt to prevent the belt from moving in reverse in case of a power or mechanical failure.

25.3.2.3 Belt Cleaning

Idlers and snub pulleys on the return run support the belt on the material carrying surfaces. Cleaning these pulleys and the belt of materials that adhere is often necessary. A variety of scrappers or cleaners is available.

25.3.2.4 Power Requirements

Electric motors are commonly employed to operate the belts and to overcome the resistances. Power requirements contribute significantly to the cost of operation.

25.3.2.5 Alternate Belt Design

Modified belts currently available include the following:

Flexible sidewall belts: They consist of three elements: two flat sections for first loading and second unloading. An accordion-pleated flexible section is available with cleats or dividers for sections to raise or lower the solid material. In this latter section, sidewalls range from 40 to 400 mm, angles up to 90°, lift heights up to 80 m, and capacities up to 1000 metric ton/hr.

Air-cushioned belts: Air films are formed in U-shaped troughs beneath the belt. This air film reduces power requirements. Such belts tend to be limited to low levels of feeds.

Sandwich belts: Two belts sandwich the solid granules in order to transport them upward at angles up to 90°. Rates of transfer can be large, even more than 400 metric tons/hr.

Tubular-type conveyors: In these conveyors, the belt, after being loaded, is bent to form a closed tube. Such an arrangement minimizes the loss of solids, dust releases, cleaning, and weather-related problems.

Folded-belt and enclosed belt conveyors: Both types of conveyors can be used for moving solids at angles up to vertical.

25.4 SCREW CONVEYORS

A rotating screw is employed to push (or pump) solid powder through a tube or U-shaped trough. Screw conveyors are generally of relatively simple design and rather low cost, but power requirements are high. Sometimes cooling is required as considerable power is converted to heat. The abrasiveness and average size of the granular powder are important. For cohesive materials that pack or adhere, problems occur. Solid particles that easily break into smaller particles are much easier to convey via screw conveyors. Solids with hard and rather large lumps often cause problems in these conveyors. Screw conveyors that provide up to 30-m lifts have been built. Screw rpm often ranges from 200 to 400.

25.5 BUCKET ELEVATORS

A series of metal or plastic buckets are used to lift solid particles. These buckets are attached to an endless belt or chain. The buckets are first filled with the solid particles, and the buckets are unloaded after the moving belt has lifted the buckets. Continuous elevators can handle a wide range of materials, from light to heavy, free-flowing granular and pulverized materials with lumps up to 100 mm. This elevator handles material rather gently. Bucket speeds range from 30 to 46 m/min. The lower speeds are used in order to properly fill the buckets when fluffy, low-density materials are handled. Capacities range up to 75 m^3/hr on standard elevators.

Super-capacity elevators are continuous-type elevators in which buckets are mounted between two strands of chains. This arrangement makes it possible to handle a larger volume because the bucket can be extended in back of the chain. Elevators of this type are capable of handling up to 375 m^3/hr.

25.6 VIBRATING CONVEYORS

A vibrating conveyor consists of a trough supported by tuned springs and/or hinged links, having a drive system. The drive system is arranged to oscillate the trough, causing solid particles to be moved along the trough. Such conveyors are sometimes called oscillating conveyors. There are two types: reciprocating and vibrating.

On a reciprocating conveyor, material is carried forward in a horizontal direction by frictional contact with the trough. Inertia causes the material to be left in that position as the trough is quickly returned to its initial position. These conveyors are useful for granular free-flowing materials with a minimum of attrition. They provide gentle handling of food products, such as friable flakes and pellets, pharmaceuticals, powdered and granular chemicals, and minerals. Vibrating conveyors are uniquely suited for handling metal parts, abrasive, hot, and dusty materials, and can be designed to withstand heavy impact loads from materials such as rocks, iron and steel casting, and metal and wood scrap.

Tubular troughs are useful where dust-tight operation is required. Inclined flat bottom troughs with a sawtooth-shaped carrying surface can be used for conveying granular materials up to 10° to 20° slopes. Troughs can be provided with multiple discharge openings and can be designed to handle materials at temperatures up to 900°C (1652°F). Tubular or rectangular troughs wound in a vertical spiral can be used for vertical conveying of granular materials. This type of conveyor also operates at sub-resonance and is shop or field fine-tuned by weight adjustment on the trough before being put in service. This design requires fewer moving parts than the direct drive machine, but requires more attention to design and tuning. The exciters usually operate at frequencies of 15 to 20 Hz.

Excitation can also be supplied by an electromagnetic exciter that uses a rectified, pulsed AC power supply, or AC supply to an apposed electromagnet/permanent magnet drive. These units operate at very short strokes and frequencies of 50 to 60 Hz.

Compressed air or hydraulically driven reciprocating piston or rotary exciters are sometimes used in short conveyors. They are particularly useful where explosion hazards limit the use of electrical drives.

25.7 EN-MASSE CONVEYORS

An en-masse conveyor consists of an endless chain or cable pulling a series of spaced skeleton or solid plug flights through an enclosed casing or housing. Material is introduced through an opening in the casing, where it is captured by the flights and drawn through the casing until it reaches an opening in the housing where it discharges by gravity.

En-masse conveyors are compact and totally enclose the bulk material; they handle many materials with little particle attrition; they can have a L-shaped or a Z-shaped path, therefore

eliminating transfer points that are required by conventional straight line conveyors; they can combine feeding, conveying, and elevating in one machine; and they can have multiple inlet and discharge openings.

These conveyors are best suited for nonabrasive, free-flowing, granular or powder materials. Sticky or smearing materials can build up between flight and casing, causing a mechanical overload.

25.8 AIR-ACTIVATED GRAVITY CONVEYOR

The air-activated gravity conveyor is a simple, low-cost, essentially maintenance-free, and low power-using device for conveying fine, dry, easily fluidized powders. There are two types of air activated conveyors: closed and open.

The closed type used for transporting powders consists of a downward-sloped rectangular trough, bisected by a porous membrane that defines a lower and upper channel. Air supplied to the lower channel permeates through the membrane and aerates powders in the upper channel, causing the fluidized powder to flow like a liquid on the surface of the inclined membrane. Powder flow occurs even if the membrane is only partially covered with material: the pressure drop through the membrane is such that the air flow is uniformly distributed across the membrane surface independent of the depth of material above. Simple gates or valves are used to control inlet and discharge at the end or at intermediate points. The air that permeates through the membrane exits with the powder to the receiving vessel, and this air must be vented through appropriate filters. On long runs, it is often necessary to vent the air at intermediate points to avoid a build-up within the powder flow channel. Conveying capacity is dependent on the material air retention properties, trough cross-section, and slope angle. Trough widths range from 100 to 850 mm; capacities range up to 1500 m^3/hr with slopes from 3° to 8°. Air pressures beneath the membrane range from about 0.07 to 0.2 atm. Air flows range from about 0.9 to 2.5 m^3/m^2 of the membrane surface.

In the open-type air-activated conveyors, the cover over the powder flow channel is omitted. They are installed on sloped walls of silo hoppers or on sloped supports mounted on flat silo bottoms, with the membrane exposed to the stored material. This arrangement promotes powder flow within the silo and causes the material to flow toward the outlet. Air pressure below the open type membrane usually ranges from 0.2 to 0.33 atm.

Manufacturers usually determine size, slope, and air requirements for a particular situation by scale-up from tests on simple air-activated laboratory test rigs.

25.9 PNEUMATIC CONVEYORS

In a pneumatic conveyor, bulk solids particles are transported through a closed duct in a gas stream. A wide range of particle sizes, from powders to large lumps, can be handled through these systems. Restrictions are that the conveying pipe should be able to accommodate the largest particle. Such conveyors are classified as either dilute phase conveying or dense phase conveying. In dilute phase systems, relatively high-air velocities lift and drag particles through the conveying pipe in a dilute suspension. The ratio of mass of solids to the mass of conveying air ranges from 0.25 to 15, with the higher values achieved only in short distances. In dense phase systems, air velocities are lower, pressures are higher, and the particles move a much denser stream, with a faster moving layer superimposed over a denser moving layer at the bottom of the pipe. Both horizontal and vertical conveying is possible.

25.10 SUMMARY

Numerous conveyors are available for transporting solid powders, granules, etc. Generally, considerable information needs to be assembled relative to the character and amount of solid to be

transported, distances and heights of transport, etc. Manufacturers of conveyors can generally aid in the selection of a preferred conveyor. Both operating and capital costs need be considered in selecting the preferred conveyor.

26.1 INTRODUCTION

Electrochemical methods of producing energy (primary and secondary batteries and fuel cells), fabricating materials (e.g., electroplating, electrowinning, and electromachining operations), purifying chemical compounds (electrodialysis membrane separations), and synthesizing chemicals (e.g., the industrial electrosynthesis of chlorine, caustic soda, and organic chemicals) are attractive due to their inherent energy efficiency, the moderate temperature of operation, and the ease of measuring and controlling current and voltage. Electrochemical routes are often less polluting than chemical schemes because electrons perform the oxidation and reduction reactions rather than chemical reagents. The application of electrochemistry to real-world systems requires the same understanding of chemical engineering fundamentals (thermodynamics, reaction kinetics, and mass transport) as needed for traditional chemical or petrochemical processes, with two exceptions. There is the need to consider the ionic species in an electrolyte that may react heterogeneously at an electrode surface and to include electrical potential effects, which drive both electrochemical reactions and the mass transfer of ionic species in solution.

The merging of electrochemistry and chemical engineering into electrochemical engineering formally began in the 1950s. Since its inception, this subfield of chemical engineering has grown considerably. This chapter provides an overview of electrochemical principles and applications. First, thermodynamics, kinetics, and mass transfer, as applied to electrochemical systems, are reviewed. Next, specific examples of electrochemical processes/applications are presented, including electroplating and etching, environmental clean-up technologies, corrosion of metals, electrochemical reactor design, organic and inorganic electrochemical syntheses, and batteries and fuel cells.

26.2 FUNDAMENTALS

All electrochemical cells consist of at least two electrodes, an anode where oxidation reactions occur and a cathode for reduction reactions, with a conductive electrolytic solution between the anode and cathode. To maintain an overall charge balance, the electrons produced at the anode are consumed at the cathode; an external wire connecting the electrodes provides the pathway for electron flow. The electrical circuit is completed by current flow through the electrolyte solution,

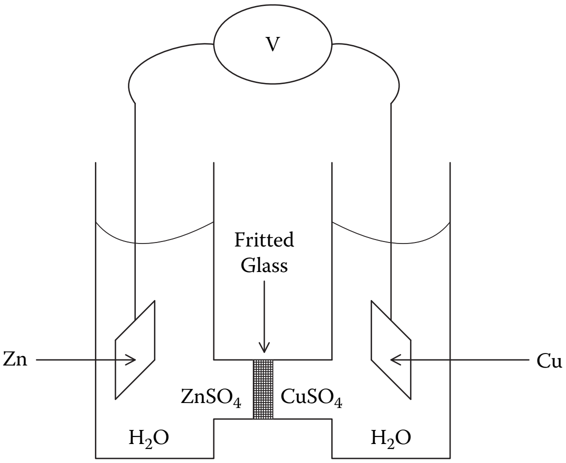

FIGURE 26.1 Electrochemical cell with zinc and copper electrodes.

where positively charged cations migrate to the cathode and negatively charged anions move to the anode. Figure 26.1 shows an electrochemical cell consisting of zinc and copper electrodes immersed in an aqueous electrolytic solution containing $ZnSO_4$ (which dissociates into Zn^{2+} and SO_4^{2-} ions) and $CuSO_4$ (Cu^{2+} and SO_4^{2-}). A porous glass frit or semipermeable membrane is often used to separate the two electrolytes; this separator minimizes the mixing of the two salt solutions and still permits ion movement. The electrochemical reactions at each electrode, which can be deduced from the composition of the electrodes and electrolyte solutions, are

$$Cu^{2+} + 2e^- = Cu(s) \tag{26.1}$$

$$Zn^{2+} + 2e^- = Zn(s) \tag{26.2}$$

As is standard practice, the above reactions are written as equilibrium reduction reactions and the total chemical change in an electrochemical cell is found by adding the individual anode and cathode reactions (the so-called half-cell reactions). Thus, the overall reaction for the Cu/Zn cell in Figure 26.1 is

$$Zn + Cu^{2+} = Cu + Zn^{2+} \tag{26.3}$$

Equation (26.3) is written as an equilibrium reaction because we do not know a priori from the half-cell reaction chemistry if the overall reaction will proceed spontaneously in the forward or backward direction. Thermodynamic free energy arguments used below answer this question for any set of half-cell reactions. As written, the Gibbs free energy of Equation (26.3) is negative and the overall reaction will proceed to the right when the two electrodes are connected by an external wire, with spontaneous Cu^{2+} reduction to copper metal (at the cathode) and Zn oxidation to Zn^{2+} (at the anode). As the cathode solution chamber is depleted of Cu^{2+} and the Zn^{2+}, concentration increases in the anode compartment, SO_4^{2-} anions will move from the cathode to the anode compartment, and Zn^{2+} cations will migrate from the anode to the cathode chamber so that the electroneutrality of the electrolytic solutions will be maintained. To reverse the direction of the cell reaction (i.e., for Cu oxidation and Zn^{2+} reduction), electrical energy must be supplied to the cell by means of an external direct current power source.

In general, individual electrode reactions can involve a variety of differently charged or neutral inorganic or organic chemical compounds in either the solid, liquid, or gaseous state. Examples of electrochemical oxidation and reduction reactions are

Anode Oxidation Reactions

$$2H_2O \rightarrow O_2(g) + 4H^+ + 4e^- \tag{26.4}$$

$$2Cl^- \rightarrow Cl_2(g) + 2e^- \tag{26.5}$$

$$Fe^{2+} \rightarrow Fe^{3+} + e^- \tag{26.6}$$

$$Ag(s) + Cl^- \rightarrow AgCl(s) + e^- \tag{26.7}$$

$$2[CH_3OCO(CH_2)_4COO^-] \rightarrow CH_3OCO(CH_2)_8COOCH_3 + 2CO_2 + 2e^- \tag{26.8}$$

Cathode Reduction Reactions

$$2H_2O + 2e^- \rightarrow H_2(g) + 2OH^- \tag{26.9}$$

$$2H^+ + 2e^- \rightarrow H_2(g) \tag{26.10}$$

$$PbO_2(s) + SO_4^{2-} + 4H^+ + 2e^- \rightarrow PbSO_4 + 2H_2O \tag{26.11}$$

$$C_6H_{12}O_6 + 2H^+ + 2e^- \rightarrow C_6H_{14}O_6 \tag{26.12}$$

Examples of half-cell and overall reactions for industrially important electrochemical processes and commercial electrochemical devices are listed in Table 26.1.

Knowing that a given combination of anode and cathode half-cell reactions will proceed spontaneously does not ensure that the electrode reaction rates will be sufficiently high for practical applications. Reaction kinetics at the anode and cathode and mass transfer of reactants/products to/from the electrodes may play important roles in an electrochemical cell and may influence the choice of cell design and operating conditions. These important points will be addressed later in this chapter.

Since electrode reactions involve electron transfers, the measurement of current with units of amperes (where 1 ampere = 1 coulomb/sec) quantifies the rate of an oxidation or reduction reaction at an electrode. For the following generalized electrode reaction

$$\chi(Ox) + ne^- = \varepsilon\,(Red) \tag{26.13}$$

we see that χ/n moles of oxidized species (denoted as *Ox*) or ε/n moles of reduced species (abbreviated *Red*) react for each mole of electrons that is transferred into or out of the electrode.

Since the charge of an electron is 1.6×10^{-19} coulombs, one mole of electrons contains a total charge of 96,487 coulombs. This quantity, known as Faraday's constant, relates the current to the molar rate of product formation or reactant consumption in an electrochemical reaction. Molar rate expressions for the forward and backward reactions of Equation (26.13) are integrated to give Faraday's Law:

$$M_{oxid} = \frac{\int_0^{t^*} I(t)\,dt}{\left[\frac{n}{\chi}\right]F} \quad \text{and} \quad M_{red} = \frac{\int_0^{t^*} I(t)\,dt}{\left[\frac{n}{\varepsilon}\right]F} \tag{26.14}$$

TABLE 26.1
Half-Cell and Overall Cell Reactions for Electrochemical Processes

Process	Half-Cell Reactions	Overall Cell Reaction
Chlor-alkali membrane cell process (for the production of chlorine gas and concentrated NaOH)	Anode: $2Cl^- \rightarrow Cl_2(g) + 2e^-$ Cathode: $2H_2O + 2e^- \rightarrow H_2(g) + 2OH^-$	$2H_2O + 2Cl^- \rightarrow Cl_2 + H_2 + 2OH^-$
Electrolysis of water for the production of hydrogen and oxygen gases	Anode: $H_2O \rightarrow 1/2O_2(g) + 2H^+ + 2e^-$ Cathode: $2H_2O + 2e^- \rightarrow H_2(g) + 2OH^-$	$2H_2O \rightarrow O_2(g) + 2H_2(g)$
Magnesium dioxide synthesis	Anode: $Mn^{2+} + 2H_2O \rightarrow MnO_2 + 4H^+ + 2e^-$ Cathode: $2H^+ + 2e^- \rightarrow H_2$	$Mn^{2+} + 2H_2O \rightarrow MnO_2 + 2H^+ + H_2$
Production of sodium chlorate	Anode: $6Cl^- \rightarrow 3Cl_2(aq) + 6e^-$ With subsequent chemical reactions: $3Cl_2(g) + 3H_2O \rightarrow 3HCl + 3HOCl$ $2HOCl + OCl^- \rightarrow ClO_3^- + 2HCl$ Cathode: $6H_2O + 6e^- \rightarrow 3H_2(g) + 6OH$	$NaCl + 3H_2O \rightarrow NaClO_3 + 3H_2(g)$
Copper electroplating	Anode: $Cu \rightarrow Cu^{2+} + 2e^-$ Cathode: $Cu^{2+} + 2e^- \rightarrow Cu$	Cu(anode) $\rightarrow$ Cu(cathode)
Monsanto's acrylonitrile electrohydrodimerization	Anode: $H_2O \rightarrow 1/2O_2(g) + 2H^+ + 2e^-$ Cathode: $2CH_2{=}CHCN + 2H_2O + 2e^- \rightarrow (CH_2CH_2CN)_2 + 2OH^-$	$2CH_2{=}CHCN + H_2O \rightarrow (CH_2CH_2CN)_2 + 1/2O_2(g)$

where M denotes moles, I is the applied (measured) current in amperes, and F is Faraday's constant. The integral is simply the total charge passed during the electrolysis. For a constant current process, the numerator in Equation (26.14) simplifies to the product of I and t^*, hence,

$$\frac{M_{red}}{\varepsilon} = \frac{M_{ox}}{\chi} = \frac{It^*}{nF} \tag{26.15}$$

When multiple oxidations or reductions occur simultaneously on an anode or cathode, the total moles of each product formed for a given time period is obtained by combining Faraday's Law with the total current and the current efficiency for each electrochemical reaction, where the current efficiency of the rth electrochemical reaction is defined as the fraction of the total current that is consumed by that reaction:

$$\textit{Current efficiency for the rth reaction} = \frac{\int_0^{t^*} I_r(t)\,dt}{\int_0^{t^*} I_{total}(t)\,dt} \tag{26.16}$$

where I_{total} is the total current, which is the summation of the partial currents associated with each electron transfer reaction at the anode or cathode.

In the next three sections of this chapter, fundamental theories and principles of thermodynamics, reaction kinetics, and mass transfer processes, as applied to electrochemical systems, are reviewed.

26.2.1 Thermodynamics

Thermodynamics is used in the analysis of electrochemical cells: (1) to predict which electrode reactions occur spontaneously in the anodic and cathodic directions if the two electrodes are in equilibrium with their respective adjacent solutions and are connected to one another via an external wire, and (2) to quantify chemical potentials and activity coefficients in nonideal electrolytic solutions.

26.2.1.1 Thermodynamics of Electrochemical Cells

In chemical systems, the state variable used to determine the spontaneity of a given reaction in the forward or reverse direction is the Gibbs free energy. For the electrochemical cell shown in Figure 26.1, we stipulate that the two electrodes are connected through a high-resistance voltmeter to essentially stop any current flow, in which case the overall cell reaction [given by Equation (26.3)] is at thermodynamic equilibrium. The Gibbs energy for this or any overall cell reaction at standard state conditions (where the temperature is 25°C, the pressure is one atmosphere, and the activities of reactants and products are unity) is given by

$$\Delta G^\circ = \Sigma\Delta G^\circ_{products} - \Sigma\Delta G^\circ_{reactants} \tag{26.17}$$

where ΔG° denotes the standard state Gibbs energy. When the cell is not at standard state conditions, we can further write

$$\Delta G = \Delta G^o + RT \ln K = \Delta G^o + RT \ln \frac{\prod_i (a_{i,P})^{x_{i,P}}}{\prod_i (a_{i,R})^{y_{i,R}}} \tag{26.18}$$

where K is the equilibrium constant of the reaction, R and T are the gas constant and absolute temperature, the $a_{i,P}$ and $a_{i,R}$ terms are the activities of the product and reactant species, respectively, $x_{i,P}$ and $y_{i,R}$ are the stoichiometric coefficients of the products and reactants in the reaction (e.g., ε and χ in Equation 26.13), and Π denotes the arithmetic product. When ΔG° or ΔG is < 0, the forward reaction as written is spontaneous, whereas the reverse reaction is spontaneous when the Gibbs energy change is >0. Electrochemists use the electric potential (E) rather than the Gibbs energy to assess the spontaneity of a given set of anode/cathode reactions. At constant temperature and pressure, the Gibbs energy and emf (electric potential) are related by

$$\Delta G^o = -nFE^o \quad and \quad \Delta G = -nFE \tag{26.19}$$

where n is the number of electrons participating in the anode or cathode reactions ($n = 2$ for the Zn/Cu example above). Since the overall reaction in an electrochemical cell is given by the combination of anode and cathode "half-cell" reactions, the cell emf can also be decomposed into two individual electric potentials. An abbreviated listing of such standard half-cell reactions and their associate reduction potentials is in Table 26.2. Extensive listings of potentials are in electrochemical texts and chemical handbooks [see, for example, references (1–4)].

TABLE 26.2
Standard Half-Cell Reduction Potentials at 25°C

$Au = Au^{3+} + 3e^-$	+1.498
$O_2 + 4H^+ + 4e^- = H_2O$	+1.229
$Pt^{2+} + 2e^- = Pt$	+1.2
$Ag^+ + e^- = Ag$	+0.799
$Fe^{3+} + e^- = Fe^{2+}$	+0.771
$O_2 + 2H_2O + 4e^- = 4OH^-$	+0.401
$Cu_{2+} + 2e^- = Cu$	+0.337
$2H^+ + 2e^- = H_2$	0.000
$Pb^{2+} + 2e^- = Pb$	–0.126
$Ni^{2+} + 2e^- = Ni$	–0.250
$Cd^{2+} + 2e^- = Cd$	–0.403
$Fe^{2+} + 2e^- = Fe$	–0.440
$Zn^{2+} + 2e^- = Zn$	–0.763
Al3+ + $3e^-$ = Al	–1.662
$Mg^{2+} + 2e^- = Mg$	–2.363
$Na^+ + e^- = Na$	–2.714
$K^+ + e^- = K$	–2.925

Since only the electric potential *difference* between two electrodes can be measured, one half-cell reaction is chosen to fix the zero (reference) potential condition at all temperatures. Electrochemists have chosen the standard hydrogen electrode (SHE) as this reference, where the electrode reaction is

$$2H^+ + 2e^- = H_2 \tag{26.20}$$

and where the proton and H_2 activities are unity and the temperature is 25°C. Half-cell potentials are measured in electrochemical cells against the standard hydrogen electrode. By convention, the emf of a cell is the difference between the right and left electrode half-cell reduction potentials,

$$E^o_{cell} = E^o(right) - E^o(left) \tag{26.21}$$

which requires that the hydrogen electrode also be the left-side electrode in the cell. Similarly, for half-cell reactions where there is no listed standard reduction potential, one can combine the half-cell reaction of interest with the hydrogen evolution reaction [Equation (26.20)], compute the free energy difference between reactant and products, and then use Equation (26.19) to convert ΔG^o to E^o. For example, the equilibrium potential for the methanol/formic acid reaction is computed by writing the relevant electrode reaction as a reduction reaction:

$$HCOOH + 4H^+ + 4e^- = CH_3OH + H_2O \tag{26.22}$$

This reaction is combined with the hydrogen evolution reaction, $H_2 = 2H^+ + 2e^-$, to give

$$HCOOH + 2H_2 = CH_3OH + H_2O \tag{26.23}$$

The standard Gibbs energy (at 25°C) for this reaction is

$$\Delta G^o = \Sigma\Delta G^o(\text{products}) - \Sigma\Delta G^o(\text{reactants})$$
$$= [\Delta G^o(CH_3OH) + \Delta G^o(H_2O)] - [\Delta G^o(HCOOH) + 2\Delta G^o(H_2)] \quad (26.24)$$
$$= [-39.9\text{kcal/mol} - 56.7\text{kcal/mol}] - [86.4\text{ kcal/mol} + 0]$$
$$\Delta G^o = -10.2\text{ kcal/mol} = -42.6\text{ kJ/mol}$$

From Equation (26.19) (with $n = 2$), E^o is computed from this value of ΔG^o

$$E^o = \frac{-\Delta G^o}{nF} = \frac{42.6\times 10^3}{2F} = +0.22\text{ V vs. } SHE \quad (26.25)$$

Once the two half-cell reactions in an electrochemical cell have been assigned/identified and the standard half-cell potentials have been either ascertained from standard reduction potential tables or computed using Gibbs energy data, one can determine which reaction proceeds spontaneously in the anodic and cathodic directions. Using Equation (26.19) and our definition of zero potential, the half-cell reaction with the more negative standard reduction potential is the anode in an electrochemical cell and the reaction with the more positive half-cell potential proceeds in the cathodic direction. For the Cu/Zn cell given by Equation (26.3), we see from Table 26.2 that $(E^o)_{Cu/Cu2+} = +0.337$ V vs. SHE (an abbreviation for the standard hydrogen electrode) and $(E^o)_{Zn/Zn2+} = -0.763$ V vs. SHE, hence Zn will spontaneously oxidize and cupric ions will be reduced in the cell shown in Figure [26.1]). The standard reduction potentials in Table 26.2 are invariant in sign and independent of the position of the half-cell electrode reactions in an electrochemical cell. The cell potential (as defined by Equation 26.21), on the other hand, depends on the relative positions of the two electrodes (i.e., which electrode is on the left). For example, if the Zn electrode is the left-hand electrode in the cell, E_{cell} will be 0.34 V – (–0.76 V) = +1.1 V, whereas the cell potential will be –0.76 V – (0.34 V) = –1.1 V if the copper electrode were positioned on the left.

To determine the potential of a half-cell reaction when the reactants and products are not at unit activity, the Nernst equation is used. Consider again the general half-cell reaction given by Equation (26.13). When this reaction is combined with the standard hydrogen electrode reaction (Equation (26.20)), the overall cell reaction is

$$(n/2)H_2 + \chi\ (\text{Oxid}) \rightarrow \varepsilon\ (Red) + nH^+ \quad (26.26)$$

Combining Equations (26.18) and (26.19) for this reaction results in the following formula:

$$E^e = E^o + \frac{RT}{nF}\ \ln\frac{(a_{\text{Re}d})^{\varepsilon}\ (a_{H+})^{n}}{(a_{Oxid})^{\chi}\ (a_{H2})^{n/2}} \quad (26.27)$$

where E^e is defined as the equilibrium half-cell potential with respect to the standard hydrogen electrode. For simplicity, the activities in Equation (26.27) are replaced with concentrations. Also, by definition of the standard hydrogen electrode, $a_{H+} = a_{H2} = 1$, in which case we arrive at the Nernst equation:

$$E^e = E^o + \frac{RT}{nF}\ \ln\frac{(C_{\text{Re}d})^{\varepsilon}}{(C_{Oxid})^{\chi}} \quad (26.28)$$

Equations (26.20) and (26.27) are combined when two hydrogen electrodes are connected in an electrochemical cell. The left electrode is the standard hydrogen electrode with a half-cell potential of 0.0 V. The right electrode is a hydrogen electrode immersed in a solution at a particular pH (where $a_{H+} \neq 1$). The resulting equilibrium cell potential, in terms of the right electrode compartment pH, is

$$E^{e}_{H_2/H^+} = -\frac{2.303RT}{F}\text{pH} \tag{26.29}$$

This equation is the basis for commonly used pH electrodes, where a pH variation in solution produces a measurable voltage signal.

26.2.1.2 Activity Coefficients and the Concept of an Electrochemical Potential

The electrochemical potential is used for charged ionic solutions in the same way as the chemical potential in uncharged systems. At constant temperature and pressure, any change in the system proceeds from a state of high to low Gibbs energy. If a system contains n_i components in a given phase, then we cannot specify its state without some elucidation of the composition of that phase. It follows that we can write

$$(dG)_{T,P} = \sum_i \left[\frac{\partial G}{\partial n_i}\right]_{T,P,n_i} dn_i \tag{26.30}$$

The term $[\partial G/\partial n_i]_{T,P,n_j}$ is the chemical potential (μ_i). The electrochemical potential, often denoted as $\bar{\mu}_i$, is the corresponding quantity for a system containing ionic charges, where the energy state of one ion depends on both chemical and electrical interactions with solvent molecules and other ions in the system. Guggenheim [5] separated the electrochemical potential of ion species i in phase α into chemical and electrical components:

$$(\bar{\mu}_i)^{\alpha} = (\mu_i)^{\alpha} + z_i F \Phi^{\alpha} = \mu^{o}_{i} + RT \ln a_i + z_i F \Phi^{\alpha} \tag{26.31}$$

where Φ^{α} is the electric potential in phase α, μ_i is the standard state chemical potential, z_i is the charge number of species i ($z_i < 0$ for anions and $z_i > 0$ for cations), and a_i is the activity of species i. Cation and anion activities in the above equation are usually defined in terms of molal (or molar) concentrations (denoted as m_i or C_i, respectively) and their corresponding activity coefficient (denotes as γ_i or f_i, respectively):

$$a_i = \gamma_i m_i = f_i C_i \tag{26.32}$$

The use of Equation (26.31) requires definitions of the standard state of a solid (a pure material at 25°C), an electrolyte solution (an infinitely dilute solution at 25°C and 1 atm pressure), and a gas (the ideal gas state at 1 atm pressure and 25°C). The combination of Equations (26.31) and (26.32) implies that the activity is independent of the electrical state of the system since there are separate a_i and Φ terms in the mathematical relationship for μ_i.

Unfortunately, the electrical potential in Equation (26.31) is not well defined and the individual ion activities in Equation (26.32) are not measurable because one cannot create an electrolytic

solution containing only anions or cations (i.e., only neutral salt molecules, containing both cations and anions, can be dissolved in a solvent during an activity measurement experiment). To circumvent this problem, electrochemists have defined the electrochemical potential of neutral salt molecules in terms of mean activities and mean activity coefficients. For a salt $M_{\upsilon+}X_{\upsilon}$ that dissociates completely into one type of cation species and one anion species when dissolved in a solvent, one can write the following equation:

$$M_{\upsilon_+}X_{\upsilon_-} \rightarrow (\upsilon+)M^+ + (\upsilon-)X \tag{26.33}$$

Relationships for the electrochemical potential of a neutral salt electrolyte ($\bar{\mu}_e$) are written as,

$$\begin{aligned} \bar{\mu}_e &= (\bar{\mu}_e)^o + \nu RT \ln a_\pm \\ &= (\bar{\mu}_e)^o + \nu RT \ln(\gamma_\pm m_e) \\ &= (\bar{\mu}_e)^o + \nu RT \ln(f_\pm C_e) \end{aligned} \tag{26.34}$$

where m_e and C_e are the molal and molar concentrations of the salt, respectively, $a_\pm$ is the mean activity of the salt, $\upsilon = (\upsilon+) + (\upsilon-)$, $\bar{\mu}_e = (\nu+)\bar{\mu}_+ + (\nu-)\bar{\mu}_-$, and $\gamma_\pm$ and $f_\pm$ are the mean molal and mean molar activity coefficients, which are defined in terms of the individual ion activity coefficients

$$(a_\pm)^\nu = (a_+)^{\nu+}(a_-)^{\nu-} \tag{26.35}$$

$$(\gamma_\pm)^\nu = (\gamma_+)^{\nu+}(\gamma_-)^{\nu-}\ ;\ (f_\pm)^\nu = (f_+)^{\nu+}(f_-)^{\nu-} \tag{26.36}$$

In Equation (26.34), $\bar{\mu}_e$ is dependent on the electrical state of the system through the mean activity coefficient terms, which in turn are related to the individual ion activities.

Values of electrolyte activities, as measured by osmotic pressures, freezing point depression, and other experimental methods are in the literature (References 5 and 6, for example) or one can calculate activity coefficients based on models of molecular-level interactions between ions in electrolyte solutions. For illustrative purposes, mean molal activity coefficients for various salts at different aqueous molal (m_e) concentrations at 25°C are listed in Table 26.3 [7].

Numerous models predict the activity coefficient of individual ions in solution. The one by Debye and Hückel [8] considers only electrostatic (columbic) interactions between cations and anions in a dilute solution of a single, completely dissociated salt. It is assumed that ion–ion interactions (as opposed to other phenomena such as ion–solvent interactions, ion solvation effects, and variations in the solvent dielectric constant with salt concentration) cause the ion activity coefficients to deviate from 1.0. From a practical point, only the Debye-Hückel activity coefficient relationship is needed, along with some knowledge of the theory's shortcomings, which restrict its application. For a dilute electrolytic solution containing a binary salt (i.e., a salt with one type each of cation and anion species), the ion activity coefficient from Debye-Hückel theory is given by

$$\ln \gamma_i = \ln f_i = \frac{z_i^2 A \sqrt{I_S}}{1 + B\alpha\sqrt{I_S}} \tag{26.37}$$

where α is the mean diameter of the ion (nm) and

TABLE 26.3
Mean Molal Activity Coefficients ($\gamma_{\pm}$) of Aqueous Salt Solutions at 25°C

Molality (m_e)	$CuSO_4$	HCl	KCl	NaCl	NaOH
0.1	0.150	0.796	0.770	0.778	0.764
0.2	0.104	0.767	0.718	0.735	0.725
0.3	0.083	0.756	0.688	0.710	0.706
0.4	0.070	0.755	0.666	0.693	0.695
0.5	0.062	0.757	0.649	0.681	0.688
0.8	0.048	0.783	0.618	0.662	0.677
1.0	0.042	0.809	0.604	0.657	0.677
1.6		0.916	0.580	0.657	0.690
2.0		1.01	0.573	0.668	0.707
3.0		1.316	0.569	0.714	0.782
4.0		1.762	0.577	0.783	0.901
5.0		2.38		0.874	1.074
7.0		4.37			1.60
8.0		5.90			2.00

$$B = \frac{F\sqrt{\rho_o}}{\sqrt{\varepsilon RT/2}} \quad \text{and} \quad A = \frac{\sqrt{2\rho_o}\,F^2 e}{8\pi(\varepsilon RT)^{3/2}} \tag{26.38}$$

In Equations (26.37) and (26.38), α is the mean hard sphere diameter of the ion, ρ_o is the pure solvent density, ε is the permittivity of the electrolyte solution (the permittivity is equal to the product of the dielectric constant of the electrolyte solution and the permittivity of a vacuum, 8.8542 $\times 10^{-14}$ C/V-cm), e is the charge of an electron (1.60210×10^{-19} C), and I_S is the molal ionic strength of the electrolyte solution, defined as

$$I_S = \frac{1}{2}\sum_i z_i^2 m_i = \frac{\frac{1}{2}\sum_i z_i^2 C_i}{C_o M_o} \tag{26.39}$$

where C_o and M_o are the concentration and molecular weight of the solvent, respectively. The mean molal or mean molar activity coefficient is obtained by combining Equations (26.36) and (26.37):

$$\ln\gamma_{\pm} = \ln f_{\pm} = \frac{z_+ z_- A\sqrt{I_S}}{1 + B\alpha\sqrt{I_S}} \tag{26.40}$$

Values of the parameters A and B for aqueous solutions of any binary salt at four different temperatures are given in Table 26.4 [4].

For the asymptotic limiting condition where the ionic strength approaches zero, the denominators in Equations (26.37) and (26.40) reduce to unity and the following activity coefficient equations are obtained:

$$\ln\gamma_{\pm} = z_+ z_- A\sqrt{I_S} \tag{26.41}$$

TABLE 26.4
Debye-Hückel Activity Coefficient Parameters for Aqueous Solutions of Any Binary Salt

Temperature (°C)	0	25	50	75
A $(kg/mol)^{1/2}$	1.1324	1.1762	1.2300	1.2949
B $(kg/mol)^{1/2}/nm$	3.248	3.287	3.326	3.368

Data from [4].

$$\ln \gamma_i = -z_i^2 A \sqrt{I_S} \tag{26.42}$$

Equation (26.41) predicts to within approximately 10% mean molal activity coefficients for salt concentrations up to 0.1 molal. The more accurate form of the activity coefficient equation [Equation (26.40)] allows the model to be extended to salt concentrations up to 0.5 molal. To expand the applicability of the Debye-Hückel theory to higher concentrations, additional terms are added to Equation (26.40), such as [4]

$$\ln \gamma_{\pm} = \frac{z_+ z_- A\sqrt{I_S}}{1 + B\alpha\sqrt{I_S}} + \frac{4(\nu_+)(\nu_-)\Theta}{(\nu_+) + (\nu_-)} m \tag{26.43}$$

where values of the parameter Θ for various aqueous electrolytes at 25°C [9] are listed in Table 26.5. For additional activity correlations and for a review of activity coefficients in multicomponent solutions, the reader is directed to [10, 11].

26.2.2 Kinetics of Electrode Reactions

Electrochemical reactions at an electrode surface differ from normal heterogeneous chemical reactions in that they involve the participation of one or more electrons that are either added to (reduction) or removed from (oxidation) the reactant species. The explicit inclusion of electrons as reactants or products means that the reaction rate depends on the electric potential. Electron transfer processes occur within a small portion of the double layer immediately adjacent to the electrode surface (10 to 50 nm in thickness) where solution-phase electroneutrality does not hold and where very strong electric fields (on the order of 10^6 V/cm) exist during a charge transfer reaction. We begin the analysis of electrochemical kinetics by defining a generic electrode reaction:

$$Red = Ox^{n+} + ne^{-} \tag{26.44}$$

Several molecular-level processes occur within the double layer when the above reaction proceeds in either the forward or reverse direction. They include the transfer of the *Red* species through the double layer, the adsorption of *Red* onto the electrode, the removal of an electron from *Red*, the desorption of the *Ox* product from the electrode surface, and the reorientation of solvent molecules around *Ox* since its sign has changed from that of *Red*. These processes require an additional input of energy so that the anode and cathode reactions can proceed at an acceptable rate. A single electric voltage-dependent driving force (often called the surface or activation overpotential) is assigned to the sum total of all energy-related mechanistic events in the double layer. This voltage-dependent kinetic driving force distinguishes electrochemical reactions from heterogeneous chemical reactions. Thus, the electrode reaction rate can be altered by varying the magnitude and sign of the surface overpotential, and the analysis of reaction kinetics at an electrode requires the inclusion of reaction rate constants that are dependent on the electric potential.

For many, but not all, electrochemical reactions, the Butler-Volmer rate expression describes the interrelationship between the reaction rate (given in terms of the current density *i*, with units of A/cm^2) and the electrode potential [12]:

$$i = i_o\left[\, e^{(1-\beta)nF\eta_s/RT} e^{-\beta nF\eta_s/RT} \right] \tag{26.45}$$

where η_s is the surface or activation overpotential, defined as the deviation of the electrode potential away from its equilibrium potential, i.e., $\eta_s = \Phi - \Phi^e$. The first term on the right side of the Butler-Volmer equation denotes the anodic reaction rate, and the second term gives the rate of the cathodic reaction, i.e., anodic currents (forward reaction dominating) are positive, whereas cathodic currents are negative. The net reaction rate is thus defined as the difference between the anodic (forward) and cathodic (backward) rates, as is done in the kinetic analysis of strictly chemical reactions. We also see from Equation (26.45) that a positive value of η_s accelerates the reaction in the forward (oxidation) direction and a negative value of η_s promotes the reduction reaction.

There are two kinetic parameters in Equation (26.45): the symmetry factor (β) that is defined as the fraction of the potential change in the double layer that accelerates the backward (cathodic) reaction and the exchange current density (i_o). Normally, β is set equal to 0.5. Physically, the exchange current density is a measure of the inherent reactivity of the electrode for a given electrochemical reaction. At equilibrium, the net current density at the electrode is zero, the electrode potential is equal to the equilibrium potential for the electrode reaction as defined by the Nernst equation Equation (26.28), and the forward (anodic) and backward (cathodic) reaction rates are equal. The magnitude of this equilibrium reaction rate is the exchange current density. Thus, a large value of the exchange current density is characteristic of an electrode reaction that is said to be reversible and where a small overpotential (a small departure in voltage away from the equilibrium

potential) produces a large current density. Electrode reactions with a low-exchange current density, on the other hand, are slow and are often referred to as irreversible because large overpotentials are required for appreciable current densities. Mathematically we can write an equation for i_o in terms of the chemical kinetic rate constants for the reaction in the anodic and cathodic directions (k_a and k_c, respectively) and the concentrations of the reduced and oxidized species at the electrode surface (C_{Red} and C_{Ox}, respectively) [4, 12]:

$$i_o = n\,F\,k_c^{(1-\beta)}\,k_a^{\beta}\,C_{Ox}^{(1-\beta)}\,C_{Red}^{\beta} \tag{26.46}$$

Figures 26.2 and 26.3 show typical current density-overpotential plots where i varies exponentially with η_S, in accordance with the Butler-Volmer equation. In Figure 26.2, the effect of varying β on i-η_S curves is shown (as β decreases, i increases at a given value of η_S). The increase in current density at a given η_S for increasing values of i_o is shown in Figure 26.3. From these two figures it can be concluded that electrochemical reactions that follow Butler-Volmer kinetics will be facile when the kinetic parameter β is small and the value of i_o is large.

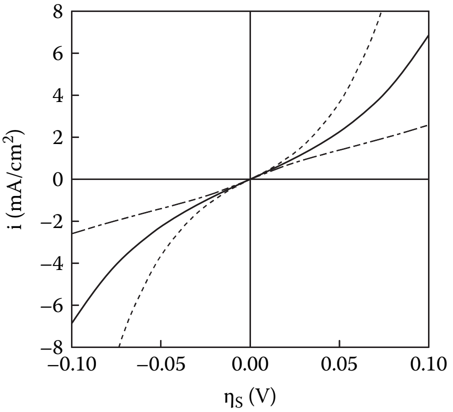

FIGURE 26.2 Current density-surface overpotential plots showing the effect of the transfer coefficient for a redox reaction (Equation (26.45)) with $n = 1$, $T = 298$K, and $i_o = 1.0$ mA/cm². - - - - $\beta = 0.74$; ——— $\beta = 0.5$; — – – — $\beta = 0.25$.

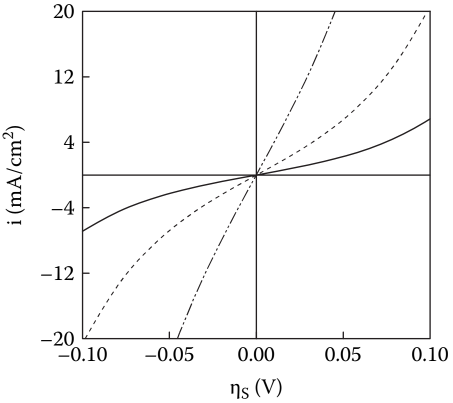

FIGURE 26.3 Current density-surface overpotential plots showing the effect of the exchange current density for a redox reaction [Equation (26.45) with $n = 1$, $T = 298$K, and $\beta = 0.5$. ——— $i_o = 1.0$ mA/cm²; - - - - $i_o = 3.0$ mA/cm²;—— ——$i_o = 5.0$ mA/cm²].

The Butler-Volmer rate expression can be simplified for small and large surface overpotentials (i.e., for small or large deviations in the electrode potential away from the equilibrium potential). For large positive or large negative surface overpotentials (where $|\eta_s|$ is >50 to100 mV), one of the exponential terms in the Butler-Volmer equation will dominate over the other. The resulting relationship can be rewritten in the general form

$$\eta_s = a + b \ln i \tag{26.47}$$

Equation (26.47) is known as the Tafel equation and b is defined as the Tafel slope. When η_s >> 0 (large anodic surface overpotentials), the Tafel equation takes the form

$$\eta_s = \frac{2.303RT}{(1-\beta)\,nF}\log i_o + \frac{2.303RT}{(1-\beta)\,nF}\log i \tag{26.48}$$

and the anodic Tafel slope is given by

$$b_a = \frac{2.303RT}{(1-\beta)nF} \tag{26.49}$$

Similarly, the form of the cathodic Tafel equation and the expression for the cathodic Tafel slope are

$$\eta_s = \frac{2.303RT}{\beta nf}\log i_o + b_c \log i \tag{26.50}$$

$$b_c = \frac{-2.303RT}{\beta nF} \tag{26.51}$$

According to Equations (26.48) and (26.50), the extrapolated linear Tafel line will intercept the x-axis of a η_s vs. log i plot at $i = i_o$ (i.e., when $\eta_s = 0$ in Equations (26.48) and (26.50), $i = i_o$).

The Tafel relationship is a powerful tool for determining Butler-Volmer kinetic parameters. The experimental apparatus needed to collect current density-overpotential data for Tafel plots is diagramed in Figure 26.4. A three-electrode apparatus is used, with a working electrode (the anode or cathode electrode at which the measurements are made), a counter electrode (to complete the cell circuit), and a reference electrode (an electrode of known and near-constant potential). The reference electrode measures overpotential changes at the working electrode (since the overall cell potential includes the overpotential at the working and counter electrodes). Current voltage data can be collected either galvanostatically (by setting the current using a DC power supply and measuring the working electrode voltage relative to the voltage of the reference electrode) or potentiostatically (by setting the working electrode potential relative to that of the reference electrode and measuring the resulting current). A representative η_s versus log i plot is shown in Figure 26.5. At high anodic or cathodic overpotentials the plots are linear, in accordance with the Tafel approximation, and the intercept of the anodic and cathodic Tafel lines on the $\eta_s = 0$ axis gives the value of log i_o. Additional details of the experimental setup and procedures for measuring kinetic parameters are found in many electrochemistry texts [2, 3, 12, 13].

Exchange current densities and cathodic Tafel slopes for the hydrogen evolution reaction ($2H^+ + 2e^- = H_2$) at different electrodes and with different electrolytes are listed in Table 26.6 [3, 12–14].

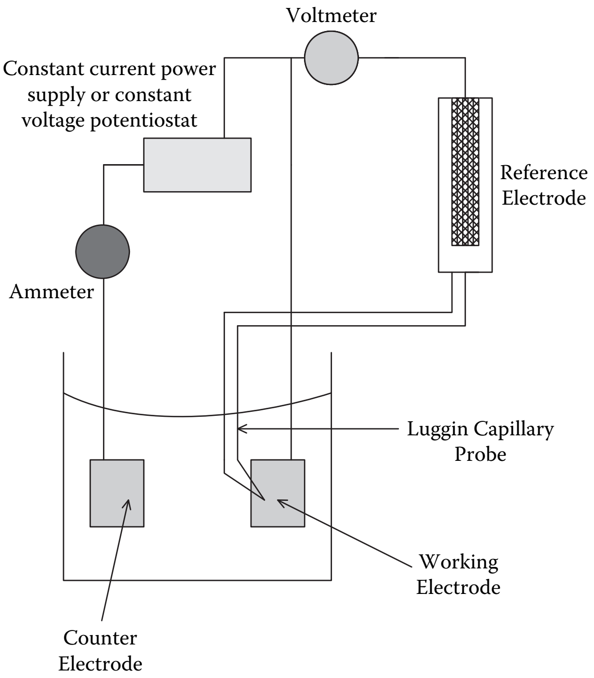

FIGURE 26.4 Three-electrode electrochemical cell for the collection of current-voltage data at the working electrode.

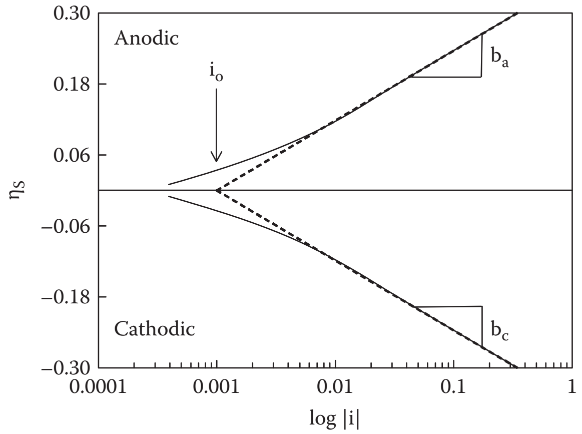

FIGURE 26.5 Surface overpotential vs. current density plots for a kintetically controlled redox reaction. Overpotentials less than zero refer to the reaction proceeding in the cathodic direction. The anodic and cathodic Tafel lines are drawn for high overpotentials.

TABLE 26.6
Exchange Current Densities and Cathodic Tafel Slopes for the Hydrogen Evolution Reaction at 25°C

Metal	Electrolyte	i_o (A/cm²)	b_c (V/decade)
Pt	1N H_2SO_4	10^{-3}	0.03
Ni	1N H_2SO_4	10^{-5}	0.11
Ta	1N HCl	10^{-5}	0.10
Ag	0.1N HCl	$\approx 10^{-6}$	0.09–0.12
Cu	0.1N HCl	$\approx 10^{-7}$	0.115
Fe	0.5N HCl	$\approx 10^{-7}$	0.13
	0.1N NaOH	10^{-6}	0.12
Pb	0.1N HCl	$\approx 10^{-13}$	0.12
Hg	0.1N HCl	$\approx 10^{-12}$	0.115
	0.1N KOH	$\approx 10^{-15}$	0.10
Au	0.1N NaOH	$\approx 10^{-6}$–10^{-8}	0.119
W	0.5N HCl	$\approx 10^{-6}$–10^{-7}	0.070–0.112
Mo	0.1N HCl	$\approx 10^{-6}$–10^{-7}	0.078–0.104
	0.1N NaOH	10^{-3}	0.087–0.116

Whereas the Tafel slope (and β) is nearly constant, i_o differs by many orders of magnitude, depending on the concentration of H^+ and the catalytic activity of the electrode.

The Butler-Volmer equation can also be simplified for small values of η_s ($|\eta_s| \leq 10$ mV) since terms of the form e^x can be replaced by the function $(1 + x)$ for x small. The resulting linear current density equation is

$$i = \frac{i_o n F}{R T} \eta_s \tag{26.52}$$

From Equation (26.52), we see that the exchange current density can be obtained from the slope of a linear plot of η_s vs. i (for η_s small).

The Butler-Volmer equation is an empirical kinetic rate expression. It can be used for modeling and analysis purposes when the applied current density varies exponentially with the surface overpotential and when the two kinetic parameters, the exchange current density and the symmetry factor, are known. Readers interested in learning more about electrode kinetics, the Butler-Volmer equation, and mechanisms of electrode reactions should consult [2–4, 12]. Many electrode reactions of technical importance in electrochemistry, however, do not follow Butler-Volmer kinetics; chief among these is the anodic dissolution of some metals where a protective metal oxide film forms on the electrode surface at high values of η resulting in a drop in the current density. The formation of such passive films is an important phenomena during metal corrosion and electromachining (both of these topics will be discussed later).

26.2.3 Mass Transport

In Section 26.2, the rate of an electrochemical reaction was shown to be dependent on the electrode potential, the intrinsic rate constants for the forward and backward reactions at the electrode, and the concentrations of oxidized and reduced species at the electrode surface. When the transport of reactants and/or products to and/or from the electrode surface is the rate-controlling step, C_{Ox} and C_{Red} in Equation (26.46) will differ from those in the bulk solution. For uncharged species in solution, transport

is governed by the usual processes of diffusion (where concentration or activity gradients are the driving force for transport) and convection, which is dependent on bulk fluid motion. Because of the electric field between the anode and cathode, there is an additional mode of transport for charged species in solution, called migration, where the driving force is the gradient in the electric potential.

26.2.3.1 Transport Equations

The analysis of mass transfer in electrochemical cells requires the use of equations that describe the condition of electroneutrality (which applies for the entire electrolyte outside the double layer at an electrode), species fluxes, mass conservation, current density, and fluid hydrodynamics. Often, mass transport events are rate limiting, as compared to kinetics processes at the electrode surface, in which case the overall electrode reaction rate is solely dependent on species mass transfer (e.g., during high-rate electroplating of some metals and for those electrochemical reactions where the concentration of reactant in solution is low).

Isothermal mass transport in electrochemical systems is described by the following relationships [4], which are strictly applicable for infinitely dilute electrolyte solutions:

1. The equation for electroneutrality in the bulk electrolytic solution,

$$\sum_i z_i C_i = 0 \tag{26.53}$$

   where z_i is the charge number of species i ($z < 0$ for anions and $z > 0$ for cations) and C is concentration with units of mol/cm^3.
2. The molar flux (N_i) equation for charged ions in solution, with diffusion, migration, and convection terms,

$$N_i = -D_i \nabla C_i - z_i u_i F C_i \nabla \Phi + C_i v \tag{26.54}$$

   where D_i is the diffusivity, u_i is the electric mobility of ion species i in solution and v is the fluid velocity.
3. A material balance equation for species i in the bulk electrolyte,

$$\frac{\partial C_i}{\partial t} = -\nabla \cdot N_i + R_i \tag{26.55}$$

   where R_i represents the rate of homogeneous chemical reaction in solution that produces or consumes species i.
4. The current density equation,

$$i = F \sum_i z_i N_i \tag{26.56}$$

To apply the above equations to electrochemical mass transfer, the solution velocity [v in Equation (26.54)] must be known, which requires the solution of a separate set of fluid mechanics equations. Also, the transport parameters, D_i and u_i, must be specified, as will be discussed in some detail below.

Manipulation of Equations (26.53)–(26.56) leads to a number of important mass transfer relationships. When the molar flux, current density, and electroneutrality equations are combined

and simplified for the case where there are no concentration gradients in solution (i.e., when $\nabla C = 0$), the following Ohm's law expression for an electrolyte solution is obtained [4]:

$$i = -\kappa \nabla \Phi \tag{26.57}$$

where κ is the ionic conductivity of the electrolytic solution:

$$\kappa = F^2 \sum_i z_i^2 u_i C_i \tag{26.58}$$

Assuming no concentration gradients nor any homogeneous reactions in solution, the material balance equation (with $R_i = 0$) can be multiplied by $z_i F$, summed over all ionic species in solution, and simplified by substitution of the electroneutrality equation. The resulting expression describes charge conservation in solution:

$$\nabla \cdot i = 0 \tag{26.59}$$

Substitution of Ohm's law into Equation (26.59) (with κ constant since there are no concentration gradients) yields Laplace's equation, which is the governing relationship for the electric potential distribution in an electrolyte solution of uniform composition:

$$\nabla^2 \Phi = 0 \tag{26.60}$$

For the case of a binary electrolyte (i.e., a single salt that dissociates in solution into one cation and one anion species), we can rewrite the molar flux equations for positive and negative ions in terms of a salt concentration gradient diffusion term, a migration term explicit in the current density (as opposed to the $\nabla\Phi$ driving force term in Equation (26.54)), and a bulk convection term:

$$N_+ = -\nu_+ D \nabla C + \frac{t+i}{z_+ F} + \nu_+ C_v \tag{26.61}$$

$$N_- = -\nu_- D \nabla C + \frac{t_i}{z_F} + \nu_- C_v \tag{26.62}$$

where C is the concentration of the electrolyte salt, which is related to the individual ion concentrations and the number of cations and anions produced by the complete dissociation of one salt molecule:

$$C = \frac{C_+}{\nu_+} = \frac{C_-}{\nu_-} \tag{26.63}$$

where v_+ and v_- are the number of cations and anions, respectively, in a neutral salt molecule. In Equations (26.61) and (26.62), there are two transport parameters, the transference number t_i and the binary electrolyte diffusivity D, which are defined mathematically in terms of u_+, u_-, D_+, and D_-,

$$t_+ = 1 - t_- = \frac{z_+ u_+}{z_+ u_+ - z_- u_-} \tag{26.64}$$

$$D = \frac{z_+ u_+ D_+ - z_- u_- D_-}{z_+ u_+ - z_- u_-} \tag{26.65}$$

The convective diffusion equation for a binary electrolyte dissolved in an incompressible fluid is derived by combining the anion and cation flux relationships (using Equation [26.54]) with the corresponding material balance equations [Equation (26.55)], with $R_i = 0$ and $\nabla \cdot v = 0$) to give

$$\frac{\partial C}{\partial t} + v \cdot \nabla C = D \nabla^2 C \tag{26.66}$$

where D is the average ion diffusivity, as defined by Equation (26.65). Curiously, this equation for the movement of charged species in solution has no term explicit in the electric potential, although there is an electric potential gradient driving force acting on the ionic species when current is flowing between the anode and cathode. Thus, for the binary electrolyte case, one does not need a full description of the electric potential distribution between the anode and cathode to determine the concentration distribution of ion species in solution. This result greatly simplifies the mathematical analysis of transport in electrochemical systems. Also, the absence of an electric potential term in Equation (26.66) means that the convective transport equation for a binary electrolyte is of a similar form as that used in heat transfer and nonelectrolytic mass transfer systems. Consequently, many solutions to nonelectrochemical convective transport problems in the literature can be utilized by electrochemical engineers, as shown below.

To increase the electrolyte conductivity, an additional ionic component that does not participate in the electrochemical reactions is often added to a solution. This nonreactive component is called a supporting electrolyte or indifferent electrolyte. In the presence of a supporting electrolyte, there is a lowering of the electric field in solution, due to the electrolyte's high conductivity. Transport of the minor ionic species in solution is due primarily to diffusion and convection, in accordance with Equation (26.54) with $\nabla \Phi = 0$. Also, in the presence of a supporting electrolyte, the convective diffusion equation for a minor component in solution is written as

$$\frac{\partial C_i}{\partial t} + v \cdot \nabla C_i = D_i \nabla^2 C_i \tag{26.67}$$

This equation is similar in form to that obtained for the case of no supporting electrolyte (Equation (26.66)) except for the use of an individual tion concentration and diffusion coefficient.

To illustrate the use of the transport equations, the following problem is posed. An electrochemical cell containing vertical flat sheets of copper as the anode and cathode is operated with an aqueous $CuSO_4$ electrolyte. The copper plates are connected to a DC power supply so that oxidation and reduction reactions proceed at the anode and cathode ($Cu^{2+} + 2e^- \rightarrow Cu$ at the cathode; $Cu \rightarrow Cu^{2+} + 2e^-$ at the anode). For the case when there is no forced or natural convection during current flow, we derive a simple expression between the constant applied current density and the steady-state cupric ion concentration profile. The cation flux and current density equations for the flat plate electrode/no convection cell are

$$N_+ = -\nu_+ D \frac{dC}{dy} + \frac{t_+ i}{z_+ F} \tag{26.68a}$$

$$i = z_+ F N_+ \tag{26.68b}$$

where y is the perpendicular distance from the electrode, as measured from one electrode surface. Since only cupric ions react at the two electrodes, the steady-state flux of SO_4^- is zero and there is only one molar flux term in the current density equation (Equation (26.68b)). Equating N_+ in the above two equations and solving for current density yields

$$i = \frac{-z_+ \nu_+ DF \dfrac{dC}{dy}}{(1 - t_+)} \tag{26.69}$$

We see from the above equation that the concentration profile will be a linear function of y (i.e., dC/dy = constant) for the entire electrolyte region between the anode and cathode when the current density is constant, fluid convection is nonexistent (diffusion and migration are the only modes of transport), and the diffusion coefficient and transference number are constant and independent of concentration.

If the flat plate cell were to contain an aqueous solution of $CuSO_4$ with an excess of H_2SO_4 supporting electrolyte (e.g., 0.05 M $CuSO_4$ and 1.0 M H_2SO_4), the current density/concentration gradient relationship analogous to Equation (26.69) would be derived by combining the following equations:

$$N_+ = -D_+ \frac{dC_+}{dy} \tag{26.70}$$

$$i = z_+ F N_+ \tag{26.71}$$

to give

$$i = -D_+ z_+ F \frac{dC_+}{dy} = -D_+ z_+ \nu_+ F \frac{dC}{dy} \tag{26.72}$$

Equation (26.72) differs from Equation (26.69) in two ways: (1) the absence of a transference number term (i.e., in the presence of a supporting electrolyte, the transference number of cupric cations is nearly zero and the $1 - t_+$ term in Equation (26.69) is equal to unity), and (2) the difference in the diffusion coefficients (with a supporting electrolyte, cupric ions diffuse independently of sulfate anions and the cation diffusivity, D_+, is used in Equation (26.70)).

26.2.3.2 Transport of Electro-Active Species in the Mass Transfer Boundary Layer

We saw above that the concentration gradient at an electrode will be linear with respect to the spatial coordinate perpendicular to the electrode surface if the anode/cathode cell were operated at a constant current density and if the fluid velocity were zero. In actuality, there will always be some bulk liquid electrolyte stirring during current flow, either an imposed forced convection velocity or a natural convection fluid motion due to changes in the reacting species concentration and fluid density near the electrode surface. In electrochemical systems with fluid flow, the mass transfer and hydrodynamic fluid flow equations are coupled and the solution of the relevant differential equations is often a formidable task, involving complex mathematical and/or numerical solution techniques. The concept of a stagnant diffusion layer or Nernst layer parallel and adjacent to the electrode surface is often used to simplify the analysis of convective mass transfer in

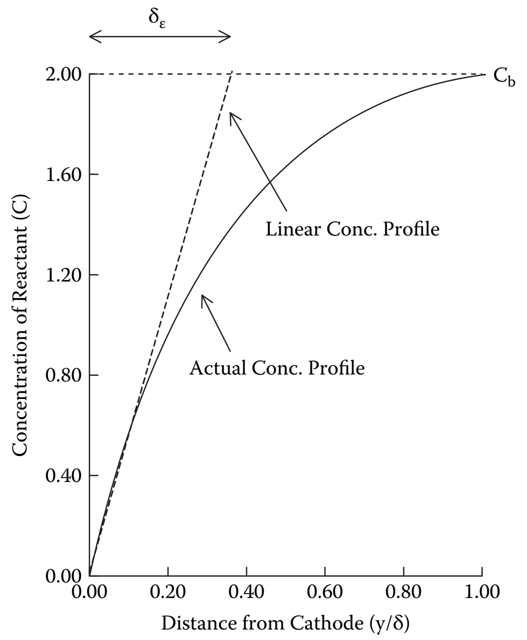

FIGURE 26.6 Concentration profile of reacting reacting species near an electrode surface under mass transfer controlled conditions.

electrochemical systems. One assumes that there is a small region very close to the electrode surface where all fluid velocities are zero and transport to and from the electrode surface occurs by diffusion (and migration) only, hence the terminology stagnant diffusion layer. Within this motionless fluid, the concentration profiles of the electro-active species are linear, as was the case in the example given above. The actual concentration profile in the mass transfer boundary layer is nonlinear, due to the presence of finite fluid velocities near the electrode (the velocity is only zero at the electrode surface). A typical nonlinear concentration profile and the region over which the concentration differs from that in the bulk fluid, which defines the actual mass transfer boundary-layer thickness (denoted as δ), are shown in Figure 26.6. The effective mass transfer boundary layer is also shown in this figure, where the linear concentration profile is tangent to the actual concentration variation at the electrode surface.

Equation (26.69) (or Equation (26.70) for the case of a supporting electrolyte) was originally derived under the assumption of no convective velocities. These same relationships can be utilized within the effective mass transfer boundary layer when fluid stirring exists. A current density/concentration equation with fluid stirring can now be generated starting with Equation (26.69) or Equation (26.70). The dC/dy term in Equation (26.69) is replaced by $\Delta C/\delta_e$ (where δ_e is the effective mass transfer boundary-layer thickness):

$$i = \frac{-z_+ \nu_+ DF \left.\dfrac{dC}{dy}\right|_{y=0}}{(1-t_+)} = \frac{-z_+ \nu_+ DF \left(\dfrac{C_\infty - C_o}{\delta_e}\right)}{(1-t_+)} \tag{26.73}$$

where $y = 0$ is the location of the electrode surface, and C_∞ and C_o are the concentrations of the reacting species in the bulk and at the electrode surface, respectively. Similar arguments can be used to generate a linear concentration profile current density equation when an excess supporting electrolyte is present (starting with Equation (26.70)).

Changes in the bulk electrolyte velocity far from the electrode and/or variations in the electrolyte flow pattern (as might occur if the cell geometry were altered) can be accounted for in Equation (26.73) by a change in the value of δ_e, as is well known from boundary-layer theory in nonelectrochemical systems. For given values of C_∞ and C_o, an increase in bulk electrolyte velocity will decrease δ_e, resulting in an increase in the current density. Frequently, δ_e is related to the mass transfer coefficient (k_d), a common mass transfer parameter,

$$k_d = \frac{D}{\delta_e} \tag{26.74}$$

so that Equation (26.73) can be rewritten as

$$i = \frac{-z_+ \nu_+ F k_d (C_\infty - C_o)}{(1 - t_+)} \tag{26.75}$$

As the current density is increased during a metal deposition process (or any electrochemical reaction where the electroactive species in the bulk electrolyte is consumed at the electrode surface) with a constant value of δ_e (i.e., for a given forced convection velocity), the surface concentration (C_o) decreases since C_∞ and δ_e are constant and independent of the electrode reaction rate. The linear concentration gradient in Equation (26.73) or (26.75) has a maximum value when $C_o = 0$. The current density corresponding to this surface concentration condition is known as the limiting current density (i_L):

$$i_L = \frac{-z_+ F D C_\infty}{\delta_e (1 - t_+)} = \frac{-z_+ F k_d C_\infty}{(1 - t_+)} \tag{26.76}$$

When there is a supporting electrolyte present, $t_+ \approx 0$ and D is replaced by D_+ in the above equation. If there are multiple ions in the electrolyte that can react at an electrode, then each species will have its own limiting current density, which will be dependent on its charge number (z_i) and bulk concentration. Also, once i_L is known, the surface concentration of reacting species at any current density less than i_L is given by

$$C_o = C_\infty \left(1 - \frac{i}{i_L} \right) \tag{26.77}$$

The limiting current density is an important parameter for the analysis of mass transfer controlled electrochemical processes and represents the maximum possible reaction rate for a given bulk reactant concentration and fluid flow pattern. During anodic metal dissolution, a mass transfer limiting current does not exist because the surface concentration of the dissolving ion (e.g., Cu^{2+} when the anode is composed of copper metal) increases with increasing current density, eventually leading to salt precipitation that blocks the electrode surface.

A typical current-voltage curve showing the limiting current density condition is shown in Figure 26.7. These data were collected at a vertical flat sheet copper cathode during Cu^{2+} reduction with assisting (upward direction) natural and forced convection velocities [15]. The limiting current density is identified by the horizontal plateau in this figure. When the surface concentration of reactant reaches zero, the electrode potential shifts (increases) until there is sufficient electrode energy for a secondary reaction to begin. During copper deposition from a $CuSO_4/H_2SO_4$, for example, the second reaction at high-cathodic overpotentials is hydrogen gas evolution (i.e., $2H^+$

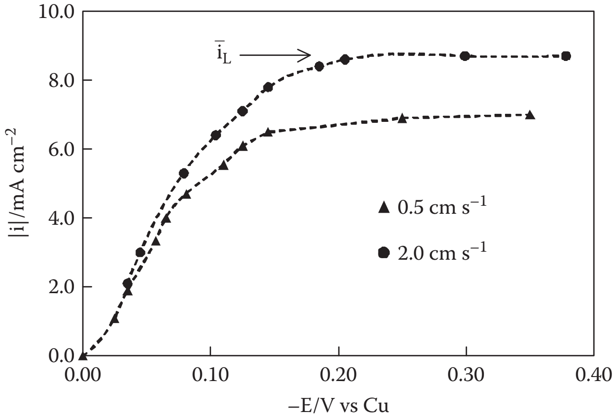

FIGURE 26.7 Current density (*i*) – voltage (*E*) plots showing the limiting current density during copper plating at a vertical flat plate cathode with assisting (upward) natural and force convection stirring (the forced convection fluid velocity is either 0.5 or 2.0 cm/sec). Data from [15]. Copyright Elsevier (1993).

+ $2e^- \rightarrow H_2$). As one would expect, the data in Figure 26.7 show that i_L increases (δ_e decreases) as the forced convection velocity is increased from 0.5 to 2.0 cm/sec.

There may be situations where there is a significant amount of hydrogen gas evolution during metal deposition. In this case, i_L may not be easily observed in a current density-voltage plot, as is the case in Figure 26.8 [16] for copper deposition at a rotating disk electrode from a $CuSO_4$ solution containing H_2SO_4 as the supporting electrolyte and Gleam-PC, a polyethylene glycol–based copper plating additive manufactured by LeaRonal, Inc. In order to determine the limiting current density, separate current density-voltage measurements must be made in the absence of $CuSO_4$. Such data gives the hydrogen evolution rate on the cathode as a function of cathode potential. Subtraction of the hydrogen current densities for the *i*-*V* curve representing hydrogen evolution and copper reduction then gives the copper deposition limiting current density, as shown in Figure 26.8.

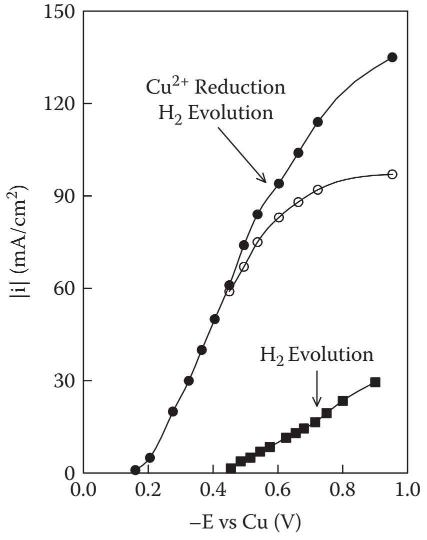

FIGURE 26.8 Current density (*i*) – voltage (*E*) plots for simultaneous cupric ion reduction + hydrogen gas generation and only hydrogen gas generation. The open circle curve (obtained by subtracting the two *solid line curves*) shows the Cu2+ limiting current. Data from [16]. Reproduced by permission of ECS—The Electrochemical Society.

The limiting current density for a given electrode reaction, cell geometry, and fluid flow condition is most easily determined experimentally, from a polarization curve such as that shown in Figures 26.7 and 26.8. The experimental apparatus to perform such measurements is shown in Figure 26.4 and consists of a working electrode (where the limiting current density is determined), a counter electrode, and a reference electrode. The use of a reference electrode permits the determination of the potential at the working electrode without interference from the counter electrode.

Rather than measure i_L experimentally, limiting current relationships can be derived theoretically by solving the relevant fluid flow and convective mass transport equations for a given electrode geometry and fluid stirring system. The solution of such equations gives k_d or δ_e in the limiting current equation. Alternatively, mass transfer coefficient correlations in the literature for nonelectrochemical systems have been used to derive i_L correlations in terms of the Sherwood (*Sh*) number, a dimensionless mass transfer coefficient, the Reynolds (*Re*) number for forced convection fluid flow, the Grashof (*Gr*) number for natural convection stirring, and the Schmidt (*Sc*) number. Such an approach is permissible because the convective diffusion equation for a binary salt solution with or without a supporting electrolyte is identical to that for an uncharged chemically reacting system. Here, k_d is determined from a *Sh* number correlation of the form

$$Sh_F = f(\mathrm{Re}, Sc) \tag{26.78a}$$

$$Sh_N = f(Gr, Sc) \tag{26.78b}$$

where

$$Sh = \frac{k_d L}{D} \tag{26.79a}$$

$$\mathrm{Re} = \frac{Lv\rho}{\mu} \tag{26.79b}$$

$$Sc = \frac{\mu}{\rho D} \tag{26.79c}$$

$$Gr = \frac{\rho_b g L^3 \Delta\rho}{\mu^2} \tag{26.79d}$$

In Equations (26.78a,b), the subscripts F and N refer to forced and natural convection stirring. In Equations (26.79a–d), L is a characteristic electrode dimension, D is the diffusion coefficient, v is velocity, g is the gravity acceleration constant, μ is viscosity, ρ_b is bulk solution density, and $\Delta\rho$ is the difference in density between the bulk solution and the solution at the electrode surface. Once a *Sh* or k_d expression has been found/generated, it is combined with Equation (26.70) (or the analogous equation for a supporting electrolyte system) to obtain an i_L relationship. Examples of mass transfer correlations follow.

1. Mass transport to a rotating disk electrode with laminar flow over the disk surface:

$$Sh = 0.62(\mathrm{Re})^{1/2}(Sc)^{1/3} \tag{26.80}$$

or

$$Sh = 0.62\left[\frac{r^2\omega}{\nu}\right]^{1/2}\left[\frac{\nu}{D}\right]^{1/2} \tag{26.81}$$

where ω is the disk rotation speed (with units of s^{-1}), r is the disk radius, v is the kinematic viscosity ($v = \mu/\rho$), and the characteristic length for the Sh number is the disk radius (r). For this system, the fluid velocity can be varied by changing the disk rotation speed. The above correlation has been generated theoretically by Levich and verified in numerous experimental studies [17–19]. The corresponding limiting current correlation is

$$|i_L| = 0.62 z_+ F C_\infty D^{2/3} \nu^{-1/6} \omega^{1/2} \tag{26.82}$$

2. Laminar flow parallel to a flat plate [20]:

$$Sh = 0.677(\mathrm{Re})^{1/2}(Sc)^{1/3} \tag{26.83}$$

where both Sh and Re are defined in terms of the flat plate length, measured in the direction of fluid flow, hence the value of k_d in this correlation represents an average mass transfer coefficient over the entire plate length.

3. Laminar flow in a tube [21]:

$$Sh = 1.07(\mathrm{Re})^{1/3}(Sc)^{1/3}\left(\frac{d}{L}\right)^{1/3} \tag{26.84}$$

In the above equation, L is the tube length, the characteristic length in Sh is the tube diameter d, and Re is defined in terms of the tube diameter and the average velocity in the tube. Equation 26.84 does not take into account possible disruptions in the laminar flow condition at the entrance of the tube, nor can it be used at distances far down the tube (it has been shown that the correlation is accurate for $L < 5000$ d) [4].

4. Natural convection at a vertical flat plate [22, 23]:

$$Sh = 0.66(ScGr)^{1/4} \tag{26.85}$$

where Gr and Sh are defined in terms of the plate length in the direction of the natural convection fluid flow.

5. Combined forced and free convection at a vertical flat plate, where the forced convection velocity is in the same direction as the natural convection flow (the so-called assisting mixed convection case). Here, researchers have combined Sherwood numbers for the pure forced and natural convection cases in the following way [15, 24–26]:

$$Sh_{mixed}^{3.2} = Sh_N^3 + Sh_F^3 \tag{26.86}$$

where Sh_N for natural convection is given by Equation (26.85) and Sh_F (forced convection) is defined by Equation (26.83). Additional limiting current correlations can be found in [27].

26.2.3.3 Infinite Dilution Transport Parameters

Transport parameters, which appear in the various forms of the infinite dilute transport equations, are the electrolyte conductivity, the ion mobility, the ion diffusion coefficient, and the ion transference number. All of these parameters can be determined from ionic equivalent conductances (λ_i, with units of (S-cm^2)/equiv) of cations and anions in solution. The ion mobility u_i, which appears in Equation (26.54), is related to λ_i by

$$u_i = \frac{\lambda_i}{|z_i| F^2} \tag{26.87}$$

The electric conductivity of an electrolyte solution (κ with units of S/cm) containing a single salt of concentration C is

$$\kappa = z_+ \nu_+ C(\lambda_+ + \lambda_-) \tag{26.88}$$

The ion diffusion coefficient and mobility are related by the Nernst-Einstein equation:

$$D_i = RTu_i \tag{26.89}$$

where the units for R are 8.314 J/mol K. By combining Equations (26.87) and (26.89), the ion diffusion coefficient is written in terms of the equivalent ionic conductance:

$$D_i = \frac{RT\lambda_i}{|z_i| F^2} \tag{26.90}$$

Finally, the transference number of an ion in a binary salt solution is

$$t_+ = 1 - t_- = \frac{\lambda_+}{\lambda_+ + \lambda_-} \tag{26.91}$$

The temperature and viscosity dependence of the ionic diffusion coefficient can be estimated from

$$\frac{D_i \mu}{T} = \text{constant} \tag{26.92}$$

where μ is the solution viscosity. Representative values of equivalent conductances of cations and anions in 25°C water at infinite dilution are listed in Table 26.7.

26.2.4 Driven vs. Self-Driven Cells and the Concept of Overpotential

We saw earlier that one can predict the thermodynamic open circuit (zero current) potential of an electrochemical cell by combining two half-cell reactions, one for the anode and the second for the cathode. The half-cell reaction with the lower (i.e., more negative) equilibrium potential will proceed spontaneously in the anodic direction, where the electrode acts as an electron sink for the anodic de-electronation (oxidation) reaction and the higher equilibrium potential reaction will occur spontaneously at the cathode, where the electrode acts as an electron source for the electronation (reduction) reaction. A cell with spontaneous reactions at the anode and cathode is called a self-

TABLE 26.7
Equivalent Conductances of Cations and Anions in 25°C Water at Infinite Dilution

Ion	z_i	λ_i (S-cm²)/equiv	Ion	z_i	λ_i (S-cm²)/equiv

driven cell. One can reverse the direction of spontaneous anode and cathode reactions in an electrochemical cell by introducing a power supply in the external circuit between the electrodes. In such a driven cell, the negative terminal of the power supply is connected to the cathode and the positive lead is connected to the anode.

We have already discussed equilibrium electrode potentials and how they can be used to determine the tendencies for anodic de-electronation and cathodic electronation reactions at the electrode–solution interfaces in an electrochemical cell. For a self-driven cell, the current density will set up a number of current-produced potentials, known as overpotentials, that decrease the overall cell potential from its equilibrium value. In the development of energy-producing devices such as batteries and fuel cells, the variation of the cell potential with current is often more important than its open circuit, equilibrium potential. By proper engineering designs, one seeks to lower these overpotentials in order to obtain as much energy as possible from the cell. Similarly, in a driven cell, the open circuit, equilibrium potential represents the minimum thermodynamic potential driving force needed to carry out the anodic and cathodic reactions. Once these reactions begin and current flows, overpotentials are generated that increase the cell potential above that at open circuit. These overpotentials need to be minimized to ensure operation of the cell with the lowest possible energy input.

The overpotentials (denoted as η) that must be taken into account when designing and operating both driven and self-driven electrochemical cells describe energy consuming processes that occur during current passage. Due to the electrical conductivity of the electrolyte that separates the anode and cathode, the IR drop (sometimes called the resistance or ohmic overpotential η_{ohm}) depends on the magnitude of the current density, the distance between the anode and cathode, and the conductivity of the electrolyte solution. Normally, the concentration of ionic species in the bulk electrolyte is constant during current flow and variations in concentration are relegated to Nernst diffusion layers adjacent to the electrode surfaces, as described above. For this situation, the composition and conductivity of the bulk electrolyte are constant and one can write for η_{ohm}

$$|\eta_{ohm}| = \frac{|i|}{\kappa}\Delta y \tag{26.93}$$

Overpotentials associated with concentration variations in the electrolyte are called concentration overpotentials (η_c). When the concentration near an electrode surface differs from that in the bulk, a concentration cell is established to equalize the two concentrations. Also, when there is diffusion of one ionic species (anion or cation) in the electrolyte due to a spatial variation in its concentration, a diffusion potential will be established to slow down the movement of the diffusing ion and speed up the movement of the oppositely charged ion so that electroneutrality in the solution is maintained. For the case where the electrolyte conductivity is assumed to be a weak function of concentration, the concentration overpotential can be expressed as the sum of a concentration cell potential and diffusion potential in the following way [4]:

$$\eta_c = \frac{RT}{nF}\ln\frac{C_{i0}}{C_{i\infty}} - \frac{F}{\kappa}\int_0^{\delta}\sum_i z_i D_i \frac{(C_{i\infty} - C_{i0})}{\delta_e}dy \tag{26.94}$$

where C_{i0} is the electrode surface concentration of species i (which is reacting at the electrode surface), $C_{i\infty}$ is the bulk solution concentration of species i, δ_e is the effective boundary layer thickness, and y is the distance perpendicular from the electrode surface. Of course, κ, the electrolyte conductivity, would have to included within the integral if it were not assumed constant. When there is an excess of supporting electrolyte present, the diffusion potential term in the above equation is small and we can write

$$\eta_c = \frac{RT}{nF}\ln\frac{C_{i0}}{C_{i\infty}} \tag{26.95}$$

We have already seen by way of Equation (26.77) that the electrode surface concentration of a reacting species is related to its bulk solution concentration, the applied current density, and the diffusion limiting current density. Substitution of Equation (26.77) (which is applicable to an electro-active species that is consumed at the electrode) into Equation (26.95) gives a more useful form of the concentration overpotential, since it does not contain the surface concentration, which is often difficult to measure:

$$\eta_c = \frac{RT}{nF}\ln\left[1 - \frac{i}{i_L}\right] \tag{26.96}$$

One can now substitute various mass transfer/limiting current density correlations for i_L (such as Equation [26.82]) in order to relate η_c with the electrolyte flow conditions.

The third category of overpotential, known as the surface or activation overpotential, deals with those changes in the cell potential that are needed to create a sufficient driving force for an appreciable reaction rate at the electrode surface. From a thermodynamic viewpoint, once the electrode potential is negative to the equilibrium (open circuit) potential for a given electrochemical reaction, that reaction will proceed in the cathodic direction. Similarly, the reverse (anodic) reaction will occur if the electrode potential were more positive than the equilibrium potential. Thus, once the electrode potential deviates even a small amount from the equilibrium potential, there should, according to thermodynamics, be significant reaction rates and large anodic or cathodic currents. This does not usually occur because of finite reaction kinetics, in which case an additional potential (the surface or activation overpotential) is needed to drive the reaction at a given rate. For many, but not all, electrochemical reactions, the surface overpotential (η_s) is related to the current density and the surface concentration of reactant and product species by the Butler-Volmer equation. This equation as discussed earlier is as follows:

$$i = i_o[e^{(1-\beta)nF\eta_S/RT} - e^{-\beta nF\eta_S/RT}] \quad (26.97)$$

where i_o is a function of the electrode surface concentrations of reactants and products. By definition, $\eta_s < 0$ favors reduction reactions, whereas $\eta_s > 0$ favors anodic reactions.

We now estimate the anode/cathode potential difference during current flow for driven and self-driven cells. First, we define the cell potential (V) as the difference in the anode and cathode potentials. For a self-driven cell, the cell voltage at a given current density will be less than the difference in equilibrium electrode potentials (ΔE_e) due to the presence of various overpotentials,

$$\begin{aligned} V = \Delta E_e - |\eta_S(anode)| - |\eta_c(anode)| \\ -|\eta_S(cathode)| - |\eta_c(cathode)| - |\eta_{ohm}| \end{aligned} \quad (26.98)$$

where ΔE_e = E_e(cathode) – E_e(anode). Since the thermodynamic quantity ΔE_e is always greater then zero for a self-driven system, the overpotentials in Equation (26.98) decrease the magnitude of the available anode/cathode electric potential difference. For a driven electrochemical cell, Equation (26.98) also holds, but E_e(cathode) – E_e(anode) < 0 and the various overpotentials add to ΔE_e. Thus, the anode/cathode voltage drop will be greater than that predicted from thermodynamic arguments alone.

In the remaining sections of this chapter, overviews of various electrochemical processes/systems are presented. Where appropriate, these overviews refer back to the fundamental principles and theories presented above.

26.3 ELECTROCHEMICAL REACTORS AND REACTOR DESIGN

An important task of electrochemical engineers is to design and operate electrochemical reactors (cells) for the manufacture of chemical products, including inorganic compounds (e.g., Cl_2 and concentrated NaOH), organic chemicals (e.g., adiponitrile), and purified metals (e.g., aluminum electrorefining). This aspect of electrochemical engineering deals with fundamental electrochemistry, heat and mass transfer, fluid flow, reactor configuration, scale-up, ancillary equipment for product purification, capital and operating costs analyses, and process optimization.

The configuration of an electrochemical reactor in an industrial process is geared to certain performance criteria. For example, in an organic electrochemical synthesis, reactors are designed to maximize product yield and current efficiency. A number of practical and general rules should be considered when deciding upon the design of an electrochemical reactor. The most general rules include (1) *simplicity of cell design and operation*, to lower capital and operating costs, minimize reactor down-time, and facilitate plant expansion; (2) *operational stability and reliability*, to ensure product purity and to enable automated operation; (3) *low cell cost and long lifetime*, to improve process economics; and (4) *safety of operation*, to minimize the dangers associated with electrical sparking and the possible production of explosive side-products during reactor operation.

26.3.1 Characterizing the Performance of an Electrochemical Reactor

There are numerous ways of quantifying the energy efficiency and product selectivity of an electrochemical reactor, for both scale-up calculations and capital/operating cost analyses. Although products are formed at both the anode and cathode in such reactors, the cell performance is normally characterized in terms of the electrode where the desired product is generated.

1. Current efficiency: The current efficiency (CE) of an electrochemical reaction is defined as the ratio of the electric charge used in forming the product of interest to the total

charge Q passed through the reactor during an electrolysis. The CE can be viewed as the product yield based on the electrical charge and is given by

$$CE = \frac{nF(Vol)}{Q}\Delta C_P \tag{26.99}$$

where Vol denotes the volume of the reaction medium, n is the number of electrons needed to synthesize one product molecule (in accordance with the electrode reaction), F is Faraday's constant, and ΔC_P is the concentration change of the product over the course of the electrolysis. The overall current efficiency is found by setting Q equal to the total charge passed during an electrolysis, whereas the differential current efficiency is determined by setting Q equal to the charge passed during a finite time interval during an electrolysis. In both cases, the charge is found by the time-integral of the current (for constant current operation, Q is the product of the current and reaction time).

2. Product selectivity: The product selectivity (S_p) is the ratio of the moles of the desired product to the total products formed from the starting material:

$$S_P = \frac{\text{number of moles of desired product}}{\sum \text{ moles of all products}} \tag{26.100}$$

3. Electrical energy consumption: The electrical energy required to synthesize a given product is dependent on the CE of the electrode reaction and the voltage difference between the anode and cathode (E_{cell}) during reactor operation. On a mass basis, we can write the specific energy consumption as follows:

$$\text{Specific Energy Consumption} = \frac{nFE_{cell}}{CE \times MW} \tag{26.101}$$

where MW is the molecular weight of the desired product. On a volume basis, the energy consumption is

$$\text{Volumetric Energy Consumption} = \frac{nFE_{cell}}{CE \times V_m} \tag{26.102}$$

where V_m is the partial molar volume of the desired product. For constant current I operation for time period t, the specific energy consumption can be written as

$$\text{Specific Energy Consumption} = \frac{E_{cell}It}{\Delta C_P(vol)MW} \tag{26.103}$$

4. Space-time-yield: The space-time-yield (τ) is the mass of product per unit time that can be obtained in a given electrochemical reactor of volume:

$$\tau = \frac{A_S \times I \times CE \times MW}{nF} \tag{26.104}$$

where A_S is the active electrode area per unit reactor volume.

26.3.1.1 Initial Design Experiments

The first step in designing an electrochemical reactor is to identify the electrode and electrolyte components and to determine baseline operating conditions. Data are collected using bench-scale batch or semicontinuous reactor experiments, with a single anode and cathode, to determine (1) the choice of electrode materials, (2) the nominal operating current density and voltage of the reactor, (3) the cell temperature and pressure, (4) the proper reactant concentration, (5) the type of solvent and the type and concentration of supporting electrolyte, and (6) the method and extent of electrolyte agitation. The following general rules assist in designing an electrochemical reactor.

Choice of Electrode Materials

The anode and cathode should be stable in the electrolysis medium, allow the desired oxidation/reduction reactions at the highest possible rates with minimal by-product formation, and be of reasonable cost. In actuality, the electrodes may corrode or undergo physical wear during reactor operation, which may limit their lifetime. Often, if an expensive electrode material is needed for a given reaction, it can be plated or physically coated on a less costly, inert, and electronically conducting substrate. Common anode and cathode materials are listed in Table 26.8.

The form and shape of the electrodes are tailored for the specific reactor configuration. Typical shapes include flat metal sheets, perforated or expanded metal grids, metal foams and meshes, and three-dimensional packed bed electrodes formed by stacking metal meshes, pressing catalyst powders, or by use of microporous carbon felts and cloths (three-dimensional electrodes are particularly attractive for low-current density reactions because the electrode surface per unit reactor volume can be made very large) [28].

Electrolysis Medium

The reaction medium normally consists of a solvent into which the electroactive species is dissolved. Often, a supporting electrolyte salt is added to increase the conductivity of the solution. The concentration of electroactive species should be made as high as possible in order to pass the maximum feasible current through the reactor. When choosing a solvent, one must consider such factors as proton activity (the required pH for the electrode reactions), dielectric constant (which affects ion conductivity), solubility of electrolyte salts and other inorganic/organic substrates, accessible temperature range, vapor pressure, viscosity, toxicity, and price. Water is the solvent of choice, based on its low cost, high-salt solubility, and lack of toxicity. The solubility of organic compounds in an aqueous electrolytic solution, however, may be limited, necessitating the use of other protic solvents (e.g., methanol or acetic acid). In some cases an aprotic solvent such as

TABLE 26.8
Common Electrode Materials

Cathodes	Anodes
High hydrogen overpotential metals such as Hg, Pb, Sn, Zn, and metal amalgams (Zn-Hg)	Precious metals on an inert substrate (e.g., Ti) including Pt, Ir, and Pt-Ir
Graphite and other forms of carbon (including porous carbon and carbon powders bound in an inert polymer matrix)	Graphite or other forms of carbon
Steels and stainless steels	PbO_2 on Ti, Nb, or carbon
Coatings of low hydrogen overpotential metals (e.g., Ni, Ni/Zn, Ni/Al) on steel	Ni (for alkaline media)
Low hydrogen overpotential Raney metal powders pressed into a bed or bound in a polymer matrix	Dimensionally stable anodes such as mixed Ru-Ti oxide or Ti for Cl_2 production or IrO_2 on Ti for O_2 generation
Precious metal powders (Pt, Pd, and Pt on carbon)	Magnetite ($Fe_{3-x}O_4$)
Hastelloys (such as Bi-Mo-Fe and Ni-Mo-Cr alloys)	Conducting ceramics, such as Ti_4O_7
TiO_x

From [29].

acetonitrile, dimethylformamide, or propylene carbonate may work best. On the other hand, it may be desirable to employ a molten salt electrolyte with no separate solvent species, as is done in aluminum electrorefining. The primary criteria in choosing a solvent is its useful potential range. In an electrochemical reactor, the solvent must be less reactive than the electroactive substrate(s) so that it is not oxidized or reduced at the electrodes. Approximate values for the anodic and cathodic limits of some commonly used solvent are given in Table 26.9 [29].

Operating Current Density and Voltage

While the combination of the applied current and current efficiency in an electrochemical reactor is a measure of the overall rate of product output, it is the product of the current and cell voltage that will determine the reactor's electrical power consumption, as indicated by Equation (26.103). The overall voltage in an electrochemical reactor is composed of the following components: (1) thermodynamic cell potential, (2) anode kinetic and mass transfer overpotentials, (3) anolyte IR drop, (4) diaphragm/membrane IR drop, (5) catholyte IR drop, and (6) cathode kinetic and mass transfer overpotentials. For more information on each of these terms, the reader should refer to Section 26.1.

Temperature and Pressure

Electrolyses at an elevated or reduced pressure are generally avoided because of the added complexity in cell design, unless high pressures are needed to avoid evaporation of the solvent. Electrochemical reactors are often operated at elevated temperatures in order to enhance electrode reaction rates, improve mass transfer of electroactive species to the electrode surface, and to increase the conductivity of the electrolyte. Joule (IR) heating during current flow through the reaction medium in conjunction with exothermic electrode reactions may require extensive cooling of the electrochemical reactor.

Mass Transport Effects

Mass transfer of reactants/products to/from the electrode surface may limit electrochemical reaction rates. To increase the concentration of reactants at the electrode surface, high Reynolds number flows are favored. High flow rates, however, increase pumping costs and could lead to undesirable mixing of the anolyte and catholyte.

26.3.2 Choosing an Electrochemical Reactor

Factors to consider when selecting an electrochemical reactor are listed in Table 26.10 [30]. Batch reactors are chosen for the synthesis of high value-added products in small quantities, whereas continuous reactors are more amenable to large-scale production. When the anolyte and catholyte

TABLE 26.10

are to remain unmixed (to prevent unwanted side reactions at the electrodes, to isolate electrode products, and/or to prevent the formation of explosive or toxic mixtures), an ion-exchange membrane or some other kind of ionically conducting separator is placed between the anode and cathode chambers (the divided cell configuration). For simplicity of design and operation, most electrochemical reactors utilize flat plate electrodes.

Electrochemical reactors operate on DC current and, thus, high-voltage alternating current must be rectified and transformed before being sent to the cells. When the reactor contains multiple electrodes, electrical connections can be made using either a monopolar or bipolar design (see Figure 26.9). In a monopolar reactor, there are alternating anodes and cathodes, and both sides of each flat sheet electrode have the same polarity. External electrical contact is made to each electrode and the cell voltage is applied between each anode and cathode. In a bipolar design, electrical connections are made only to the two end electrodes, and the opposite faces of each electrode will have opposite polarities. Monopolar reactors require a low-voltage, high-current power supply, whereas the current is low and voltage high for a similar reactor geometry with bipolar connections. Although the electrical connection scheme is much simpler in a bipolar reactor, there may be leakage currents between cells (also known as bypass or shunt currents).

To minimize the cell voltage in an electrochemical reactor, the anode and cathode electrodes are placed as close as possible to minimize the resistance (IR) overpotential. Such voltage minimization is achieved in zero-gap and capillary cells [31, 32], by placing the electrodes directly adjacent to the membrane/diaphragm that separates the anode and cathode compartments. Figure 26.10 shows a bipolar capillary gap cell that was used in electro-organic processing [29], where

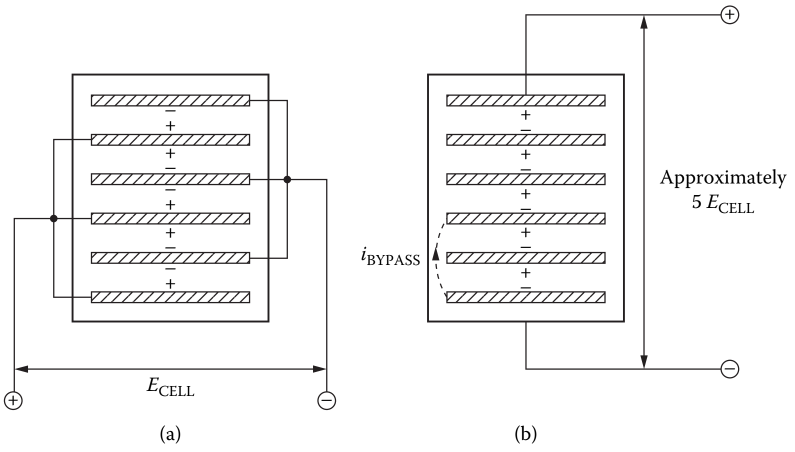

FIGURE 26.9 Electrical connections in multi-electrode cells. (a) Monopolar connection, (b) Bipolar connection (showing bypass current). From [30] (with kind permission from Springer Science and Business Media).

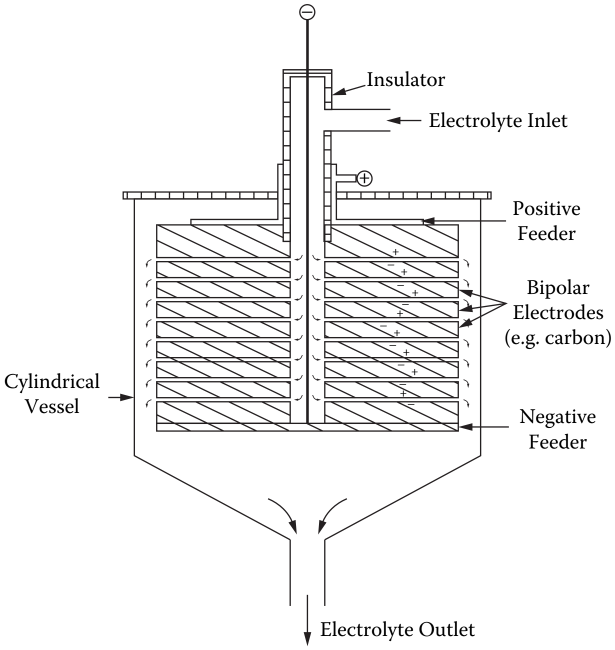

FIGURE 26.10 A capillary gap electrochemical reactor with bipolar connections. The electrodes are a stack of closely spaced disks and the electrolyte flows outward through the inter-electrode gap in the radial direction [31]. Pletcher and Walsh, Figure 2.33(a).

the narrow anode-to-cathode spacing (125 to 200 μm) is advantageous for low-conductivity electrolytes. The cell consists of a series of cylindrical bipolar graphite plates, precisely spaced by means of thin, radially positioned polyester strips. Electrolyte enters through a central channel and flows radially to the periphery of the cell, where it is collected and withdrawn.

Different reactors have been employed for various bench-scale and industrial-scale electrochemical processes. A partial listing of typical cell designs follows. More information on electrochemical reactors can be found in [28, 30, 33].

1. Tank cells: The tank cell shown in Figure 26.11 is a simple electrochemical reactor design where a series of alternating anode and cathode plates or expanded metal grids are placed in a single tank, either open or closed, with the electrodes extending the full width and depth of the tank. Batch tank reactors are used in metal electroplating, while semi-batch cells are employed for aluminum extraction, fluorine generation, and water electrolysis (i.e., the generation of H_2 and O_2 from water). The electrodes are usually placed vertically in the tank so that electrochemically generated gases can be easily removed from the inter-electrode gap. Electrical connections to the electrodes can be either monopolar or bipolar. The anode/cathode gap is made as small as possible to reduce the overall cell voltage, and the anolyte and catholyte chambers can be separated by means of a series of ion-exchange membranes or diaphragms (e.g., in water electrolysis cells, diaphragms are used to prevent mixing of hydrogen and oxygen gases). Normally, there is no externally applied stirring of the electrolyte in tank cells, although rising gas bubbles evolving at an electrode can create fluid agitation.
2. Parallel-plate flow cells: Most electrochemical flow cells are based on a parallel-plate electrode design with either horizontal or, more commonly, vertical electrodes in a monopolar or bipolar configuration (see Figure 26.12). With vertical electrodes, the cell is usually constructed in a plate-and-frame arrangement and mounted on a filter press.

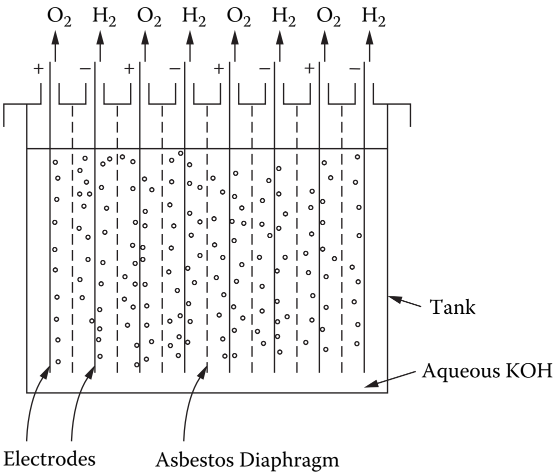

FIGURE 26.11 Tank cell with flat sheet electrodes for the electrolysis of water [30] (with kind permission from Springer Science and Business Media).

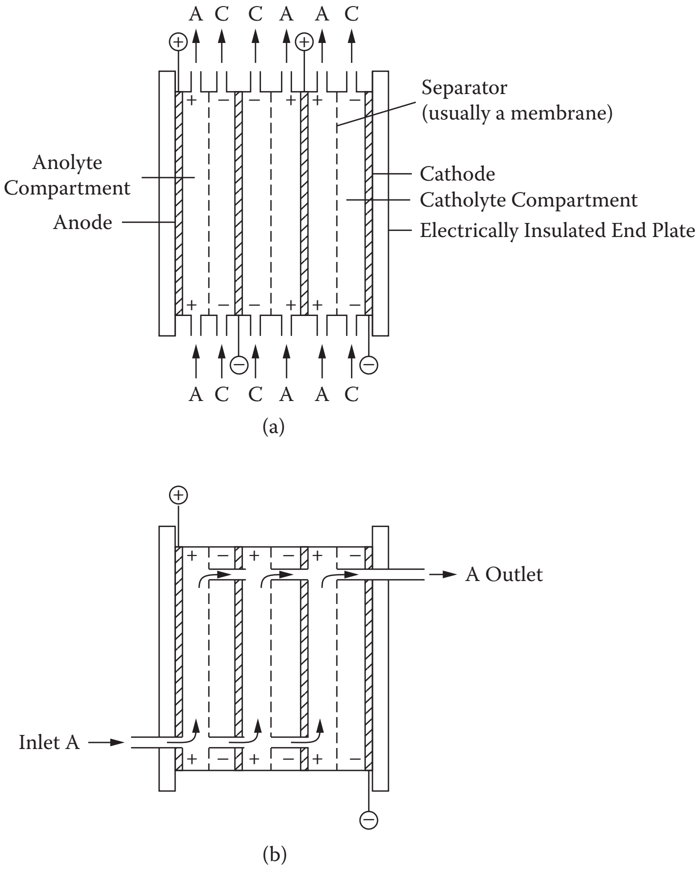

FIGURE 26.12 Plate and frame (filter-press) electrochemical flow cells. (a) Monopolar connection with external fluid flow manifolding. (b) Bipolar connections with internal manifolding [30] (with kind permission from Springer Science and Business Media).

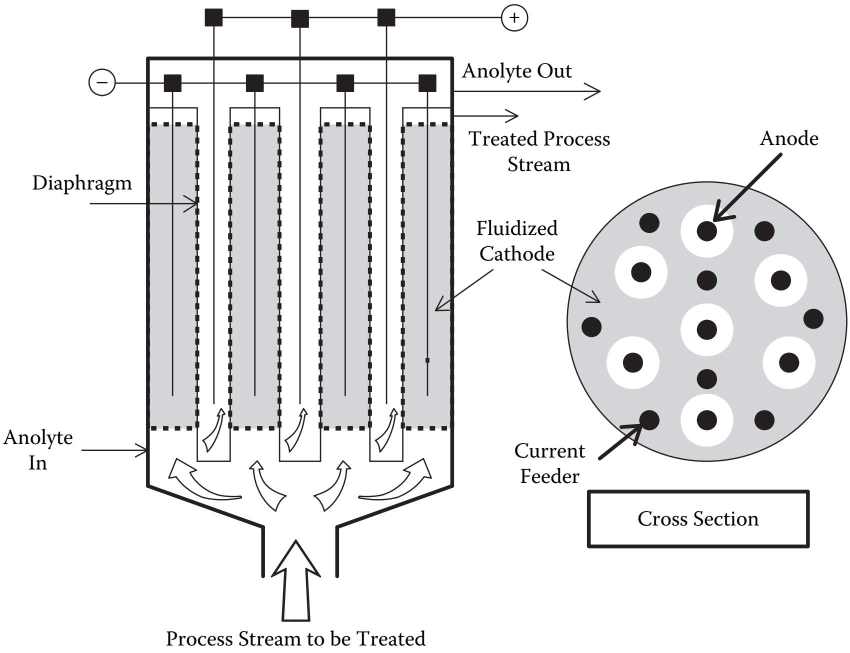

FIGURE 26.13 A schematic diagram of the Akzo fluidized bed electrochemical reactor (which resembles a shell-and-tube heat exchanger) [30].

Individual anode/cathode cells (as many as 100 cells in one reactor) can be divided (i.e., where a membrane or diaphragm separates the anolyte and catholyte solutions) or undivided. The interelectrode gap is normally between 0.5 and 5.0 cm and electrolyte is pumped at high flow rates over the electrodes The parallel-plate design is popular for many electrochemical processes e.g., water electrolysis, mercury cells for the production of Cl_2 and NaOH, and the electrohydrodimerization of adiponitrile. The advantages of this reactor type are (a) wide availability of electrode materials and separators, (b) simplicity of construction, (c) the ease of enhancing mass transfer by use of turbulence promoters and high fluid velocities, (d) the filter-press construction is similar to hardware commonly used by chemical engineers, and (e) scale-up simplicity, by either increasing the electrode size and/or increasing the number of electrodes.

3. Fluidized bed cells: In a fluidized bed reactor [34–36], one or both electrodes are composed of electrically conductive particles (e.g., metal-coated glass of polystyrene beads) that are fluidized by the upward flow of electrolyte, resulting in a bed expansion of 10% to 20% (Figure 26.13). The flow of current to the particle bed(s) can be provided by metal gauze conductors. The high electrode surface area to volume ratio (often >100/1) in this type of reactor is advantageous when the operating current density is small. The reactor can be operated in either a divided or undivided mode (i.e., with or without a separator to minimize anolyte and catholyte mixing). Although the space-time-yield may be high, the potential and current distribution may be highly nonuniform, leading to a low-product current efficiency and poor reaction selectivity. Additionally, the scale-up of these reactors is less predictable than flat plate electrode cells.
4. Swiss-roll cell: This cell, shown in Figure 26.14, has been proposed for both electro-organic syntheses and wastewater treatment [29, 37, 38]. It is fabricated from a multilayer stack of the following sheet materials: (a) a polymeric cathode spacer cloth or mesh, (b) a cathode mesh, (c) an ion-exchange membrane, (d) a polymeric anode spacer cloth or mesh, and (e) an anode mesh. These sheets are assembled in the sequence a-b-a-c-de-d-

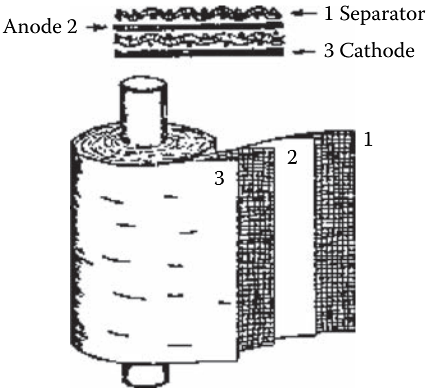

FIGURE 26.14 The Swiss-roll cell [30] (with kind permission from Springer Science and Business Media).

c to give a 5- to 6-mm thick sandwich that is rolled around an anode rod and inserted into a cylindrical container. Electrolyte flow is usually in the axial direction, through the mesh electrodes. Electrical connection to the rolled anode is provided by the anode rod, whereas a bolt through the side of the container makes electrical contact with the cathode. The close inter-electrode spacing (as small as 0.2 mm) minimizes the electrolyte IR drop and provides a high space-time-yield (a high electrode area per unit reactor volume), while the mesh spacers and electrodes promote turbulence and enhance mass transfer.

26.4 INORGANIC AND ORGANIC ELECTROCHEMICAL SYNTHESIS

26.4.1 Inorganic Processes

26.4.1.1 Aluminum Electrorefining

In our natural environment, metals are most stable in an oxidized state, e.g., Fe_2O_3 or Al_2O_3. As a consequence, one step of metal ore refining is the reduction of the metal oxide to its zero oxidation state. An electrochemical reduction process, where the electrolysis medium is a molten salt, is preferred for very electropositive metals (e.g., aluminum, sodium, lithium, and magnesium) and for metal refining where the chemical route suffers from environmental problems.

The electrolytic production of aluminum is carried out in Hall-Heroult cells that have changed little in nearly 100 years [39]. The Hall-Heroult process operates at a high temperature (about 1250 K) and utilizes a molten salt electrolyte of alumina (Al_2O_3) and cryolite (Na_3AlO_2), with additives such as calcium fluoride and aluminum trifluoride. The cathode reaction is the reduction of Al^{3+}, with a consumable carbon anode. The overall reaction in the Hall-Heroult cell (shown schematically in Figure 26.15) is

$$2Al_2O_3 + 3C \rightarrow 4Al + 3CO_2 \qquad (26.105)$$

The cells are strong steel boxes, lined with alumina (to act as a refractory), a thermal insulator, and carbon. The cathode is a liquid pool of aluminum that lies at the base of the cell, above a current collector consisting of a number of carbon blocks inlaid with steel bars. A frozen crust of electrolyte protects the cell housing from erosion. The cell has ports for the periodic addition of alumina through the crust, for the removal of Al metal, and an extractor to vent anode gases (mainly CO_2). As the carbon anode is consumed, it is lowered to maintain a constant anode/cathode gap (about 5 cm). In a typical plant for the production of 70,000 tons of Al per year, 200 Hall-Heroult cells, each 3 m × 8 m in size with 15 m^2 of anode area, are arranged in series. The operating current density is

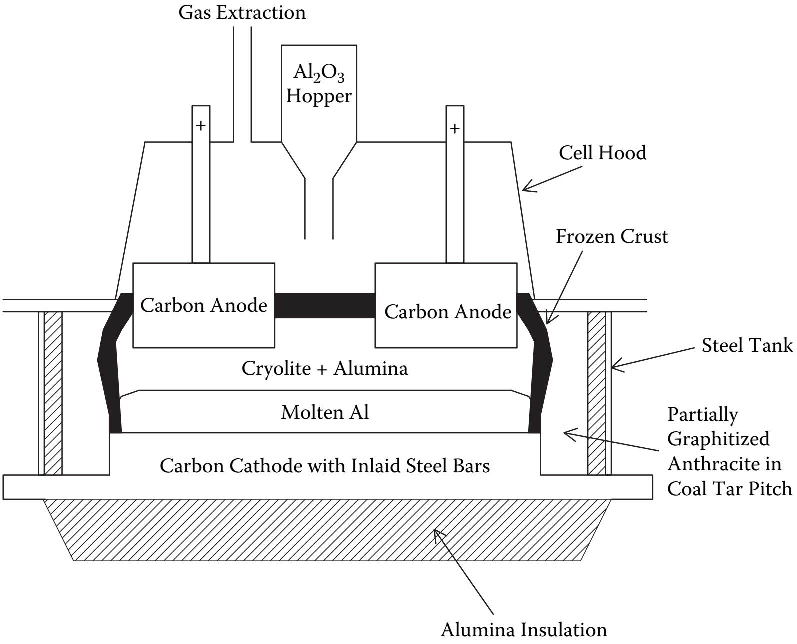

FIGURE 26.15 Hall-Heroult cell for aluminum extraction process [30] (with kind permission from Springer Science and Business Media).

about 1.0 A/cm^2 with an anode/cathode cell voltage of 4.0-4.5 V and a current efficiency of 85% to 90%. The energy requirement of the process is 14,000 to 16,000 kWh per ton of aluminum.

26.4.1.2 Chlor-Alkali Process

In the chlor-alkali process, an aqueous solution of NaCl is electrolyzed to give Cl_2, H_2, and NaOH, according to the following anode and cathode reactions:

$$\text{Anode: } 2Cl^- \rightarrow Cl_2 + 2e^- \quad (26.106)$$

$$\text{Cathode: } 2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (26.107)$$

This process is the single largest of the electrolytic industries; U.S. chlorine demand in 2002 was 14,000,000 mt [40].

Several cell designs have evolved over the years for the electrochemical production of Cl_2 and NaOH [30]. The oldest commercial process utilized a mercury cell, where the anode and cathode reactions are

$$\text{Anode: } 2Cl^- \rightarrow Cl_2 + 2e^- \quad (26.108)$$

$$\text{Cathode: } 2Na^+ + 2Hg + 2e^- \rightarrow 2NaHg \quad (26.109)$$

A subsequent hydrolysis step outside the electrochemical cells (and in the presence of a catalyst) was used to convert the sodium amalgam to OH and hydrogen gas:

$$2NaHg + 2H_2O \rightarrow H_2 + 2NaOH + 2Hg \quad (26.110)$$

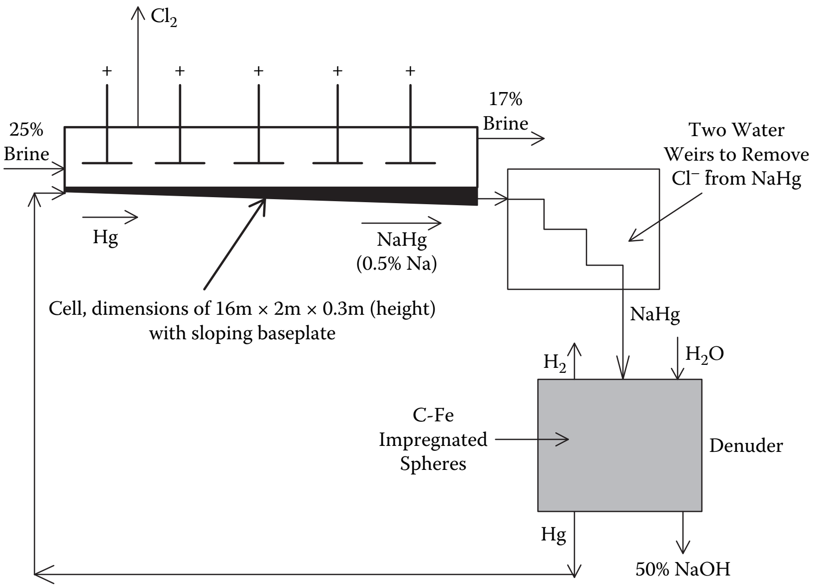

FIGURE 26.16 A schematic diagram of a mercury cell and the coupled Hg denuder [30] (with kind permission from Springer Science and Business Media).

A schematic diagram of a mercury cell is shown in Figure 26.16. The cell consists of a large shallow trough with a sloping base. Mercury flows along the bottom of the cell and acts as the cathode, while graphite or RuO_2-coated titanium (dimensionally stable anode) is used as the anode, with an anode/cathode gap of about 1 cm. Brine at an NaCl concentration of about 25% and a temperature of 60°C enters the cell and is electrolyzed, exiting at a concentration of about 17%. Cl_2 exits the top of the cell and the sodium amalgam leaves the base, where it is first washed with water to remove NaCl and then enters a denuder where a concentrated (50%) NaOH solution is generated from the amalgam and the proper amount of water. Hydrogen gas is vented from the top of the denuder and the Hg is recycled to the cells. Mercury cells typically operate at a current density of 1.0 A/cm^2, at an anode/cathode cell voltage of –4.4 V. Energy consumption is approximately 3150 kWh per ton of NaOH. Due to environmental concerns over the use of Hg, this cell design is being phased out in the U.S. and Japan and replaced by diaphragm and membrane cells.

In a diaphragm cell (shown schematically in Figure 26.17), an asbestos separator is deposited directly onto a steel cathode (or a cathode composed of steel with a nickel coating to lower the overpotential for hydrogen evolution) to physically inhibit mixing of the NaOH cathode product and brine feed (typically about 30%). The anode (graphite or dimensionally stable anode) is placed close to the cathode. A small fraction of the brine feed is allowed to diffuse through the asbestos diaphragm and H_2 and NaOH are formed on the opposite (cathode) side of the separator. The concentration of NaOH at the cathode is restricted to below 12%, otherwise OH ions will diffuse across the diaphragm and react with Cl_2 to form hypochlorite. A high pH brine also increases the rate of oxygen evolution (from water) at the anode, which lowers the current efficiency of the process and contaminates the Cl_2 gas. Also, the NaOH solution leaving the cathode contains some NaCl impurity. To synthesize a higher quality/higher concentration caustic product, water can be evaporated from the catholyte to give a 50% caustic solution. Removal of water also results in the crystallization of NaCl, but it is difficult to lower the salt concentration to <1%. Of course this added purification step is energy intensive and adds to the overall cost of the process. Diaphragm cells operate at an elevated temperature of 60°C to 80°C, a current density of about 0.2 A/cm^2, and a cell voltage of –3.45 V. When the water evaporation step to produce 50% caustic is added to the electrical energy for the electrolysis, a total of 3260 kWh is required per ton of NaOH.

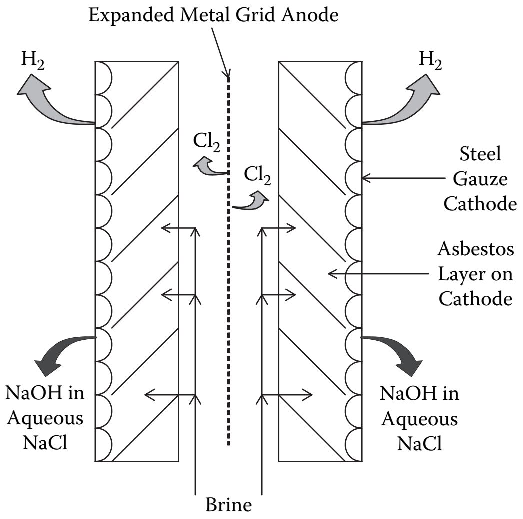

FIGURE 26.17 Principles of operation of a diaphragm cell for Cl_2 production.

In the 1970s, cation-exchange membranes composed of chemically resistant, perfluorinated polymers (e.g., DuPont's Nafion® and Flemion® from Asahi Glass) were developed and incorporated into chlorine-caustic cells. The resulting membrane cells utilized the same electrode reactions as the diaphragm cells, but the cation-selective permeability of the membrane (i.e., the membrane's ability to restrict the passage of OH^- and Cl^-) allowed for the direct synthesis of 30% to 40% sodium hydroxide solutions, essentially free of chloride ions. The very low leakage of OH^- across the membrane also lowered the oxygen contamination of the Cl_2 product and minimized current losses due to electrochemical oxygen evolution. Most membrane cells are based on a filterpress design, with vertical electrodes (louvered or expanded metal grids) and a "zero-gap" configuration where the anode and cathode are in contact with the opposite sides of the membrane. A coating on the membrane surface ensures proper gas bubble release. The anolyte feed is 25% NaCl in water and the catholyte is dilute caustic. A typical filterpress cell, for the production of 10,000 tons of Cl_2 per year, consists of 50 to 100 anode/cathode pairs, with each electrode 1 m × 1 m. The cell operates at a temperature of about 80°C, a current density of about 0.4 A/cm^2, and an anode/cathode cell voltage of –2.95 V. Electrical energy consumption by the cells is about 2520 kWh per ton of NaOH. Extensive brine feed purification is normally required for membrane cells in order to remove divalent cations (in particular Mg^{2+} and Ca^{2+}) that absorb into the membrane and lower the membrane's ability to reject Cl^- and OH^-.

26.4.1.3 Water Electrolysis

The electrolysis of water molecules in an electrochemical cell is carried out to generate high purity oxygen and hydrogen gases according to the following anode and cathode reactions:

$$\text{Anode: } 2H_2O \rightarrow O_2 + 4H^+ + 4e^- \tag{26.111}$$

$$\text{Cathode: } H_2O + 2e^- \rightarrow H_2 + 2OH^- \tag{26.112}$$

The most important product of water electrolysis is hydrogen gas, which is used as in the chemical catalytic hydrogenation of organic compounds (e.g., liquid oils that are hydrogenated to synthesize solid or semisolid fats), the refining of high-purity metals, the synthesis of ammonia, and the manufacture of semiconductors. The water-splitting route to H_2 gas, however, is much more

energy-intensive (expensive) than traditional reformer processes (e.g., natural gas reforming), but the electrochemical route may be cost-effective for small-scale hydrogen production plants and/or where low-cost hydroelectric power is available. With the above two electrode reactions, the thermodynamic cell voltage is –1.23 V and independent of solution pH. Industrial water electrolyzers are designed to minimize the cell voltage. Typical cell configurations include tank cells, filterpress cells, and zero-gap cells utilizing a solid polymer electrolyte [28].

26.4.2 Organic Electrochemical Syntheses

In an organic electrochemical process, heterogeneous electron transfer reactions at the anode and cathode replace chemical oxidizing or reducing agents in solution. Electrons may be added or removed directly from an organic species at the electrode surface or the electron transfer reactions can generate anion or cation radicals, which initiate radical, electron-transfer, nucleophilic/electrophilic and acid/base reactions. The electrode potential influences the nature of the organic product or the electro-generated intermediate and its production rates. The field of organic electrochemical synthesis encompasses not only the oxidation or reduction of suitable functional groups, but also more intricate reactions, such as anodic or cathodic substitution, addition, coupling, cleavage of bonds, and polymerization [29, 41–44]. Thousands of organic compounds have been synthesized in the laboratory by means of electrochemical methods. In over 100 cases, the electrochemical process was sufficiently promising to build either pilot- or commercial-scale plants (see for example, Table 6.2 in [30] and Chapter 30, Table 2, in [29]). Several types of chemical transformations that can be performed electrochemically are presented in Table 26.11.

Electrochemical methods for the production of organic compounds are attractive for a number of reasons:

1. High yields and high selectivity are attained under appropriate electrolysis conditions; the desired compounds may be produced at a lower cost, as compared with traditional methods.
2. Electrical energy is used instead of chemical reagents (e.g., $LiAlH_4$ for organic reductions); accordingly, electrochemical processes may be less expensive with less pollution. Also, it may be possible to regenerate electrochemically spent redox agents in situ, so that large quantities of product can be produced from a small inventory of reagents.
3. Reactions occur at moderate temperature and pressure.
4. Oxidation and reduction reaction rates can be controlled by the current or electric potential.

Possible complications of an electrochemical route are listed below.

1. The rate of electron transfer at the anode or cathode may be slow for a complex reorganization of the substrate. This problem may be circumvented by: (a) three-dimensional packed, stacked, or fluidized bed electrodes with a high ratio of surface area to volume; (b) mediated reactions (a fast redox reaction at the electrode followed by a bulk solution homogeneous reaction with the organic substrate which consumes the electrogenerated reagent); and (c) phase-transfer catalysts, where the active species is electrogenerated, usually in an aqueous phase and then transferred by the catalyst into a nonaqueous phase where it reacts with a water-insoluble organic.
2. The high charge requirement of 96,487 coulombs (1 Faraday) per mole of electrons is a detriment for multiple electron transfer steps. Consequently, ideal candidates are (a) the synthesis of high value-added products, (b) compounds that cannot be made by traditional catalytic methods, and (c) organic compounds with a high molecular weight

3. Solubilizing an inorganic supporting electrolyte salt in the organic starting material or dissolving the organic substrate in an aqueous electrolyte solution is often a problem. To address this problem, the following have been used: (a) nonreactive aprotic solvents; (b) a single or mixed polar organic solvent (such as an alcohol or alcohol/water mixture, which can solubilize the organic reactant); (c) special supporting electrolyte salts, such

as quaternary ammonium and hydrotropic salts (e.g., tetramethylammonium acetate or tetraethylammonium p-toluenesulfonate [45]); (d) an emulsified reaction medium (where the organic reactant is dispersed in a water/supporting electrolyte solution [46]); (e) close placement of the anode and cathode to compensate for the low-salt concentration and low conductivity of the reaction medium; and (f) the use of a solid polymer electrolyte reactor (described below).

4. A counter electrode reaction is needed in the organic electrochemical reactor. The reactant and product(s) of this reaction must not interfere with the primary organic electrode reaction. Hence, a membrane separator is often used to divide the anode and cathode compartments of the reactor; the membrane adds to the cost of the reactor and usually increases its operating voltage.
5. Usually, only one product is synthesized in a reactor, with the counter electrode reaction forming a product that interferes minimally with the primary organic reaction. Thus, 50% of the reactor's energy consumption is wasted. This problem has been addressed by employing "paired" electro-organic syntheses, where the reactions at both the anode and cathode generate one or more useful organic product(s) [47].

26.4.2.1 Essential Components of an Electro-Organic Reactor System

When formulating an electro-organic synthesis on a laboratory scale, the proper choice of reactor, electrolyte composition, and electrode materials must be made.

26.4.2.1.1 Reactor Design

Batch Cells

Normally, a batch reactor is employed for small-scale preparative syntheses. Two-dimensional (flat sheet) electrodes provide proper operating conditions (e.g., electrode potential, ohmic resistance, and mass transfer) because high space-time-yields are not required. Cells can be either undivided (no separation of the anolyte and catholyte) or divided. In its simplest configuration, a laboratory beaker is used as an undivided organic electrochemical reactor, with working and counter electrodes, a conducting electrolytic solution, and means for stirring the reaction medium. To avoid unwanted side reactions and mixing of the anolyte and catholyte (which could complicate organic product extraction from the electrolytic solution downstream from the reactor), the anode and cathode chambers can be separated by a microporous barrier such as a fritted glass disk or ion-exchange membrane. The most widely used divided batch reactor for organic syntheses is the H-cell (shown schematically in Figure 26.18 [29, 48] for a cell open to the atmosphere with a Hg cathode and graphite anode). In more elaborate experiments, it is often desirable to use a closed cell [49] with accessories for working under an inert atmosphere or in vacuum [50], at elevated temperatures and pressures, with reflux, or to allow for the identification of gaseous products. For operation at a constant electrode potential, a reference electrode (calomel, Ag/AgCl, hydrogen, etc.) is inserted into the reaction medium, close to the working electrode.

Flow Cells

Electro-organic flow reactors can also be either divided or undivided. One well-studied flow reactor employs two-dimensional parallel plate electrodes in a plate-and-frame filter press design [28, 30, 51] (see Figure 26.12). Other reactors use three-dimensional packed bed electrodes; these cells have a variety of configurations, including trickle bed [52], fluidized bed [35, 36], flow-by [53], flow-through [54], and radial-flow [55] designs. Recently used solid-polymer electrolyte reactors have been employed for organic electrosyntheses, where the liquid electrolyte solution between the anode and cathode is replaced by a wetted ion-exchange membrane [56]. Thus, the need for a solvent/supporting electrolyte is eliminated, which is a significant improvement. This type of reactor will be discussed later.

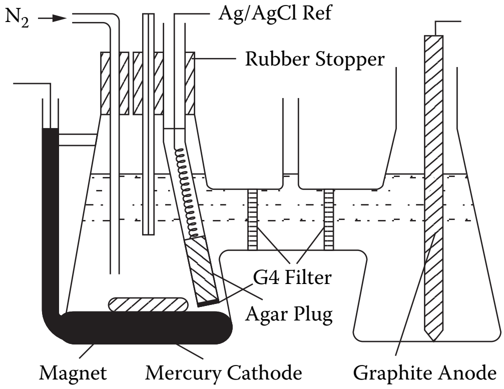

FIGURE 26.18 H-cell for semi-macroscale electro-organic syntheses [48]. (Used with permission from the *Journal of Chemical Education,* Vol. 48, No. 2, 1971, 136–137; © 1971, Division of Chemical Education, Inc.)

26.4.2.1.2 Separator Materials

The separator for a divided electrochemical reactor should ideally be chemically inert and an electric insulator, with a porosity that allows for the facile movement of supporting electrolyte cations and/or anions but prevents the passage and intermixing of organic compounds. Inert porous materials, such as sintered glass, ceramic refractories, filter paper, nylon cloth, and porous plastic provide a barrier for inter-diffusion. Ion-exchange membrane separators (such as DuPont's Nafion® perfluorosulfonic acid cation-exchange membranes) generally provide effective barriers (see Section 26.6.3 and Table 26.15 for more information regarding ion-exchange membranes).

26.4.2.1.3 Electrode Materials

The proper choice of electrode materials is important when designing a cell [57]. A general discussion of electrode materials was presented in Section 26.3.1.1. Factors that must be considered include: the catalytic properties of the electrode material, substrate absorption, the presence of solution-phase impurities (often due to electrode corrosion/degradation when using water as the electrolyte solvent), the physical state of the electrode, and the electrode history [58]. Popular cathode materials for organic electrochemical reactions include:

Mercury—The very high hydrogen overvoltage of Hg is useful for organic reduction reactions in protic solvents, where competing H_2 gas electrogeneration must be suppressed. The liquid state of mercury places certain restrictions on the design of such electrochemical cells (see Figure 26.18). Environmental concerns over the toxicity of mercury also limit its use.

Lead and Cadmium—The hydrogen overvoltage on Pb and Cd is high, and they are easy to work mechanically. For many reactions, a lead or cadmium cathode yields the same chemical products as mercury.

Tin—Electrodes composed of Sn are used mostly for the reduction of nitro compounds.

Nickel and Platinum—These two metals (in the form of Raney nickel and Pt-black) are used for electrocatalytic organic hydrogenation reactions (i.e., the electrochemical generation of hydrogen on the catalytically active, high surface area cathode followed by the chemical reaction of adsorbed hydrogen with the organic substrate).

Aluminum and Iron (Steel)—These metals are widely used in large-scale electro-organic processes, due primarily to their low cost.

The choice of anode material for electro-organic reactions is limited, due to anodic dissolution of most metals. The most common materials are

Platinum—The high standard reduction potential for platinum makes it an ideal anode material (although Pt corrosion does occur during some oxidations reactions, such as the Kolbe oxidative coupling reaction [29, 58, 59]). For anode potentials greater than about 0.50 V (on the hydrogen scale), an oxide film covers the Pt surface, so the electrode material is often platinum oxide. Large anodes are often titanium coated with platinum in order to reduce costs.

Carbon—Graphite electrodes are often used, but they are less stable toward corrosion/physical degradation than platinum. Graphite is available in many forms, including woven cloths, reticulated foam, and glassy (vitreous) carbon rods and plates. Organic products at different types of graphite anodes may differ considerably [60].

Lead—Alloying lead with silver, tin, or cobalt often improves the corrosion resistance of lead anodes. In many cases, the surface of a lead anode is actually lead dioxide [58]. PbO_2 electrodes are stable in sulfate media at low pH and the oxygen overpotential is high, but the material has poor mechanical properties and corrodes in HCl.

Dimensionally Stable Anodes—These anodes are composed of a base metal such as titanium, coated with a precious metal oxide (e.g., ruthenium dioxide). Such anodes can be used instead of Pt or carbon for oxygen evolution counter electrodes in an organic electrosynthesis. They have also found some applications for organic oxidation reactions [61].

26.4.2.1.4 Solvents

Important properties of the solvent in an organic electrosynthesis are (a) electrochemical stability (nonreactivity) at high anodic and cathodic potentials, (b) control of proton activity (which often influences cathodic reduction reactions), (c) the ability of the solvent to dissolve both supporting electrolyte salts and organic substances, (d) temperature stability, (e) low vapor pressure, (f) low/moderate viscosity, (g) minimal toxicity, and (h) reasonable cost. Solvents can be generally categorized as protic (proton containing) and aprotic. Aprotic solvents are preferred when aqueous or proton-containing solvents have undesirable properties, as is the case for electro-generated radical anions, which are more stable in the absence of protons. A general discussion of electrolysis media and solvents for electrochemical reactions was presented in Section 26.3.1.1 (see Table 26.9). Commonly used protic and aprotic solvents for organic electrochemical reactions are

Protic solvents—(1) Acids (the most common are sulfuric, fluorosulfonic, hydrogen fluoride, trifluoroacetic acid, and acetic acid), (2) neutral solvents (water, methanol, and other alcohols), and (3) basic solvents (ammonia, methylamine, and ethylenediamine).

Aprotic solvents—Include acetonitrile, dimethylformamide, N-methylpyrrolidone, hexamethylphosphoramide, pyridine, dimethyl sulfoxide, sulfolane, nitromethane, propylene carbonate, and methylene chloride.

26.4.2.1.5 Supporting Electrolyte Salts

During an electrosynthesis, the dissociated supporting electrolyte salt in the solvent/organic reaction medium provides ions for solution-phase current flow. It is desirable to employ a salt with a high solubility, complete dissociation, and high ionic mobility in the solvent medium. Additionally, the salt should be resistant to oxidation and reduction reactions at the anode and cathode. The choice of anions is of importance for anodic reactions (during current flow, anions migrate toward the anode), whereas one must carefully choose the cation component of the supporting electrolyte for cathodic reactions. Anions difficult to oxidize include perchlorate, tetrafluoborate, hexafluorophosphate, and nitrate. In practice, only alkali and alkaline earth cations (e.g., Li^+, Na^+, and Ca^{2+}) and tetraalkylammonium ions are used for organic electrochemical reduction reactions. In aqueous solutions, quaternary ammonium cations, e.g., tetraethylammonium and tetrabutylammonium ions, are particularly effective in minimizing unwanted hydrogen evolution during an organic electroreduction reaction by forming a low proton activity organic layer on the cathode surface [62].

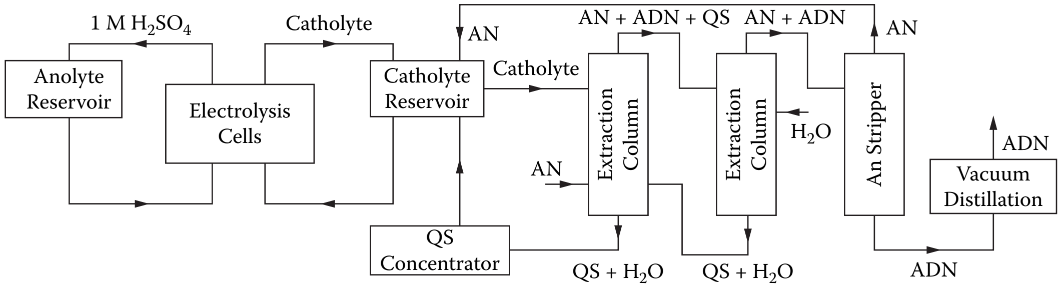

FIGURE 26.19 Schematic diagram of the adiponitrile process flowsheet. AN = acrylonitrile, ADN = adiponitrile, QS = quaternary ammonium salt [30] (with kind permission from Springer Science and Business Media).

26.4.3 Monsanto's Electrohydrodimerization Process

In 1965, the Monsanto Company started production of adiponitrile from acrylonitrile via an electrochemical route [Equation (26.113)]. Adiponitrile was then converted to either adipic acid or hexamethylenediamine by chemical means; these two compounds are reactants in the production of nylon 66.

$$2CH_2{=}CHCN + 2e^- + 2H_2O \rightarrow CN(CH_2)_4CN \tag{26.113}$$

The key to this process [63, 64] was the addition of a quaternary ammonium salt (tetraethylammonium p-toluenesulfonate or tetraethylammonium ethylsulphate) to the reaction medium, which increased the solubility of acrylonitrile in the aqueous electrolyte and generated an aprotic organic layer on the cathode surface that inhibited the synthesis of propionitrile by-products (formed by the simple reduction of acrylonitrile).

Initially, divided electrochemical cells were employed (24 cells, each with 16 anode/cathode pairs in a bipolar filterpress design), with a lead cathode, a lead-silver anode, and a cation-exchange membrane separator. Due to the low conversion rate per pass, the cells were operated in a batch recycle mode with an external catholyte reservoir. A fraction of the reservoir was bled continuously into an extraction plant and fresh acrylonitrile was added to the reservoir. In the downstream extraction plant, quaternary ammonium salt supporting electrolyte and unreacted acrylonitrile were recovered and recycled, and adiponitrile was isolated and purified. Adiponitrile and acrylonitrile were extracted from the aqueous electrolyte in a sieve tray column by addition of acrylonitrile starting material. The organic phase from this unit was washed with water to remove the last traces of supporting electrolyte salt, and the adiponitrile and acrylonitrile were then separated by distillation. The final stage of the process was a vacuum distillation purification of adiponitrile. A schematic flowsheet is shown in Figure 26.19 [30].

During the1970s, both a larger plant and a second plant were built. These expansions employed a second-generation, undivided cell design, with an emulsified reaction medium composed of 7% acrylonitrile in an aqueous solution of 15% disodium hydrogen phosphate with a low concentration (0.4%) of a quaternary ammonium salt. More information on the Monsanto adiponitrile process are found in [28–30, 42 (Part III), 65, 66].

26.4.4 Electrocatalytic Reduction (Hydrogenation) Reactions in a Solid Polymer Electrolyte (Proton Exchange Membrane) Reactor

Many electro-organic reduction reactions are performed using an aqueous reaction medium (the H atoms in water supply the necessary hydrogen for the reaction) and a high hydrogen overpotential cathode such as lead or cadmium to minimize unwanted H_2 gas evolution (from the electro-reduction

of water molecules). An alternative method for organic hydrogenation is a low-temperature electrocatalytic route, where an electrically conducting catalyst (e.g., Raney nickel or platinum black) is used as the cathode. Atomic hydrogen is generated on the catalyst surface by the reduction of protons or water molecules from the electrolytic medium. The overall hydrogenation sequence is as follows:

$$2H^+ + 2e^- = 2H_{ads} \tag{26.114}$$

$$2H_{ads} + \text{Organic} \rightarrow \text{Organic-}H_2 \tag{26.115}$$

An unwanted side reaction that consumes current but does not affect the product yield is the formation of H_2 gas, either by the combination of two adsorbed hydrogen atoms or the electrochemical reduction of adsorbed hydrogen atoms

$$2H_{ads} \rightarrow H_2(\text{gas}) \tag{26.116}$$

or

$$H_{ads} + H_2O + e^- \rightarrow H_2(\text{gas}) + OH \tag{26.117}$$

Since the concentration of H_{ads} on the cathode surface is dependent on the applied current density and the rate of the chemical reaction of hydrogen with the organic substrate, Equations (26.116) and (26.117) are not equilibrium relationships. Unlike a chemical catalytic organic hydrogenation process, the predominant reaction for supplying hydrogen to the catalyst surface is not the equilibrium form of Equation (26.116), but rather Equation 26.114, which is not at equilibrium when electrons are being pumped into the cathode via the flow of current.

For a water-based electrolytic solution, the anode reaction can be the production of O_2, which can easily be removed from the reaction medium

$$H_2O \rightarrow 1/2O_2 + 2H^+ + 2e^- \tag{26.118}$$

Numerous studies have shown that low hydrogen overpotential electrically conducting catalysts (e.g., Raney nickel, platinum and palladium on carbon powder, and Devarda copper) can be used to electrocatalytically hydrogenate a variety of organic compounds including benzene and multiring aromatic compounds, phenol, ketones, nitro compounds, dinitriles, and glucose [45, 46, 54, 55, 67–71]. These reactions have been carried out in both batch and semicontinuous flow reactors; in most cases, the reaction products were similar to those obtained from a traditional chemical catalytic scheme at elevated temperatures and pressures.

To circumvent the need for a supporting electrolyte, organic-electrohydrogenation reactions have recently been performed using a solid polymer electrolyte (denoted as SPE) reactor. In such a reactor, the anode and cathode chambers are separated by a thin, hydrated cation-exchange membrane. Thin film electrodes composed of precious metal catalyst powders (one anode and one cathode) are fixed to opposing faces of the membrane, forming a "membrane-electrode-assembly" (MEA), similar to that employed in proton-exchange membrane (PEM) hydrogen/oxygen fuel cells. Water or humidified hydrogen gas is circulated past the backside of the anode, where either water molecules are oxidized to O_2 gas and protons, according to Equation (26.118) or H_2 gas is oxidized to two protons and two electrons. The protons then migrate through the ion-exchange membranes under the influence of the applied electric field to the cathode catalyst component of the MEA, where they are reduced to atomic and molecular hydrogen [Equations (26.114) and (26.116)]. This electro-generated hydrogen can then react with the organic substrate that is circulated through the

cathode chamber and flows past the backside of the cathode. Ion (proton) conductivity between the anode and cathode occurs through the wetted cation-exchange membrane, so that pure organic and distilled water (or H_2 gas) can be circulated in the cathode and anode chambers, respectively. In this regard, the SPE reactor represents a significant advancement in electrochemical reactor design since inorganic supporting electrolyte salts are not needed (such salts would have to be removed from the reaction medium downstream from the reactor, often with considerable difficulty). The close proximity of the anode and cathode on an MEA (the electrodes are separated by the ion-exchange membrane, which is at most 200 μm thick) and the high ion-exchange capacity of the cation-exchange membrane ensures facile H^+ transport between the anode and cathode.

Solid polymer electrolyte reactors have been examined previously for oxidation and organic electrochemical reduction of organic compounds [56, 72–78]. Ogumi and co-workers studied the electrochemical hydrogenation of nitrobenzene to aniline using a Cu-Pt cathode/Nafion membrane/Pt anode MEA [76] and the reduction of cyclo-octene, diethyl maleate, ethyl crotonate, and n-butyl methacrylate (dissolved in either ethanol, diethyl ether, or n-hexane) with MEAs composed of Pt, Au, or Au-Pt cathode layers deposited onto the surface of a Nafion membrane [72]. In addition, electrochemical reduction of edible oils (such as soybean or cottonseed) results in a quite different product [79].

The high temperature of a chemical catalytic hydrogenation process promotes the undesirable *cis*-to-*trans* isomerization of fatty acid double bonds; recent studies have shown that the injestion of *trans* fatty acids in edible oils increases cholesterol blood levels and contributes to coronary heart disease. The low-temperature electrochemical hydrogenation scheme reduces such isomerization.

A schematic diagram of the SPE oil hydrogenation reactor and the principle reactions associated with electrochemical H_2 generation and oil hydrogenation are shown in Figure 26.20. The key component of the reactor is an MEA, composed of either RuO_2 or Pt/C powder (for the anode) and either Pt-black or Pd-black powder (for the cathode) that are hot-pressed as thin films onto the opposing surfaces of a cation-exchange membrane. During reactor operation at a constant applied current, water of H_2 gas is back-fed to the RuO_2 anode, where it is oxidized electrochemically to produce H^+. Protons migrate through the membrane under the influence of the applied electric field and contact the Pt or Pd cathode where they are reduced to atomic and molecular hydrogen. Oil is circulated past the backside of the cathode and unsaturated triglycerides react with the electro-generated hydrogen species. The SPE reactor was operated successfully with a low anode/cathode voltage drop for a variety of oil feeds at a constant temperature between 50°C and 80°C and an applied current density between 0.10 and 0.490 A/cm^2. Partially hydrogenated oil products had a lower percentage of total *trans* isomers (6% to 10%) and a somewhat high saturated fat (stearic acid) content, as compared to the products from a traditional chemical catalytic reaction scheme [80].

Various factors that might affect the oil hydrogenation current efficiency were investigated [81, 82], including the type of cathode catalyst, catalyst loading, the cathode catalyst binder loading, current density, and reactant flow rate. The current efficiency ordering of different cathode catalysts powders was found to be Pd > Pt > Rh > Ru > Ir (this is the same order as for chemical reactions). Oil hydrogenation current efficiencies with a Pd-black cathode decreased with increasing current density and ranged from about 70% at 0.050 A/cm^2 to 25% at 0.490 A/cm^2 (current efficiencies less than 100% were attributed solely to H_2 gas evolution at the catalytic cathode). The optimum cathode catalyst loading for both Pd and Pt was 2.0 mg/cm^2. When the oil feed flow rate was increased from 80 to 300 mL/min, the oil hydrogenation current efficiency at 0.10 A/cm^2 increased from 60% to 70%. A high (70%) current efficiency was achieved at 80 mL/min by inserting a nickel screen turbulence promoter into the oil stream. The concentration of *trans* isomers ranged from about 2% (with a Pt cathode) to about 9% with Pd-black. When a second metal (Ni, Cd, Zn, Pb, Cr, Fe, Ag, Cu, or Co) was electrodeposited onto a Pd-black powder cathode, substantial increases in the fatty acid selectivities were observed (due presumably to changes in oil adsorption/desorption on the catalyst surface) [82].

26.5 ELECTROPLATING AND ELECTROETCHING

26.5.1 Basic Principles

Electroplating is the most widely used electrochemical surface treatment process, involving the electrochemical deposition of a layer of metal or alloy onto a substrate by means of one or more cathodic metal ion reduction reactions of the form

$$M^{n+} + ne^- \rightarrow M \tag{26.119}$$

This technology is used to fabricate functional coatings (e.g., hard, nonporous, corrosion-resistant, and/or wear-resistant coatings) and decorative surface finishes on many objects used in everyday life such as auto components, screws, and kitchen utensils, as well as electronic components (e.g., printed circuit boards). The goal of an electroplating process is to create reproducibly a deposit of uniform thickness (ranging from a fraction of a micrometer to tens of micrometers) and composition that adheres well to the substrate and exhibits the necessary mechanical and physical properties. Most electroplating processes are directed toward the deposition of: (1) single metals (e.g., Cu, Ni, Sn, Cr, Zn, Cd, Pb, Ag, Au, and Pt), (2) metal alloys (e.g., Cu-Zn, Ni-Fe, Cu-Sn, Pb-Sn, Sn-Ni, Ni-Co, and Ni-Cr), or (3) metal/nonmetal composites (e.g., dispersions of Al_2O_3, SiC, WC, polytetrafluoroethylene, or graphite in Ni or some other metal matrix) [83]. The purpose of an electrodeposit is to impart a specific surface property on a material, such as corrosion and wear resistance, hardness, decorative appeal, optical or thermal reflectivity, thermal or electrical conductivity, or solderability.

The main components of an electroplating apparatus are (1) an electroplating bath containing a soluble species of the metal to be deposited; (2) an inert supporting electrolyte to increase the

TABLE 26.12
Components and Operating Conditions of Various Plating Baths

Ag	$KAg(CN)_2$ (40–60 g/L) KCN (80–100 g/L) K_2CO_3 (10 g/L)	20°C –30°C 3–10 mA/cm^2 99% current efficiency	S-containing brighteners	Ag
Sn	$SnSO_4$ (40–60 g/L) H_2SO_4 (100–200 g/L)	20°C –30°C 10–30 mA/cm^2 90%–95% current efficiency	Phenol, cresol	Sn
Zn	NH_4ZnCl_3 (200–300 g/L) NH_4Cl (60–120 g/L)	25°C 10–40 mA/cm^2 pH 5 98% current efficiency	Dextrin, organic additives	Zn
Cr	CrO_3 (450 g/L) H_2SO_4 (4 g/L)	45°C –60°C 100–200 mA/cm^2 8%–12% current efficiency	Complex fluorides to increase current efficiency	Pb-Sb or Pb-Sn coated with PbO_2

electric conductivity of the plating solution; (3) complexing agents (such as cyanide, hydroxide, and sulphamate ions) to suppress unwanted reactions at the plating surface; and (4) a variety of organic additives, including brighteners (e.g., aromatic sulphones or sulphonates, thiourea, and coumarin for nickel plating), levelers, structure modifiers, and wetting agents that improve the morphology and uniformity of the electroplate thickness, as well as the physical appearance, and physical properties of the deposit.

Most electroplating processes use a DC power supply and cells of simple geometry. Where possible, the anode in an electroplating cell is made from the same metal as that being plated at the cathode so that the concentration of the metal ion in solution remains nearly constant during the plating processes (so long as the anode and cathode current efficiencies are matched). Electrolyte stirring is accomplished by either moving the cathode through the plating bath or by pumping the electrolyte over the cathode surface. Representative examples of plating conditions are listed in Table 26.12 [30].

Electroplating is rarely used for coatings of thickness >75 μm. The upper limit on deposit thickness is governed by cost and time factors, the generation of unacceptably high internal stresses in the deposit, and/or irregular deposit growth. Most plating processes operate at a current density between 10 and 70 mA/cm^2 and are completed in a few seconds to several hours.

The key factors that control the rate of electrodeposition and the structure, physical properties, uniformity, and composition of electrodeposited metals and alloys are (1) thermodynamics (where the electric potential is based on the standard electromotive series); (2) electrode kinetics (which may vary with the structure of the electrodeposit); and (3) mass transport (which is important at high current densities, where the delivery of reactant to the cathode surface affects the local deposition rate and the structure of the deposit).

The normal goal in plating is to achieve a uniform distribution of the metal or alloy deposit, regardless of the geometry of the system. For the deposition of a single metal, the thickness of

the electrodeposit depends on the local rate of metal deposition, which, in turn, is determined by (1) the local current efficiency for the metal reduction reaction (metal reduction current efficiency may be lowered by the presence of a secondary reaction, such as H_2 evolution) and by the local electric potential on the electrode (the potential should be identical over the entire cathode surface). Studies that have analyzed theoretically current and metal distribution on a cathode surface fall into four categories:

1. *Primary current and potential distribution* [84]. This analysis is applicable at low-current densities where concentration variations near the electrode surface are neglected and the electrode reaction is reversible. The potential (Φ) distribution in solution is governed by Laplace's equation,

$$\nabla^2 \Phi = 0 \tag{26.120}$$

with a constant potential boundary condition at the electrode surface and zero potential on adjacent insulating surfaces. Once the potential distribution is computed, the current distribution on the electrode surface is found using Ohm's law ($i = -\kappa\nabla\Phi$, where $\nabla\Phi$ is the potential gradient in the solution at the electrode). Alternatively, one can solve for the potential and current distribution using Ohm's law directly as the boundary condition for Equation (26.120) at the electrode and by using $\partial\Phi/\partial y = 0$ on insulating surfaces (where y is the perpendicular distance from the electrode surface). For either solution method, the resulting current distribution depends only on the geometry of the electrochemical cell. For example, the primary current distribution for a circular disk electrode of radius r_o embedded in an infinite insulating plane with a remote counter electrode is given by [4, 84]

$$\frac{i}{i_{avg}} = \frac{0.5}{\sqrt{1 - r^2/r_o^2}} \tag{26.121}$$

This equation indicates that the current density becomes infinite at the edge of the electrode, as shown in Figure 26.21.

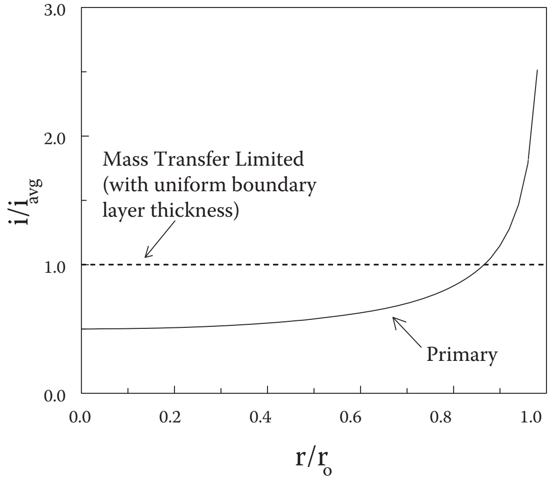

FIGURE 26.21 Primary, secondary, and mass transfer limited current distributions on a rotating disk electrode of radius r_o.

2. *Secondary current distribution* [85, 86]. Here, mass transfer effects are not controlling, but reaction kinetics are considered because of a non-negligible electrode polarization (i.e., electrode reactions that require an appreciable surface overpotential to sustain a high reaction rate). Once again, Laplace's Equation (Equation [26.120]) is solved for the potential distribution, but the boundary condition for Φ on the electrode surface ($y = 0$) is given by

$$-\kappa\nabla\Phi = f(\eta_S) \text{ at } y = 0 \tag{26.122}$$

where $f(\eta_s)$ denotes a current density/voltage electrode kinetic expression (such as the Butler-Volmer electrochemical rate equation given by Equation (26.45) in Section 26.2.2 or simplified versions thereof) and η_s (the surface overpotential) is defined as $V - \Phi$ (where V is the imposed potential of the electrode and Φ is the electric potential in solution adjacent to the electrode). For example, when the surface overpotential is sufficiently small, the Butler-Volmer kinetic equation reduces to a linear form and Equation (26.122) is written

$$-\kappa \frac{\partial \Phi}{\partial y} = (\alpha_c + \alpha_a)\frac{i_o F}{RT}\eta_S \text{ at } y = 0 \tag{26.123}$$

where α_a and α_c are the anodic and cathodic transfer coefficients, with $\alpha_a = (1 - \beta)n$ and $\alpha_c = \beta n$. A boundary condition expression also can be generated using the linear Tafel equation to relate i and η_s (when η_s is large) The secondary current distribution depends on the same electrode geometry conditions as the primary current distribution, but it also depends on electrode kinetic parameters (such as the transfer coefficient, α, and the exchange current density i_o in Equation (26.123)). The secondary current distribution on an electrode is finite at the electrode edges and is more uniform than the primary current distribution, as can be seen in Figure 26.21 for a rotating disk.

The uniformity of the secondary current distribution has been related to the value of the Wagner (*Wa*) number [87], which expresses the ratio of the polarization resistance at the electrode–electrolyte interface to the ohmic resistance of the electrolyte:

$$Wa = \frac{\kappa\left(\dfrac{\partial \eta_s}{\partial i}\right)_{i_{av}}}{L} \tag{26.124}$$

where $d\eta_s/di$ is the slope of the electric potential/current density curve at the average current density on the electrode (e.g., for Tafel kinetics, $\partial\eta_S/\partial i$ is given by the cathodic Tafel slope) and L is a characteristic electrode length. When *Wa* becomes large, i.e., when the kinetic polarization resistance dominates, the current distribution on the electrode becomes perfectly uniform and independent of geometry. An example of the secondary current distribution near the leading edge of a planar electrode in a parallel plate flow channel and the effect of *Wa* on the ratio $(i - i_\infty)/i_\infty$ (where i_∞ is the current density far from the electrode's leading edge) is shown in Figure 26.22 [33].

3. *Tertiary current distribution*. This method of analysis applies to those systems where there is significant mass transport and electrode polarization effects. Electrode kinetics is considered, with electrode surface concentrations of reactant and/or products that are no longer equal to those in the bulk electrolyte due to finite mass transfer resistance. The analysis of tertiary current distributions is complex, involving the solution of coupled

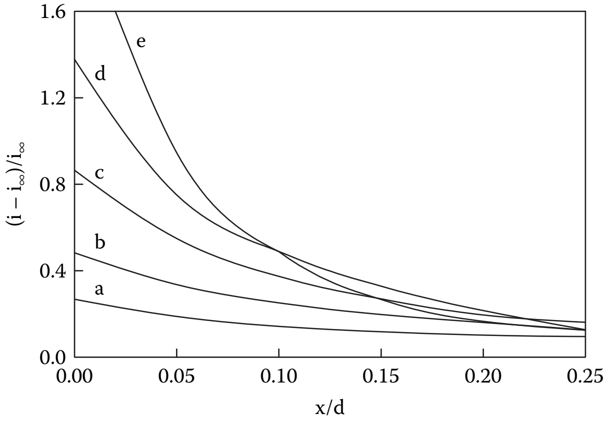

FIGURE 26.22 Secondary current distribution near the edge of a flat sheet electrode in a channel, where *d* (the inter-electrode gap) is <<*L* (*L* = electrode length). *X* is the distance along the electrode. Each curve corresponds to a different Wagner number: (a) Wa = 0.80; (b) Wa = 0.40; (c) Wa = 0.20; (d) Wa = 0.10; (e) Wa = 0. Figure from [33] (with kind permission from Springer Science and Business Media).

algebraic and differential equations for electrode kinetics, the electric potential distribution, mass transfer, and even fluid flow. For further information on this topic, see [88–90].

4. *Limiting current distribution* [91]. When the deposition rate is controlled solely by mass transfer processes and is independent of the electrode potential distribution, the current density is proportional to the concentration gradient at the electrode surface in accordance with the limiting current density formula presented previously (see Equation [26.76]). The key parameter for this analysis is the effective (Nernst) diffusion layer thickness (δ_e), which depends on the physical properties of the electrolyte, the electrode geometry, and the electrolyte stirring rate, as discussed in Section 26.2.3.2. If δ_e were everywhere the same on the electrode surface, the current density distribution would be uniform, as shown in Figure 26.21 for a rotating disk electrode.

Identifying the limiting current density (i_L) during electrodeposition is important since it represents the maximum rate of metal plating for a given bulk reactant concentration and hydrodynamic flow pattern. Also, the structure of the electrodeposit varies with current density; see Figure 26.23 [92].

The effect of current density on the structure of electrodeposits has been investigated in a special trapezoidal cell with a purposely nonuniform current distribution known as the Hull cell [93]. The shape and typical dimensions of this cell are shown in Figure 26.24 [94]. Due to the nonuniform primary current distribution on the inclined cathode (with a local current density that decreases with increasing anode-cathode separation distance), a single electroplating experiment is used to study the effect of current density on deposit morphology (and deposit composition, for the case of alloy plating).

26.5.2 High-Speed and Laser-Assisted Plating

Decreasing the time required for plating a metal, without a loss in the electrodeposit's physical/mechanical properties, tends to decrease manufacturing costs. High-speed plating has been studied repeatedly, in which the mass transfer limiting current density has been increased significantly by increasing fluid convection across the cathode surface (thereby decreasing the mass transfer boundary-layer thickness). Submerged and unsubmerged impinging jets have been widely studied for the plating of electronic and machine parts (see [95, 96]). A plating current density as high as 4 A/cm^2 can be achieved with an impinging jet. Additional studies have focused on the

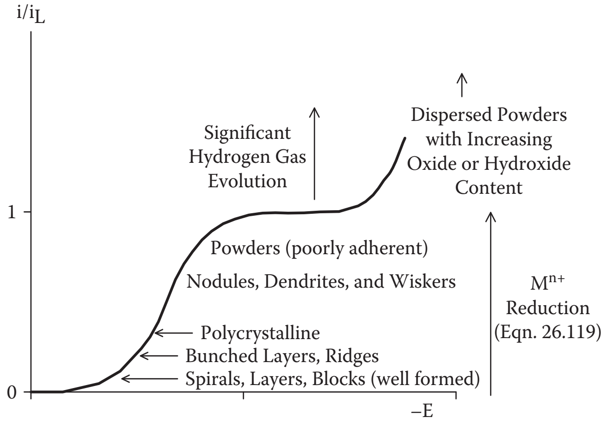

FIGURE 26.23 Variation in metal electrodeposit structure as a function of the applied current density and limiting current density. Figure from [92] (copyright Elsevier 1994).

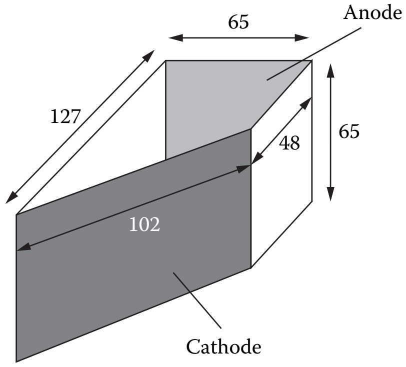

FIGURE 26.24 The classical Hull cell for electroplating. All dimensions are in mm. Figure from [94] (copyright Elsevier 1994).

current distribution in an impinging jet cell [97] and the effects of current density, electrolyte composition, electrolyte velocity, and nozzle height on the metal-thickness distribution [98].

The plating rate and the quality of the electrodeposit can also be increased by using a laser beam during the plating process. Such a technique has enhanced plating rates by factors of 1000 for nickel, copper, and gold [99, 100]. The elevated rates have been attributed to localized heating of the substrate by the laser beam [101]; higher temperatures increase the electrodeposition reaction rates when mass transfer is not controlling. Figure 26.23 shows that better quality electrodeposits are formed at current densities well below the mass transfer limiting current density. With a laser-enhanced electroplating technique, finely detailed electrodeposits can be created, with plated spots as small as 4 μm in diameter [102] (such plating precision is important when fabricating micro-circuitry and electronic devices). More recently, laser-enhanced plating, combined with an impinging jet has achieved localized high-speed plating of metal spots and fine lines of high quality [103]. In addition to increasing convective mass transport, the electrolyte jet limits the region of plating and also acts as a light pipe for the laser beam.

26.5.3 Electroless Plating

During a normal electrolytic metal deposition process, the electrons required for the reduction of the metal ions are supplied by an external current source. In an electroless deposition process, the

catalytic or electrocatalytic oxidation of a soluble reducing agent supplies the electrons required for reduction and drives the cathodic metal deposition reaction. The oxidation, reduction, and overall reactions during this plating are

$$\text{Oxidation: } R - ne^- \rightarrow O \quad (26.125)$$

$$\text{Reduction: } M^{n+} + ne^- \rightarrow M \quad (26.126)$$

$$\text{Overall reaction: } M^{n+} + R \rightarrow M + O \quad (26.127)$$

where *R* denotes the soluble reducing agent. A variety of reducing agents have been investigated, including formaldehyde and hypophosphite [104]. For example, in an electroless nickel plating bath, Ni^{2+} reduction occurs simultaneously with hypophosphite oxidation on a single substrate surface. The process is represented by the following reactions:

Reduction: $Ni^{2+} + 2e^- \rightarrow Ni \qquad E° = -0.25$ V vs. SHE

Oxidation: $H_2PO_2^- + H_2O \rightarrow H_2PO_3^- + 2H^+ + 2e^- \qquad E° = +0.50$ V vs. SHE

The overall reaction has a negative ΔG and thus is spontaneous:

Overall: $Ni^{2+} + H_2PO_2^- + H_2O \rightarrow Ni + H_2PO_3^- + 2H^+$

An electroless plating bath typically includes: (1) a soluble source of the metal to be plated; (2) a soluble reducing agent; (3) a metal-ion complexant (e.g., EDTA); (4) anion additives (also known as exaltants) such as succinate or fluoride ions that increase the plating rate by catalyzing the oxidation reaction; (5) stabilizers, such as thiourea, which adsorb onto nucleation sites in the plating bath (e.g., metallic particles or dust); and (6) buffers to control the plating bath pH, since the oxidation reaction often produces protons, as is the case for the $H_2PO_2^-$ oxidation above.

During electroless plating, the metal ion and reducing agent are consumed and the products of the oxidation reaction increase in concentration. The composition of the plating bath must therefore be monitored and the bath constituents replenished in order to maintain the consistency of the plating rates and deposit quality. The plating rate is also strongly dependent on temperature. For example, during acidic electroless nickel deposition, no plating will occur below 70°C. Above 70°C, the nickel deposition rate increases markedly, but above ~90°C, the electrolyte is unstable (i.e., at high temperatures metal deposition can occur spontaneously on the walls of the plating tank or there may be homogeneous metal ion reduction in solution). Examples of electroless plating baths, along with the plating temperature and pH conditions, are listed in Table 26.13 [30].

The cost of electroless metal coating is generally higher than conventional applied current electrodeposition processes because (1) bath chemicals are more expensive, (2) the plating bath must be heated, and (3) the plating rate tends to be slow. The use of electroless methods, therefore, is restricted to plating applications where: (1) metal is deposited on a nonconducting (e.g., plastic) substrate; (2) a uniform coating is needed; and (3) hard deposits of low porosity and good wear resistance are required. Thus, electroless plating is particularly attractive to produce small scale features on circuit boards and other electronic components since the process is not governed by the usual primary and secondary current distributions (the anode and cathode reactions occur on the same deposit substrate) and for plating metals on plastics parts in the electronics and automotive industries.

TABLE 26.13
Compositions and Operating Conditions of Electroless Plating Baths

Plating Bath	Bath Composition
Acid nickel	Nickel chloride: 20 g/dm^3 Sodium hypophosphite: 20 g/dm^3 Sodium acetate: 10 g/dm^3 Sodium succinate: 15 g/dm^3 pH: 4.5 Temperature: 93°C
Alkaline nickel	Nickel chloride: 30 g/dm^3 Sodium hypophosphite: 10 g/dm^3 Ammonium citrate: 65 g/dm^3 Ammonium chloride: 50 g/dm^3 pH: 8–10 Temperature: 90°C
Copper	Copper sulphate: 12 g/dm^3 Formaldehyde: 8 g/dm^3 Sodium hydroxide: 15 g/dm^3 Rochelle salt: 14 g/dm^3 EDTA: 20 g/dm^3 pH: 11 Temperature: 25°C

26.5.4 Alloy Plating

During alloy plating, more than one metal is deposited on the electrode. The relative importance of current distribution and mass transfer may differ for different metals and current densities; a nonuniform current density may lead to an electrodeposit of varying thickness during metal deposition and nonuniform partial currents lead to variations in alloy composition [94,105]. Thus, electroplating of specialty alloys requires tight control of the plating operating conditions, including the electrolyte bath composition (the ratio of metal ion concentrations in solution), the plating temperature, the current density, and the electrolyte flow conditions. For example, when nickel and iron are simultaneously plated onto a rotating disk cathode from a $NiCl_2/FeCl_2/H_3BO_3/NaCl$ bath at pH 3 and 25°C, the alloy composition and current efficiency for electrodeposition are dependent on the plating current density i_p and the electrolyte agitation rate, as shown in Figures 26.25 and 26.26 [106]. In this system, iron deposition is mass transfer controlled and Ni^{2+} reduction is kinetically controlled. The loss in current efficiency (<100%) is due to H_2 evolution, which is mass transfer controlled and independent of the electrode potential in the voltage regime where Ni and Fe co-deposit.

Some examples of alloy plating baths and plating conditions are listed in Table 26.14 [30]. For additional information on alloy as well as pure metal electrodeposition, see [92, 94, 105, 107–112].

26.5.5 Electrochemical Metal Removal Processes

Electrochemical metal removal processes have been developed and utilized by industry for a variety of different applications. Electropolishing as an industrial finishing operation was first demonstrated by Jaquet in 1930 [113]. Metals such as aluminum, steel, brass, cooper, and silver/nickel alloys are anodized to produce a highly reflective mirror finish. The surface to be polished is the anode with a current density in the range of 0.100 to 0.800 A/cm^2. The electrolyte is typically phosphoric

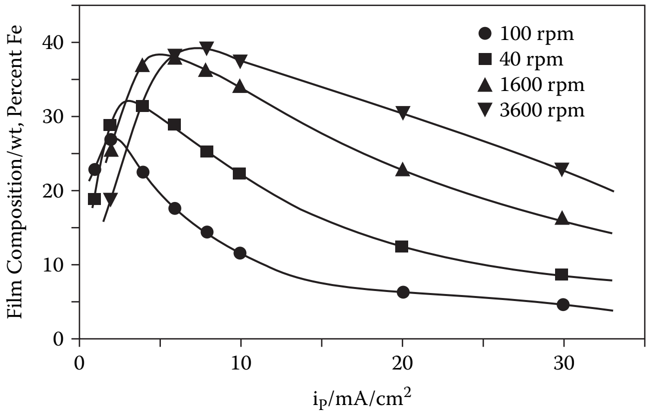

FIGURE 26.25 Composition of a NiFe film plated on a rotating disk electrode as a function of the total plating current i_p for different disk rotation speeds at 25°C. Solution composition was 0.2 M $NiCl_2$, 0.4 M H_3BO_3, and 0.5 M NaCl (pH = 3). Data from [106]. (Reproduced by permission of ECS—The Electrochemical Society.)

acid at a temperature of 60°C. Electropolishing involves selective anodic metal electro-oxidation (the potential distribution on the anode surface favors metal dissolution at surface peaks rather than troughs) as well as oxide film formation [30].

Electrochemical machining operations utilize very high current densities (5 to 400 A/cm^2) to dissolve and bore through hard and tough metals and alloys. The technique was developed in the late 1950s and early 1960s in the aerospace and power generation industries for shaping and metal finishing operations [114, 115]. The anodic metal dissolution reaction is

$$M \rightarrow M^{n+} + ne^- \tag{26.128}$$

and the cathodic reaction is hydrogen evolution from water,

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \tag{26.129}$$

TABLE 26.14
Alloy Plating Bath Compositions and Operating Conditions

Alloy	Plating Bath Composition	Operating Conditions (temp., curr. density, metal plating current efficiency)	Anode
70% Cu—30% Zn (brass)	$K_2Cu(CN)_3$ (45 g/L)	40°C–50°C	Brass
	$K_2Zn(CN)_4$ (50 g/L)	5–10 mA/cm^2	
	KCN (12 g/L)	60-80% current efficiency	
	sodium tartrate (60 g/L)		
40% Sn—60% Cu (bronze)	$K_2Cu(CN)_3$ (40 g/L)	60°C–70°C	Bronze or mixture of Sn and Cu
	Na_2SnO_3 (45 g/L)	20–50 mA/cm^2	
	NaOH (12 g/L)	70-90% current efficiency	
	KCN (14 g/L)		
65% Sn—35% Ni	$NiCl_2$ (250 g/L)	60°C–70°C	Separate Ni and Sn plates
	$SnCl_2$ (50 g/L)	10–30 mA/cm^2	
	$NH_4F{\cdot}HF$ (40 g/L)	97% current efficiency	
	NH_4OH (30 g/L)		
80% Ni—20% Fe	$NiSO_4$ (300 g/L)	50°C–70°C	Ni + Fe
	$FeSO_4$ (100-200 g/L)	20–50 mA/cm^2	
	H_3BO_3 (45 g/L)	90% current efficiency	
	NaCl (30 g/L)		
	$NiCl_2$ (0.2 M)	25°C	
	$FeCl_2$ (0.005 M)	5–30 mA/cm^2	
	H_3BO_3 (0.4 M)	pH 3	
	NaCl (0.5 M)	70-97% current efficiency	

Large volumes of electrolyte are circulated past the metal anode surface at very high velocities (typically 9 to 60 m/sec) in order to remove quickly dissolving metal ion product (so there is no precipitation of metal hydroxide salts on the anode) and heat generated during the machining process. Normally a highly conductive electrolyte with an inexpensive salt (e.g., NaCl or $NaNO_3$) is employed with small interelectrode spacing (0.10 to 1.5 mm). Complex features and shapes, including fine holes, angled holes, engine casting, and turbine components, can be produced with great precision and reproducibility. In contrast to conventional mechanical metalworking techniques, electromachining leaves the metal without scratches, unwanted sharp edges, and burrs. In addition, the machined surface is almost free of all induced stresses. More recently, electromachining has been used in the electronics industry to drill fine holes (0.25 to 0.4 mm in diameter) in tough cast alloys and to fabricate groove patterns and holes in thin metal foils. A review of such micromachining operations in the electronic industry has been compiled by Datta and Romankiw [116].

26.6 ENVIRONMENTAL CLEAN-UP PROCESSES

Effluent and waste water treatments are of growing importance due to legislation that limits toxic discharge, plus the need to recycle and reuse raw materials. Electrochemical processes are inherently less polluting because oxidation and reduction reactions at the electrodes involve "clean" electrons, as opposed to chemical oxidizing and reducing agents where the spent reagents themselves may be toxic. Several useful electrochemical methodologies have been developed to treat streams containing dissolved metal ions and/or organics, including the removal and recovery of trace metal ions in solution, the destruction of organics via electrochemically generated oxidants, and water purification by electrodialysis membrane processes.

26.6.1 Metal Ion Removal

Electrochemical cells for the removal (i.e., cathodic reduction) and recovery of metal ions from dilute aqueous waste streams have been well studied and several companies market such reactors. Electrolytic processes for metal ion clean-up offer a cost-effective alternative to traditional chemical remediation strategies, such as precipitation with sodium hydroxide, ion-exchange, and solvent extraction, because the metal is removed in its pure and valuable form. Whereas electroplating, electrorefining, and electrowinning processes utilize electrolytes containing relatively high concentrations of metal ions, the waste treatment processes described in this section deal with the removal of ppm concentrations of dissolved metals. The feeds to the electrochemical cell are often from sources associated with: (1) primary ore leaching, (2) spent and contaminated electroplating baths, (3) etching solutions and rinse waters, (4) metal-cleaning solutions, (5) catalyst liquors, (6) photographic processing solutions, and (7) reprocessing of spent batteries.

Continuous and semicontinuous electrochemical reactors are normally employed for effluent metal ion remediation, where the anode reaction is usually oxygen evolution from water [compare with Equation (26.4)]. After the metal contaminant is captured on the cathode, the cathode can be discarded, the collected metal can be resold, or the deposited metal can be chemically or electrochemically etched into a small volume of a suitable leaching liquor (e.g., water) so as to increase its concentration substantially.

In many metal ion removal processes, the waste stream contains few conducting ions and has a low electrical conductivity, thus the electrochemical cell potential will be high. The maximum electrochemical driving force is achieved by operating the reactor at or near the cathodic limiting current density for metal ion reduction. As the metals content drops during the clean-up process, mass transfer and electrolyte conductivity limitations become more severe, resulting in very low-current efficiencies (where cathodic current losses are usually due to excessive H_2 gas evolution) and high-energy costs. For a limiting current density reduction reaction that consumes n moles of electrons per mole of metal ions, and operates at the limiting current (I_L), we can write

$$I_L = k_d AnFC_\infty \tag{26.130}$$

where k_d is the mass transfer coefficient, A is the cathode area, and C_∞ is the metal ion concentration in the bulk electrolyte. To decrease the reactor size for a given effluent throughput (i.e., for a given electrolyte flow rate and ion concentration change), the k_dA product in the above equation must be maximized. This can be achieved by increasing the solution velocity so as to increase k_d and/or enlarging the surface area of the cathode. One simple reactor design is the plate-in-tank cell [30, 51, 117–119], where numerous vertical flat plate anodes and cathodes are either contained in a single tank or are mounted in a filterpress apparatus with suitable gasket materials between components to seal the assembly. A schematic diagram of a plate-and-frame cell is shown in Figure 26.12. Due to mass transport limitations, such a reactor cannot lower metal concentrations much below 200 ppm. Lower effluent concentrations can be achieved by using high surface area reticulated foam cathodes, often composed of vitreous carbon [30]. Another reactor, for small-scale removal of precious metals (e.g., silver or gold), utilizes rotating cylinder cathodes with a high ratio of cathode surface area to catholyte volume and high fluid velocities (produced by high cylinder rotation speeds) to ensure an acceptable metal ion removal rate Periodically, during reactor operation, the electrodeposit is scraped or peeled from the cylinder cathode surface. This reactor is used in the Eco-Cell process [120].

In recent years, more attention has been drawn to high surface area, three-dimensional particle bed or graphite felt cathodes, where the bed is either stationary or fluidized [52, 121, 122]. Such reactors (e.g., the AKZO/Billiton fluidized-bed reactor or the Enviro-Cell [30, 123, 124]) provide a very high surface area for metal deposition, but the inter-relationship between the fluid flow rate, local metal ion concentration, and the current density distribution in the bed is complex. Fixed,

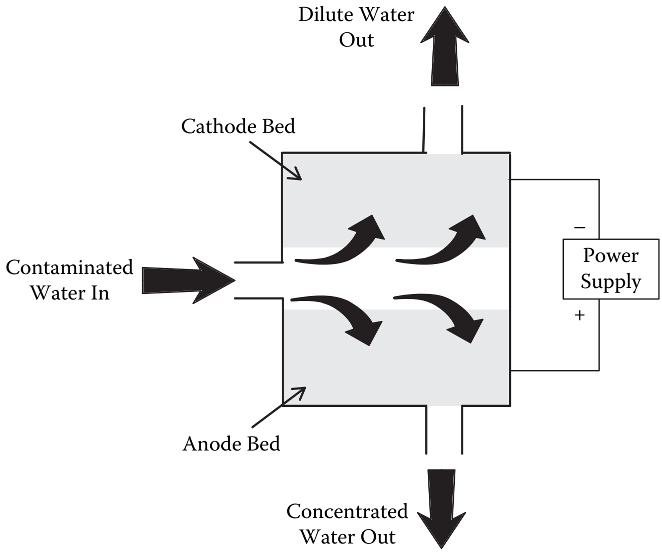

FIGURE 26.27 Schematic diagram of a flow-through packed bed reactor for the removal of dissolved metal ions.

flow-through particle bed electrode reactors have been mathematically modeled in order to better understand and improve the metal ion removal rate (see 4, Chapter 22). A schematic diagram of a flow-through particle bed electrode reactor is shown in Figure 26.27.

In this reactor, the feed solution enters via a central channel between the anode and cathode beds and then flows in the upward and downward vertical directions (where the majority of the solution passes through the porous cathode). When the cathode bed is filled to capacity with deposited metal, the polarity of the electrode beds is reversed and the metal is electrochemically etched into a small liquid volume to create a concentrated solution. The longer the contact time of the metal-laden solution in the porous cathode, the greater the extent of metal removal (where the contact time is inversely proportional to the catholyte flow rate and directly proportional to the cathode bed thickness). To maximize the energy efficiency for metal removal, the entire bed should operate at or near the metal reduction limiting current density, but this is difficult to achieve because of unwanted hydrogen gas evolution. The relevant differential equations are solved to obtain the metal ion concentration, electric potential, and current density distributions in the cathode bed are [125]

1. A material-balance relationship:

$$\frac{dC}{dy} = -\frac{ak_dC}{v} \tag{26.131}$$

2. A charge-balance equation:

$$\frac{di}{dy} = -nFak_dC = nvF\frac{dC}{dy} \tag{26.132}$$

3. Ohm's law in solution:

$$i = -\kappa \frac{d\Phi}{dy} \tag{26.133}$$

where a is the area per unit volume of the particle bed cathode, v is the average superficial catholyte velocity in the bed, n is the number of electrons involved in the metal deposition reaction, y is the distance into the cathode as measured from the front of the bed (i.e., that part of the bed closest to the anode), κ is the effective electrical conductivity of the solution in the bed, and Φ is the electric potential in solution.

The above equations are solved with the following boundary conditions: at $y = 0$, $C = C°$ (the initial concentration of metal ion); at $y = L$ (the bed thickness), $i = 0$; and at $y = 0$, $\Phi = 0$. The resulting bed profiles for $C(y)$, $i(y)$, and $\Phi(y)$ [125] are

$$\Phi(y) = \beta\,[\exp(-\alpha y) - 1 + \alpha y C(L)/C^o] \tag{26.134}$$

$$i(y) = nFvC^o[\exp(-\alpha y) - C(L)/C^o] \tag{26.135}$$

$$C(y) = C^o \exp(-\alpha y) \tag{26.136}$$

Here $\alpha = ak_d/v$, $\beta = nFv^2C°/ak_d\kappa$, and $C(L)$ is the metal concentration in the exiting catholyte for a cathode of thickness L. The bed thickness and catholyte flow rate are dictated by the maximum potential drop within the porous cathode. According to Equation (26.134), the cathode electric potential driving force for metal deposition decreases nonlinearly as one moves into the bed, away from the anode (i.e., as y increases); the greatest driving force occurring at the front face of the cathode bed, closest to the anode. Ideally, the potential should be sufficiently negative everywhere in the bed to ensure metal ion reduction, but not so negative that there is appreciable hydrogen evolution or some other unwanted side reaction. Normally, this potential drop is no more than 0.1 or 0.2 V, which then fixes the catholyte velocity according to the following equation:

$$v = \left(\frac{|\Delta\Phi|\kappa a k_d}{nFC^o}\right)^{1/2} \tag{26.137}$$

The thickness of the cathode bed is now computed from $|\Delta\Phi|$ and the required/desired change in metal ion concentration within the bed:

$$L = \frac{v}{ak_d}\ln\frac{C^o}{C(L)} \tag{26.138}$$

According to the above equations, we can estimate the performance of a particle bed cathode that treats a 667 ppm (667 mg/l) Cu^{2+} aqueous waste stream and generates a product effluent containing 1 ppm Cu^{2+}, as was done in [125]. The cathode bed particles in the reactor are assumed to have a surface area/volume ratio of 25 cm^{-1} with a bed porosity of 0.3. The reactor operates with a superficial solution velocity of 0.0036 cm/sec and a 0.2 V potential variation in the cathode bed, i.e., the front face potential of the cathode is 0.2 V more negative (more cathodic) than the back of the bed. For these conditions, the cathode bed thickness should be 5.0 cm. The length and width of the bed are determined by the volumetric feed flow rate into the reactor, hence, the flow

rate divided by the cross-sectional bed area available for flow (width × length × porosity) must be equal to the superficial fluid velocity.

26.6.2 Electrochemical Destruction of Organics

Anodic oxidation processes can effectively destroy toxic organic compounds in aqueous waste streams. The oxidation reaction may occur directly at the anode or indirectly in solution via an oxidizing agent that is electrochemically generated, reacts homogeneously in the bulk solution with the organic, and then is regenerated at the anode [124]. For many organic-laden waste streams, the electrolyte conductivity is low and a supporting electrolyte salt must be added (this salt may have to be removed eventually from the waste stream). It may also be necessary to add a solvent (e.g., water or alcohol) to the stream to increase the solubility of the electrolyte salt.

The electro-oxidation of various organic compounds directly at an anode (e.g., the oxidation of phenol to CO_2 in water) has employed either a Pt or SnO_2 anode [126–128]. SnO_2 is often preferred to minimize organic intermediates and to reduce the total organic carbon content in the water solution. Farmer and co-workers [129], studied the indirect oxidation of organic compounds using Ag^{2+} or Co^{3+} as the oxidizing agent. With HNO_3, the electrochemical oxidation of Ag^+ to Ag^{2+} forms an $AgNO_3^+$ complex. This complex then reacts with an organic pollutant (such as ethylene glycol, benzene, or a chlorinated hydrocarbon) to produce CO_2. For benzene destruction with $AgNO_3^+$, the following oxidation reaction occurred:

$$30AgNO^+ + C_6H_6 + 12H_2O \rightarrow 6CO_2 + 30Ag^+ + 30HNO_3 \quad (26.139)$$

By re-oxidizing spent Ag^+ at the anode, the organic oxidizing agent is regenerated continuously in the electrochemical reactor, thus minimizing the amount of Ag^{2+} required to destroy the organic compound. Unfortunately, for most organic electrochemical degradation reactions (including Equation (26.139)), the total charge required to oxidize the pollutant to CO_2 is very large (30 Faraday's per mole of benzene for the above reaction, where one Faraday is the charge equivalent of one mole of electrons). Thus, a reactor for organic destruction to a low-molecular-weight innocuous compound such as to CO_2 must operate at a very high current density (which may generate secondary reactions at the anode and lower the current efficiency for organic oxidation) and the electrical cost per pound of degraded organic contaminant is usually high. Whereas Ag^{2+} cannot be used to degrade chlorinated hydrocarbons (due to the formation of insoluble AgCl), Co^{3+} is an effective oxidizing agent for many chlorinated hydrocarbons such as 1,2-dichloro-2-propanol [130]. The relevant homogeneous oxidation and heterogeneous electrochemical reactions for this organic pollutant are

$$C_2H_5(OH)Cl_2 + 5H_2O + 14Co^{3+} \rightarrow 3CO_2 + 16H^+ + 14Co^{2+} + 2Cl^- \text{ (in solution)} \quad (26.140)$$

$$Co^{2+} \rightarrow Co^{3+} + e^- \text{ (at the electrode)} \quad (26.141)$$

Kaba et al. [131] employed a Ce^{3+}/Ce^{4+} redox couple and ultrasonic solution agitation to degrade human biomass waste using either a Pt or PbO_2 anode and a 12M H_2SO_4 electrolyte. The total organic carbon content of the electrolyte decreased by a factor of about 3 and the total nitrogen dropped by a factor of 2 after a 70-hour electrolysis.

Since electrochemical oxidation of organics does not yield a useful product, this technology has been driven more by governmental regulation rather than a favorable return on investment. Hence, the development of electrochemical processes for organics destruction has not progressed beyond laboratory-size or pilot-plant reactors.

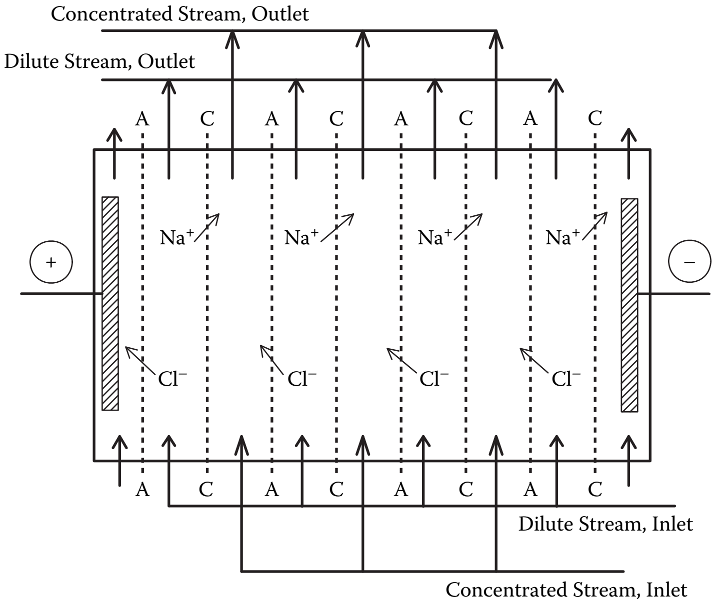

FIGURE 26.28 Diagram of an electrodialysis salt separation process. *A* denotes an anion-exchange membrane and *C* denotes a cation-exchange membrane.

26.6.3 Electrodialysis

Electrodialysis is a membrane-based process that utilizes electric fields to separate, remove, or concentrate ionic species in aqueous solutions. A schematic diagram of a typical electrodialysis cell is shown in Figure 26.28, where a series of alternating cation and anion exchange membranes are positioned between the anode and cathode. When an ion-containing solution is pumped through the feed compartments and an electric potential is established between the two electrodes, positively charged cations migrate to the cathode and negatively charged anions move to the anode. Anions can easily move through the anion exchange membranes (i.e., those membranes with fixed positive charges attached to the polymer) but cannot pass through the cation-exchange membranes (these membranes have negative fixed charges which repel mobile anions in solution). Similarly, cations pass through the cation exchange membranes but are blocked by the positively charged anion-exchange membranes. These events increase the salt concentration (i.e., both cations and anions) in alternating compartments, while the remaining compartments are depleted of salt. For an electrodialysis process to be effective, the ion-exchange membranes must repel coions (i.e., those mobile ions in solution with the same electric charge as the membrane's fixed charges) and the transmembrane flux of counterions (i.e., those mobile ions with a charge that is opposite to that of the membrane) must be high.

Electrodialysis was first developed for the desalination of brackish water in order to produce drinking water, and this application continues to be an important industrial application [132]. Another important application is the clean-up of rinse waters from electroplating processes. Process waters from a nickel plating process, for example, may contain up to 1 g/L of nickel sulfate. This solution can be concentrated to 60 g/L by electrodialysis and recyled directly to the plating bath. Similarly, electrodialysis can be used to concentrate Cr^{6+}-containing wastewaters from chromic acid plating baths [133]. Other uses of electodialysis include salt removal from effluent waters prior to reuse in industrial processes [134], the production of ultrapure water [135,136], and salt splitting, where acid and alkali are generated from a neutral salt (e.g., the electrochemical generation of NaOH and H_2SO_4 from Na_2SO_4) [137].

TABLE 26.15
Commercially Available Cation-Exchange and Anion-Exchange Membranes

Membrane Manufacturer	Chemical Composition	Ion-Exchange Capacity (mmol/g)
Cation-exchange membranes	Sulfonated polystyrene	2.4
CMV (Asahi Glass Co. Ltd.)	Carboxylated perfluorinated polymer	0.9
Flemion (Asahi Glas Co. Ltd.)	Sulfonated styrene/cross-linked with	1.4
K101 (Asahi Chemical Industry Co., Ltd.)	divinyl benzene	1.5
R-5010-L (Pall RAI, Inc.)	Sulfonated low density polyethylene	0.91
Nafion (DuPont de Nemours and Co., Inc.)	Perfluorosulfonic acid	2.0
CL-25T (Tokuyama Soda Co. Ltd)		
Anion-Exchange Membranes		
A 111 (Asahi Chemical Industry, Co. Ltd)	Styrene/divinylbenzene butadiene	1.2
AMV (Asahi Glass Co., Ltd)		1.9
103QZL386 (Ionics Inc.)		2.1
ACM (Tokuyama Soda Co. Ltd)		1.5

Clearly, the most important components of an electrodialysis process are the anion- and cation-exchange membranes. Ion-exchange membranes should possess (1) high permselectivity, where the membrane is highly permeable to counterions and impermeable to co-ions; (2) low electrical resistance, so that the transmembrane flux of ions will be high for a given electric potential driving force; (3) good mechanical strength and dimensional stability (i.e., low swelling/shrinkage); and (4) high chemical stability (since the membranes are routinely exposed to acid and alkali solutions as well as various oxidizing agents).

For cation-exchange membranes, one of the following charged moieties is normally attached to the polymer: $-SO_3^-$, $-COO^-$, $-HPO_2^-$, $-AsO_3^{2-}$, or $-SeO_3^-$, whereas an anion-exchange membrane will contain one of the following: $-NH_3^+$, $-RNH_2^+$, $-R_3N^+$, $= R_2N^+$, $-R_3P^+$, or $-R_2S^+$. These ionic groups have significant effects on the selectivity and ionic conductivity of the ion-exchange membranes. For example, sulfonic acid groups (SO_3^-) are completely dissociated over the entire pH range, but carboxylic acid groups (COO^-) are undissociated in acid solutions (at a pH <3). Similarly, quaternary ammonium groups ($-R_3N^+$) in anion-exchange membranes are completely dissociated over the entire pH range, whereas primary ammonium moieties ($-NH_3^+$) are only weakly dissociated. Table 26.15 lists some commercially available cation- and anion-exchange membranes and their associated ion-exchange capacities (with units of mmol per gram of dry membrane).

The permselectivity of an ion-exchange membrane is governed by the solubility of counterions and coions at the membrane–solution interfaces and by transport processes in the membrane. One approach to describe mathematically counterion and co-ion solubility in an ion-exchange membrane is Donnan equilibrium theory [138]. For a cation-exchange membrane (with negatively charged fixed ions of concentration X) immersed in a single 1:1 salt solution (at a concentration C^b), the counterion concentration inside the membrane (C_+) is given by

$$C_+ = \frac{X}{2} + \left[\left(\frac{X}{2}\right)^2 + \left(\frac{f_+^b}{f_+^m} C^b\right)^2 \right]^{1/2} \tag{26.142}$$

where $f_\pm^b$ is the mean molar activity coefficient of the salt in the external bulk solution and $f_\pm^m$ is the activity of salt inside the membrane. A similar relationship can be derived for the concentration of anions in an anion-exchange membrane. Once the counterion concentration in the membrane is known, the coion concentration is computed from the macroscopic electroneu-

trality equation (i.e., $C_- = C_+ - X$ for a cation-exchange membrane or $C_+ = C_- - X$ for an anion-exchange membrane). The drawback in using the Donnan equation lies in the inability to predict accurately $f_\pm^m$. When activity coefficients are neglected, the Donnan theory works well for $C^b << X$ and $C^b >> X$, but at salt concentrations comparable to or somewhat greater than the membrane fixed-charge concentration (an important concentration range for many problems), this model underestimates the counterion concentration in a variety of ion-exchange membranes (see, for example, [139, 140]). The application of Donnan theory to a multicomponent external salt solution results in the following relationship for the membrane-phase concentrations of cation species i and j [141]:

$$\left[\frac{f_i^m C_i^m}{f_i^b C_i^b}\right]^{z_i} = \left[\frac{f_j^m C_j^m}{f_j^b C_j^b}\right]^{z_j} \tag{26.143}$$

When activity coefficients were neglected, Equation (26.143) predicted incorrectly that the membrane-phase concentration ratio of any two similarly charged cations will be the same as that in the external solution [142].

Verbrugge and Hill [143] and more recently Bontha and Pintauro [144] and Pintauro et al. [145] extended the double layer theory of Gur et al. [146] to compute coion and counterion partition coefficients in a DuPont Nafion® cation-exchange membrane. This model has been successfully tested for the partition of aqueous H_2SO_4 solutions, aqueous salt mixtures containing alkali metal chlorides, alkali metal/divalent cations, and quaternary ammonium salts in Nafion. In the theoretical analysis, a cylindrical pore structure for the membrane was assumed and ion fixed-charge site electrostatic interactions and alignment of membrane-phase solvent molecules (by the strong electric field generated by fixed charges on the pore wall) were taken into account. Solvent orientation and the presence of an ion solvation interaction energy term in the model allowed one to compute different equilibrium partition coefficients for ions of like charge and different size immersed in the same solvent [143].

Cation, anion, and water transport in ion-exchange membranes have been described by several phenomenological solution-diffusion models and electrokinetic pore-flow theories. Phenomenological models based on irreversible thermodynamics have been applied to cation-exchange membranes, including DuPont's Nafion perfluorosulfonic acid membranes [147, 148]. These models view the membrane as a "black box" and membrane properties such as ionic fluxes, water transport, and electric potential are related to one another without specifying the membrane structure and molecular-level mechanism for ion and solvent permeation. For a four-component system (one mobile cation, one mobile anion, water, and membrane fixed-charge sites), there are three independent flux equations (for cations, anions, and solvent species) of the form

$$N_i = -L_1 \nabla C_i - L_2 \nabla P - L_3 \nabla \Phi \tag{26.144}$$

where Φ is the electric potential, P is pressure, and the L_j parameters are complicated functions of concentration, pressure, temperature, and binary interaction parameters (for an n component system, there are a total of $n(n-1)/2$ such parameters). The form of the flux equations does vary with membrane type, whereas the L_j terms contain information regarding molecular-level interactions and processes that distinguishes one membrane from another. Unfortunately, there have been very few studies linking any of the phenomenological parameters to membrane structure [149], and the large number of parameters for multicomponent systems make this modeling approach cumbersome and difficult to use. A review of irreversible thermodynamic transport models for ion-exchange membranes can be found in [150].

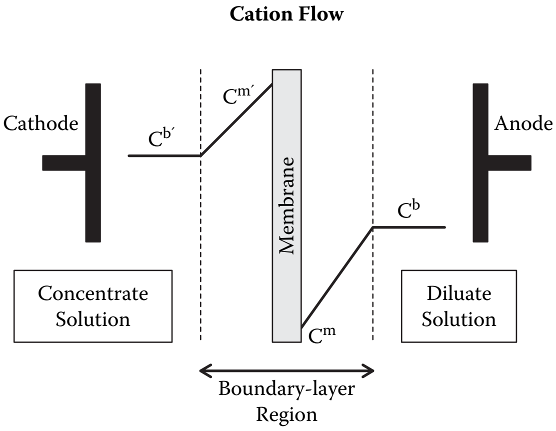

FIGURE 26.29 Schematic diagram of cation concentration profiles on the diluate and concentrate sides of a cation-exchange membrane during current flow.

Another structure/function transport model, often referred to as the "capillary" or "electrokinetic" model, predefines the microlevel structure of an ion-exchange membrane as an array of pores of known dimensions with a specified distribution of ion-exchange sites on the pore walls. Equations describing solute and solvent transport and theories for molecularlevel ion/solvent and ion–membrane interactions are then generated, based on this pore structure [151]. The fundamental transport equation for the molar flux of ionic species is the Nernst-Planck equation

$$N_i = -\frac{z_i F D_i C_i}{RT}\nabla\Phi - D_i \nabla C_i + vC_i \tag{26.144}$$

When the radius of the membrane pores is of the same order of magnitude as the Debye screening length, electroneutrality within the pores is no longer valid. A non-zero space charge produces coupling between electrical forces, mass transfer, and fluid flow within the pore. This coupling manifests itself in two ways: (1) the interaction of fluid flow and the electric field generates a body force term in the momentum balance equation, and (2) the electrostatic potential in the space charge region of the pore causes counterion enrichment and coion exclusion. Also, the interaction between the space-charge region and the driving forces for transport directed parallel to the pore wall results in such electrokinetic phenomena as streaming potentials and electroosmosis [152]. For examples of electrokinetic transport models as applied to ion-exchange membranes, see [151, 153, 154].

Two important design parameters for an electrodialysis stack are the limiting current density and current utilization. The transport of charged species to the anode or cathode through a set of ion-exchange membranes leads to a concentration decrease of counterions in the boundary layer at the membrane surface that faces the dilute compartment and an increase at the surface facing the concentrated solution (Figure 26.29). The decrease in salt concentration at the membrane surface of the diluate limits the ion flux (or current density) through the membrane. At the absolute limiting current density, the ion concentration at the surface of the cation- and/or anion-exchange membrane drops to zero. The limiting current density (i_L) in this situation is given by [132, 155]

$$i_L = \frac{C^b z_+ F k_d}{t_+ - t_+^*} \tag{26.146}$$

where C^b is the bulk solution concentration in the cell with the depleted solution, k_d is the mass transport coefficient in the diluate cell (the cell losing ion species), t_+ is the cation transference number in the diluate solution, and t^*_+ is the cation transference number in the membrane (which, for an ideal cation-exchange membrane, will be 1.0). According to the above equation, the limiting current density is proportional to the ion concentration and the mass transfer coefficient in the dilute cell (k_d is dependent on the solution flow velocity). If the limiting current density is exceeded in an electrodialysis stack, the process efficiency of the separation will be dramatically lowered, due to the increase in electrical resistance of the diluate solution (since there are no ions to carry the current in the solution in contact with the membrane) and due to a secondary reaction, such as the water splitting reaction (for aqueous solutions), which produces H^+ and OH^- (i.e., if there are no cations to carry the current through the membranes when the limiting current is exceeded, energy will be expended to generate H^+ and OH^- ions from water). As a consequence of the problems associated with operating the electrodialysis stack at the limiting current, the cells are often operated at approximately 80% of i_L.

The current utilization refers to the fraction of the total current that passes through an electrodialysis membrane stack that actually is used to transfer anions or cations from a feed solution. The current utilization is always less than 100% due to: (1) co-ion intrusion into the ion-exchange membrane (i.e., no ion-exchange membrane will completely exclude co-ions), (2) osmotic and ion-bound water transport (water will flow into the concentrate compartment due to osmosis and the electro-osmotic drag of water molecules with the transporting ions), and (3) shunt currents that skirt around the membranes and pass through the stack manifold.

The energy necessary to remove salts from a solution by electrodialysis is directly proportional to the total current flowing through the membrane stack and the total voltage drop between the two electrodes in the stack. The energy consumption is described mathematically by [132]

$$\text{Energy} = \frac{InR_e tzFQ_f \Delta C}{\xi} \tag{26.147}$$

where Q_f is the volumetric flow rate of the feed solution, ΔC is the concentration difference between the feed solution and the diluate, R_e is the resistance of an anion-exchange-membrane/cation-exchange-membrane cell pair (including the solution resistance between the membranes), n is the number of cell pairs in a stack, t is time, and ξ is the current utilization.

Capital costs for an electrodialysis stack include the stack housing, pumps, membranes, and electric rectifiers. The cost of an electrodialysis plant is strongly dependent on the total membrane area (denoted as A) needed to produce a given concentration change. The required membrane area, in turn, is directly proportional to the solution flow rate and specified concentration change and is inversely proportional to the applied current density and current utilization [132, 156]:

$$\text{Area} = \frac{zFQ_f n\Delta C}{i\xi} \tag{26.148}$$

where i is the applied current density.

26.7 CORROSION PROCESSES

Most metals occur naturally in their oxide or sulfide forms. The process of metal refining converts these ores into pure metals. Thermodynamically, a metal will return spontaneously to its original oxide form. Metal oxidation can occur at high temperatures, by direct reaction with O_2, or at a moderate temperature by reaction with water, O_2, and/or H^+. The latter oxidation, commonly referred to as wet corrosion, has as its basis the combination of electrochemical cathodic reduction and anodic metal oxidation reactions into a "corrosion cell." Thus, many corrosion processes are

basically rooted in electrochemistry. The corrosion cell may be viewed as a short-circuited electrochemical cell, where a voltage difference between the anode and cathode provides the driving force for spontaneous oxidation and reduction reactions. The anode and cathode may be physically separated from one another or, more commonly, may occur on a single heterogeneous metal surface, where discrete microcells arise due to differences in metal composition and/or spatial variations in the composition of the solution in contact with the metal surface.

The primary oxidation reaction involves the anodic electrochemical dissolution of metal species M, according to the following reaction:

$$M \rightarrow M^{n+} + ne^- \quad (26.149)$$

This reaction is driven to the right and controlled by one or more reduction reactions, typically,

Proton reduction (in acid media): $2H^+ + 2e^- \rightarrow H_2$ (26.150)

Oxygen redution (in aerated solutions): $O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$ (26.151)

Water reduction (in alkaline or pH-neutral solutions): $2H_2O + 2e^- \rightarrow H_2 + 2OH^-$ (26.152)

Oxygen reduction in neutral/alkaline solution: $1/2O_2 + H_2O \rightarrow 2OH + 2e^-$ (26.153)

The overall reaction in a corrosion cell is the sum of an anodic and cathodic reaction. For the case of metal dissolution and O_2 reduction, the overall reaction is

$$M + n/4O_2 + n/2H_2O \rightarrow M^{n+} + nOH^- \quad (26.154)$$

Dissolved metal ions can either pass into the bulk solution or react immediately with OH^- to form insoluble metal oxides/hydroxides that coat the metal surface. For iron corrosion, iron hydroxide species react further with water and oxygen to form rust ($Fe(OH)_3$) according to the following reaction sequence:

$$2Fe^{2+} + 4OH^- \rightarrow 2Fe(OH)_2 \text{ (ppt)} \quad (26.155)$$

$$2Fe(OH) + 2H_2O + O_2 \rightarrow 2Fe(OH)_3 \quad (26.156)$$

The rate of a corrosion reaction is affected by pH (via H^+ reduction and hydroxide formation), the partial pressure of O_2 (the solubility/concentration of oxygen in solution), fluid agitation, and electrolyte conductivity. Corrosion processes are analyzed using the thermodynamics of electrode reactions, mass transfer of the cathode reactants O_2 and/or H^+, and the kinetics of metal dissolution reactions [157, 158].

26.7.1 Thermodynamics of Corrosion Processes

We have seen in Section 26.2.1 that thermodynamics (i.e., equilibrium half-cell potentials) can be used to determine which of two half-cell reactions proceeds spontaneously in the anodic or cathodic direction when the two reactions occur on the same piece of metal or on two metal samples that are in electrical contact with one another. The half-cell reaction with the higher equilibrium potential will always be at the cathode. Thus, under standard conditions any metal dissolution (corrosion) reaction with an $E°$ less than 0.0 V vs. SHE will be driven by proton reduction while metal dissolution reactions with an $E°$ less than +1.23 V vs. SHE will be driven by dissolved

oxygen reduction. Noble metals such as Pd and Au have very high standard reduction potentials and, therefore, are highly resistant to corrosion. The list of standard reduction potentials (as reported in Table 26.2) indicates that the presence of O_2 in solution increases significantly the number of metals that corrode under normal environmental conditions. Thus, a simple and effective step in lowering metal corrosion is to deaerate aqueous solutions in contact with metal surfaces. For example, the copper oxidation (dissolution) reaction ($E°$ = +0.337 V vs. SHE) cannot be driven by the hydrogen evolution reaction, but it can occur spontaneously if it is coupled to the oxygen reduction reaction.

When the activity of ions in solution is not unity, the standard reduction potential must be corrected by use of the Nernst equation (Equation [26.28]) to give the equilibrium half-cell potential (as explained in Section 26.2.1). Additionally, corrosion reactions may produce or consume H^+, in which case the spontaneity of a corrosion reaction will be pH-dependent. In order to anticipate the effects of pH on electrochemical reactions and chemical reactions at an electrode during metal oxidation (such as metal hydroxide formation), electrochemists employ potential vs. pH plots for a given metal, also known as Pourbaix diagrams [159]. Such a diagram is a plot of redox potential (the ordinate) as a function of pH for a given metal in water under standard thermodynamic conditions. A Pourbaix diagram for iron in water at 25°C is shown in Figure 26.30. The chemical and electrochemical reactions that define the numbered lines are listed in the figure caption. When the applied electrode potential is greater than the equilibrium potential for a given reaction, that reaction is driven spontaneously in the anodic direction. Similarly, a reduction reaction is favored thermodynamically when the electrode potential is less than the equilibrium potential for that reaction.

Although Pourbaix diagrams provide important information regarding the stability of various metal species in different oxidation states, they are of limited use because: (1) they contain only thermodynamic information and thus provide no indication of the rate (speed) of the relevant reactions, (2) they usually refer to reactions at 25°C and one atmosphere pressure, and (3) they consider only pure metals.

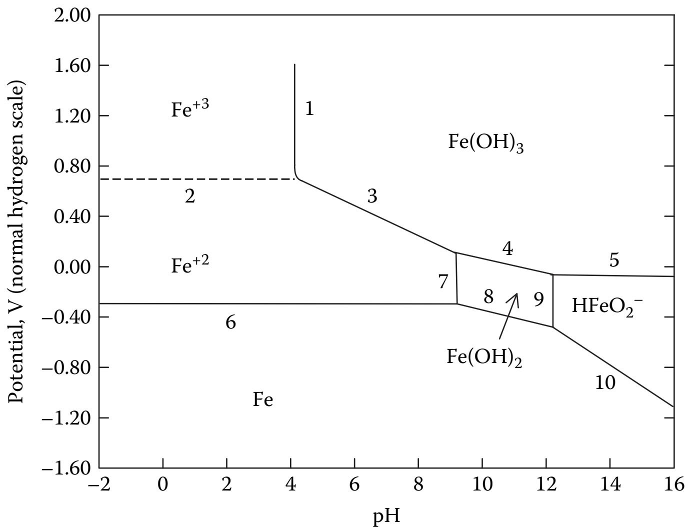

FIGURE 26.30 Simplified Pourbaix diagram for the iron-water system at 25°C. The numbers associated with each line correspond to the following reactions: (1) $2Fe^{3+} + 6H_2O = 2Fe(OH)_3 + 6H^+$, (2) $Fe^{2+} = Fe^{3+} + e^-$, (3) $2Fe^{2+} + 6H_2O = 2Fe(OH)_3 + 6H^+ + 2e^-$, (4) $2Fe(OH)_2 + 2H_2O = 2Fe(OH)_3 + 2e^-$, (5) $2HFeO_2^- + 2H_2O = 2Fe(OH)_3 + 2e^-$, (6) $Fe = Fe^{2+} + 2e^-$, (7) $Fe^{2+} + 2H_2O = Fe(OH)_2 + 2H^+$, (8) $Fe + 2H_2O = Fe(OH)_2 + 2H^+ + 2e^-$, (9) $Fe(OH)_2 = HFeO_2^- + H^+$, and (10) $Fe + 2H_2O = HFeO_2^- + 3H^+ + 2e^-$.

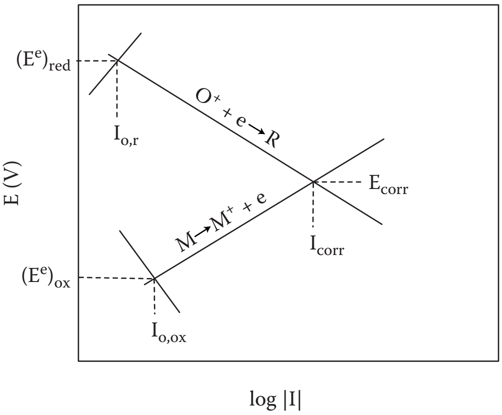

FIGURE 26.31 Current-voltage plots for metal corrosion, showing Tafel lines for metal (*M*) exidation and oxidant (*O*) reduction. The intersection of the Tafel lines gives the corrosion potential and corrosion current.

26.7.2 Kinetic Aspects of Corrosion Reactions

Almost all metals corrode, but many metals corrode very slowly under normal environmental conditions, due in part to kinetic limitations of the metal dissolution reaction. Thus, the rate of metal corrosion can be anticipated and controlled by developing kinetic rate expressions for metal oxidation reactions. There is a major difference, however, between "classical" electrochemical metal dissolution kinetics and metal dissolution in a corrosion system, that difference being the occurrence of one or more oxidation and reduction reactions on the same metal.

As stated above, wet-metal corrosion involves a metal dissolution (oxidation) reaction coupled to a reduction reaction. Electrons produced at anodic sites pass through the metal, and are consumed by reduction reactions so that there is no net charge build-up in the metal. For this situation, "mixed potential theory" is applicable. The basic premises of this theory are (1) any electrochemical reaction can be divided into two or more partial oxidation and reduction reactions, and (2) the sum of the rates (as quantified by the current densities) of all anodic reactions must be equal to the current densities for all cathodic reduction reactions on an isolated corroding metal sample because there is no net accumulation of charge. During metal corrosion, the open circuit (zero net current) electrode potential of the corroding metal, also known as the corrosion potential (E_{corr}), lies between the potentials of the relevant anodic and cathodic half-cell reactions. The partial anodic or cathodic current that flows at E_{corr} is called the corrosion current (I_{corr}) and is directly related to the rate of metal corrosion (g/sec) through Equation (26.14) in Section 26.2.2. The corrosion rate in mils of metal lost per year (abbreviated mpy, where 1 mil = 10^{-3} inches) is related to the current density at the corrosion potential (designated as i_{corr} with units of A/cm^2) by the following equation:

$$mpy = 394 \times \frac{i_{corr}}{nF} \times \frac{M}{\rho} \tag{26.157}$$

where M is the molecular weight of the corroding metal (g/mole) and ρ is the metal density (g/cm^3).

Tafel plots of E vs. log I, such as those shown in Figure 26.31, are often used to determine the rate of a corrosion process. For a corroding metal (anode) that is driven by a single kinetically controlled reduction reaction (such as hydrogen evolution from an acid-containing solution), one can write the following Tafel equations for cathodic proton reduction and anodic metal dissolution:

$$E - E^e_{H2} = -\beta_{H2}(\log I - \log I_{o,H2}) \tag{26.158}$$

$$E - E_M^e = \beta_M(\log I - \log I_{o,M}) \tag{26.159}$$

where $1/\beta_{H2}$ and $1/\beta_M$ are the cathodic and anodic Tafel slopes (b_c and b_a, respectively, as defined by Equations (26.51) and (26.49) in Section 26.2.2), E^e is the equilibrium half cell potential, as defined by the Nernst equation [Equation (26.28)], and I_o is the exchange current. These equations are shown graphically as straight lines in Figure 26.31, where E is plotted vs. log $|I|$. When the anodic and cathodic reactions are coupled to one another during a metal corrosion process, the electric potential driving force for both reactions is the same and equal to E_{corr} and the anodic and cathodic reaction rates are the same and equal to I_{corr}. Substituting E_{corr} and I_{corr} into Equations (26.158) and (26.159) for E and I and solving the resulting expressions simultaneously for I_{corr} and E_{corr} yields

$$I_{corr} = (I_{o,M})^{\beta_1}(I_{o,H2})^{\beta_2}\exp\left[\frac{2.3(E_{H2}^e - E_M^e)}{\beta_M + \beta_{H2}}\right] \tag{26.160}$$

and

$$E_{corr} = \frac{\beta_M E_{H2}^e + \beta_{H2} E_M^e}{\beta_{H2} + \beta_M} + \frac{\beta_{H2}\beta_M}{2.3(\beta_{H2} + \beta_M)}\log\left[\frac{I_{o,H2}}{I_{o,M}}\right] \tag{26.161}$$

where $\beta_1 = \beta_M/(\beta_M + \beta_{H2})$ and $\beta_2 = \beta_{H2}/(\beta_M + \beta_{H2})$. As can be seen from the above equations, the corrosion current and corrosion potential depend on both the thermodynamic equilibrium potential and the kinetic parameters I_o and β. Graphically, the anodic and cathodic Tafel lines intersect at the point I_{corr},E_{corr}, as shown in Figure 26.31. Similarly, for two or more metal dissolution and/or reduction reactions, one first writes expressions similar to Equations (26.158) and (26.159) for each reaction and then substitutes these formulas into the charge-balance expression $\Sigma\, I_{anodic} = \Sigma\, I_{cathodic}$. Again, one can perform this analysis graphically using anodic and cathodic Tafel plots, by first summing all cathodic and anodic Tafel lines (where the currents from each anodic or cathodic Tafel line are summed at each potential) and then identifying the intersection of the anode and cathode summation lines, where the intersection is at I_{corr},E_{corr} (Figure 26.32).

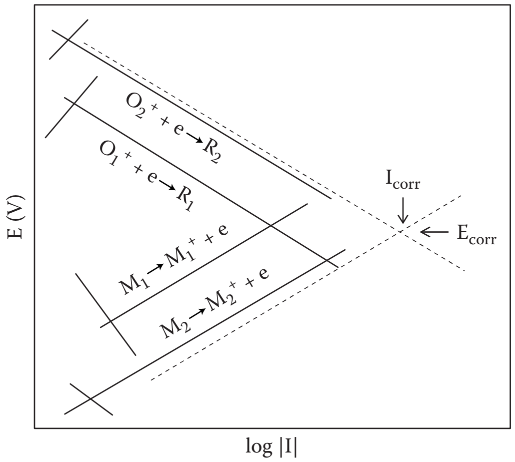

FIGURE 26.32 Current-voltage Tafel plots for metal corrosion showing multiple metal dissolution and oxidant oxidation reactions. The dotted line are the sum of all oxidation reactions and all reduction reactions. The intersection of the dotted lines gives the corrosion potential and corrosion current.

Combining the anodic and cathodic Tafel equations results in the following modified Butler-Volmer rate expression:

$$I = I_{corr}\left(\exp\left[\frac{2.3(E - E_{corr})}{b_a}\right] - \exp\left[\frac{2.3(E_{corr} - E)}{|b_c|}\right]\right) \quad (26.162)$$

Using the above equation, the deviation in the corroding metal potential away from its open circuit potential (E_{corr}) generates a net anodic or cathodic current (in the same way that a deviation of the electrode potential away from E^e for a single electrode reaction produces an oxidation or reduction current). The magnitude of the current, as given by Equation (26.162), depends on the level of electrode polarization ($E - E_{corr}$), the cathode and anodic Tafel slopes (b_c and b_a, respectively), and I_{corr} (which is analogous to the exchange current in the Butler-Volmer equation).

For a small electrode polarization (denoted as ΔE, which can be no more than ±20 mV) that produces a current of I, the exponential terms in Equation (26.162) can be linearized, resulting in the following current-voltage expression:

$$I = 2.3 \cdot I_{corr}\left[\frac{\Delta E}{b_a} + \frac{\Delta E}{|b_c|}\right] \quad (26.163)$$

When a metal corrodes, there is no external flow of current (electrons) to indicate the metal dissolution rate. One can, however, place the corroding metal in a three-electrode electrochemical cell (working electrode, counter electrode, and reference electrode, as shown in Figure 26.4), polarize the working electrode metal either anodically or cathodically away from its open circuit (corrosion) potential by no more than ±20 mV (this potential difference is measured between the working and reference electrodes), and then measure the resulting current. For this case, Equation (26.163) can be rearranged to give the following equation for the corrosion current

$$I_{corr} = \frac{b_a \cdot |b_c|}{2.3\left(b_a + |b_c|\right)} \cdot R_P \quad (26.164)$$

where R_p is known as the polarization resistance and is given by $\Delta I/\Delta E$ (i.e., the slope of the linear portion of an experimental I vs. E plot, for small polarizations of the working electrode). Once I_{corr} is known for a metal specimen of area A, then i_{corr} can be determined and the metal corrosion rate in mpy can be calculated using Equation (26.157).

The use of Tafel plots for the analysis of metal corrosion systems indicates how dissolved O_2 in solution and the subsequent O_2 reduction (which is under kinetic control) accelerates metal corrosion. Due to the high value of E^e for O_2 reduction (+1.23 V vs. SHE), the intersection of the oxygen reduction and metal dissolution Tafel lines occurs at high values of E_{corr} and I_{corr}. When the reduction of both H^+ and O_2 drives metal corrosion (with the reduction reactions under kinetic control), one simply adds together the current-voltage Tafel lines for the two reduction reactions. A new line is then drawn for the sum of the cathodic currents on the corroding metal. The intersection of this new line with the metal oxidation Tafel line gives E_{corr} and I_{corr}.

26.7.3 Mass Transfer Effects

In some situations, the oxygen or proton reduction reaction during metal corrosion will be mass transfer (diffusion) controlled, due to poor fluid agitation and/or a low concentration of H^+ or dissolved oxygen in solution (this is especially true for O_2, which has a low solubility in water at

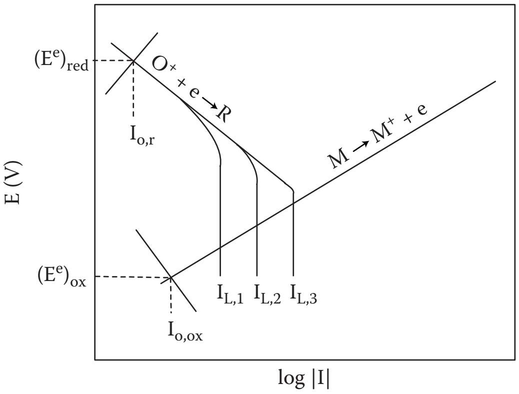

FIGURE 26.33 Current-voltage Tafel plot for a mass transfer controlled metal corrosion process, where the corrosion current is equal to the limiting current for oxidant reduction.

typical environmental conditions, i.e., atmospheric pressure and a temperature of about 25°C). Now the reduction reaction that drives metal dissolution is at or near its limiting current, as shown in Figure 26.33 (a vertical line on a E versus log $|I|$ Tafel plot is characteristic of an electrode reaction where the rate is independent of the electrode potential). In accordance with mixed potential theory, the intersection of the anodic and cathodic current-voltage curves gives I_{corr} and E_{corr}. As can be seen in Figure 26.33, I_{corr} is equal to the mass transfer limiting current for the reduction reaction, and, as such, the metal corrosion rate will increase with increasing I_L (i.e., with increasing stirring and/or increasing concentration of the cathode reactant in solution).

26.7.4 Metal Passivation

When some metals or alloys are immersed in an oxidizing solution, corrosion does not occur, although it is favored thermodynamically. For example, iron will dissolve in dilute, but not in concentrated nitric acid. Corrosion is prevented because of the formation of a protective oxide film on the metal surface. This loss in chemical reactivity of a metal is known as passivation. Metals which readily undergo passivation in damp air include Fe, Al, Cr, Ni, Ti, and Pt.

Passivation can be induced and observed in electrochemical experiments. Figure 26.34 shows a typical E versus log $|I|$ plot for a metal that exhibits active-passive behavior [157]. The metal

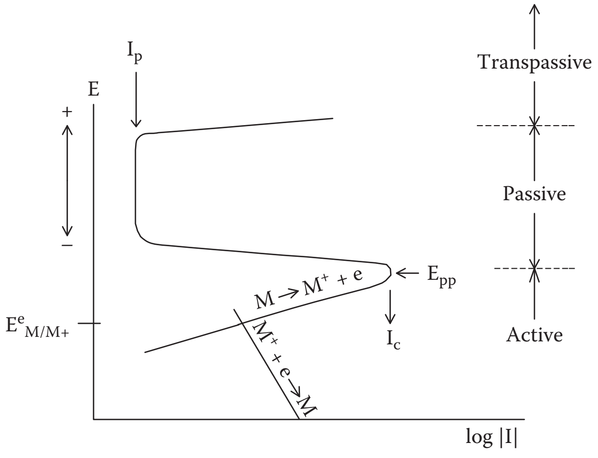

FIGURE 26.34 Current-voltage curve showing active-passive metal dissolution behavior.

initially displays dissolution behavior similar to nonpassivating metals (i.e., there is an increase in the anodic dissolution current with increasing electrode potential). As the potential increases, the dissolution rate is so high that the concentration of dissolved metal ions adjacent to the anode surface exceeds its solubility limit and a salt film precipitates on the metal. The maximum current achievable before salt film formation is called the critical current (I_c in Figure 26.34). At a designated potential known as the passivation potential (E_{pp} in Figure 26.34), there is a sharp decrease in the metal dissolution current (often by several orders of magnitude) to a value defined as the passive current I_p. The drop in metal dissolution rate at E_{pp} is due to a drastic change in the composition and properties of the precipitated salt film on the metal surface, with a reduction in film porosity and the conversion of the film from an ionic conductor to an electronic conductor. For an appreciable electrode potential range above E_{pp}, the current remains low (at I_{pass}) and independent of potential. This regime is termed the passive region. Finally, at a very high anodic potential, metal dissolution commences again, as the protective passive film breaks down. In this transpassive region, the dissolution current once again increases with increasing electrode potential. As will be discussed below, the presence of a passive film on certain metals has been exploited as a convenient way of protecting the underlying metal from further corrosion.

26.7.5 Types of Corrosion and Methods of Corrosion Prevention

26.7.5.1 Uniform Attack

Uniform attack or general overall corrosion is the most common form of corrosion, causing most metal destruction on an overall tonnage basis. During this form of corrosion, the metal becomes thinner and eventually fails. Although widespread, the form of corrosion is not of too great a concern because the corrosion rate can be accurately predicted using simple tests (immersing the metal specimen in the liquid of interest for an extended period of time and measuring the weight loss or performing electrochemical polarization experiments to determine the corrosion current) so that the metal lifetime can be estimated. As an example, this type of corrosion would occur when a steel or zinc plate is immersed in a dilute sulfuric acid solution, with rusting (corrosion) over the entire metal surface.

Prevention—Uniform corrosion can be prevented or reduced by (1) the proper choice of metal for a given environment; (2) the use of metal coatings, such as a paint coating or nonoxidizing organic inhibitors (e.g., benzotriazole or organic amines [160]) in solution that adsorb onto and protect the metal surface; or (3) cathodic protection (discussed below).

26.7.5.2 Galvanic Corrosion

A potential difference exists between any two dissimilar metals that are exposed to a corrosive or electrically conductive solution. When the two metals are in contact, the potential difference causes electrons to flow between the two metals. To a first approximation, the determination of the equilibrium potential of the two reactions on the metals (see Section 26.2.1.1) can be used to predict which metal will corrode (that metal with the lower equilibrium electrode potential will become the anode and will corrode). The greater the difference of the potentials of the two metals, the greater the driving force for corrosion and the greater the metal dissolution rate. Examples of galvanic corrosion are: (1) corrosion of aluminum tubing that is connected to brass (Cu-Zn alloy) fittings, (2) corrosion of a steel hot water tank where copper tubing is connected to the tank, and (3) corrosion of steel pump shafts and valve stems because of contact with graphite packing. Galvanic corrosion is usually greatest near the junction of the two metals. Anode/cathode area effects also play an important role during galvanic corrosion. A large cathode and small anode is unfavorable because the anode current density will be greater than that at the cathode even though both the anodic and cathode currents are equal.

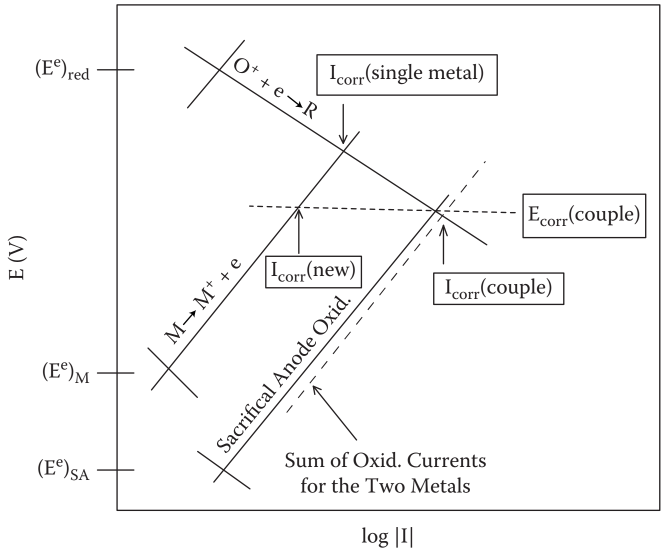

FIGURE 26.35 Current-voltage Tafel plot showing cathodic protection by use of a sacrificial anode. E^e_{red} = equilibrium potential of the reduction reaction; E^e_M = equilibrium potential of the primary metal dissolution reaction; E^e_{SA} = equilibrium potential of the sacrificial anode oxidation reaction.

Prevention—The following procedures combat galvanic corrosion: (1) dissimilar metals in contact should be as close together as possible in the galvanic series, i.e., in the list of standard reduction potentials (compare with Table 26.2 in Section 26.2.1); (2) avoid the unfavorable effect of a small anode and large cathode by fabricating small metal parts from highly corrosion resistant materials; (3) insulate dissimilar pieces of metal, wherever practical; (4) design equipment with readily replaceable anodic parts or make them thicker for longer life; (5) use an impressed DC electric current to pump electrons into the metal to be protected and thus force the mixed potential of the couple lower; or (6) connect a third metal with an equilibrium potential that is anodic to both metals in the galvanic couple (the third metal is known as a sacrificial anode and it will corrode preferentially and pump electrons into the metal to be protected).

The process of protecting either a metal undergoing uniform corrosion or one metal of a galvanic couple by methods (5) and (6) in the preceding paragraph is called cathodic protection [157, 161]. Here, electrons are pumped into the metal to be protected, thus converting it from a dissolving anode into a noncorroding cathode. Figure 26.35 shows how Tafel plots can be used to explain how cathodic protection with a sacrificial anode lowers the dissolution rate of a metal. When the metal to be protected is coupled to a second metal with a lower equilibrium potential, the E_{corr} of the two-metal couple is lowered. The overall corrosion rate of the couple increases (I_{corr} for the couple is greater than I_{corr} for the single metal, as shown in Figure 26.35), but this increase is at the expense of the sacrificial anode. The corrosion rate of the metal to be protected actually decreases (the horizontal line at $E = E_{corr}$ for the couple intersect the $M \rightarrow M^+$ oxidation line at a value of I_{corr} that is smaller than the I_{corr} for the single metal system). A practical example of cathodic protection by use of a sacrificial anode is galvanized steel, where a surface coating of zinc ($E^\circ_{Zn/Zn+}$ = –0.763 V vs. SHE) becomes the anode and electrons are pumped into the underlying steel ($E^\circ_{Fe/Fe2+}$ = –0.440 V vs. SHE), thus protecting it from corrosion.

26.7.5.3 Crevice Corrosion

Crevice corrosion is the intensive localized corrosion of a metal that occurs within crevices, overlapping metal parts, and shielded metal surfaces, where part of the metal surface is exposed

to a corrosive environment [157, 162]. Such corrosion is associated with a small volume of stagnant solution in holes, under gasket surfaces, beneath surface deposits, and under bolts and rivet heads. When two overlapping metal parts, for example, are exposed to aerated seawater, there is initially uniform corrosion over the entire metal surface, where metal dissolution is driven by oxygen reduction (low concentrations of dissolved oxygen being present in the seawater). After a short time, oxygen within the crevice is depleted due to poor fluid mixing and oxygen reduction ceases. Dissolution of metal in the crevice, however, continues (driven by O_2 reduction outside the crevice) and the metal cation concentration in the crevice increases. To maintain charge neutrality, Cl^- ions migrate into the crevice solution and the resulting metal chloride salt hydrolyzes into H^+, Cl^-, and an insoluble metal hydroxide precipitate. The production of protons and chloride anions accelerates metal dissolution in the crevice. The increase in metal dissolution increases Cl^- migration, which in turn further heightens the rate of metal corrosion in the crevice. The corrosion process within the crevice drive oxygen reduction on the adjacent metal surface outside the crevice (this metal surface is actually cathodically protected by metal corrosion in the crevice). Thus, during crevice corrosion, metal attack is localized within shielded areas while the remaining metal surface suffers little or no damage. The unfavorable cathode/anode area ratio means very rapid disintegration of metal within the crevice. There is usually a long incubation period associated with crevice corrosion (when dissolved O_2 within the crevice is depleted). Once crevice corrosion starts, it often proceeds at an accelerating rate. Metals or alloys that depend on oxide films or passive layers for corrosion resistance are particularly susceptible to crevice corrosion (the films are destroyed by H^+ and/or Cl^-).

Prevention—Crevice corrosion is prevented or minimized by: (1) closing crevices and overlapping metal parts by continuous welding, caulking, or soldering; (2) removing solid deposits from metal surfaces; and (3) increasing fluid stirring to minimize the difference in dissolved O_2 concentration within and outside of a crevice [163].

26.7.5.4 Pitting

Pitting is a destructive and insidious form of corrosion, where localized dissolution occurs in small holes or pits on the metal surface [157, 161]. Although metal weight loss is small, equipment failure occurs due to perforation of the metal. Pitting occurs in passivating metals, where certain aggressive species in solution, e.g., chlorides, bromides, and hypochlorites, break down the passive oxide film. An autocatalytic and accelerating metal dissolution process then begins at film rupture. As is the case for crevice corrosion, rapid metal dissolution creates an excess of metal cations within the pit and the electromigration of Cl^- ions into the pit to maintain electroneutrality. The subsequent hydrolysis of metal chloride species produces H^+ and metal hydroxides (which precipitates at the pit entrance). The solubility of oxygen drops to virtually zero as the solution in the pit acidifies. Cathodic reduction of oxygen on the large metal surfaces adjacent to the pit drives the dissolution reactions, in a manner similar to crevice corrosion.

Prevention—The methods outlined above to combat crevice corrosion also apply to pitting. Metals that are resistant to pitting should be used as alloying agents; their passive films are more protective and more stable to halogen attack. For example, the addition of 2% molybdenum to 18-8 (type 304) stainless steel to produce 316 stainless steel significantly increases pitting resistance.

Anodic Protection—Anodic protection procedures make use of a passive film on a metal surface to minimize corrosion. Normally, the application of an anodic current to a metal structure would increase its electrochemical dissolution rate. With metals that exhibit active-passive behavior (e.g., Ti, Ni, Fe, Cr, and their alloys), application of an anodic current or an anodic potential results in passive film formation and a dramatic reduction in the metal corrosion rate. There are essentially two methods of anodically protecting a metal: (1) the imposition of an anodic potential greater than the passivating potential (E_{pp} in Figure 26.34) or (2) the use of oxidizing inhibitors (e.g., NO_3^-, CrO_4^{2-}, SO_4^{2-}, CH_3COO^-, or OH^-) [164] at a sufficiently high concentration so that the mixed

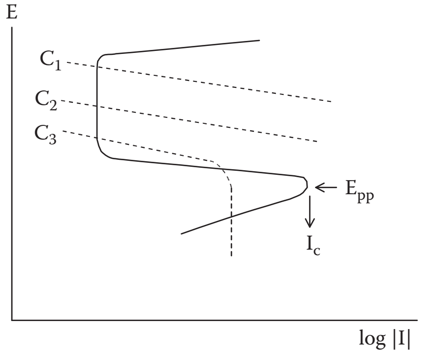

FIGURE 26.36 Tafel plot showing the anodic protection of a passivating metal by use of an oxidizing inhibitor, where the inhibitor concentrations are $C_1 > C_2 > C_3$ (C_3 is not high enough for metal passivation).

potential for metal dissolution coupled to inhibitor oxidation is raised into the metal's passive region (Figure 26.36) [157, 162].

26.7.5.5 Stress Corrosion Cracking

Stress corrosion cracking is a form of localized corrosion, where the simultaneous presence of tensile stresses and a specific corrosive environment produces metal cracks [157, 168]. Stress corrosion cracking generally occurs only in alloys (e.g., Cu-Zn, Cu-Al, Cu-Si, austenitic stainless steels, titanium alloys, and zirconium alloys) and only when the alloy is exposed to a specific environment (e.g., brass in ammonia or a titanium alloy in chloride solutions). Removal of either the stress on the metal (which must have a surface tensile component) or the corrosive environment will prevent crack initiation or cause the arrest of cracks that have already propagated. Stress corrosion cracking often occurs where the protective passive film breaks down. The continual plastic deformation of the metal at the tip of the crack prevents repassivation of the metal surface and allows for continued localized metal corrosion.

Prevention—Stress corrosion cracking can be prevented by increasing the tensile strength of the metal or alloy (to prevent formation of nucleating cracks) and/or reducing the stress on the metal (by redesigning the part or by stress-relieving heat treatments). Corrosion inhibitors and coatings (e.g., electrodeposited zinc, chromium, nickel, copper, and nitride coatings) are also effective in eliminating this type of corrosion.

26.7.5.6 Hydrogen Embrittlement

Hydrogen embrittlement is caused by penetration of hydrogen into a metal, which results in a loss of ductility and tensile strength [157, 165]. High-strength metals and alloys are particularly susceptible to this kind of corrosion. Its exact mechanism is not well understood. For titanium and other strong hydride-forming metals, dissolved hydrogen reacts within the metal to form brittle hydride compounds. Another mechanism is based on the accumulation of hydrogen near dislocation sites or microvoids in the metal. Hydrogen embrittlement is distinguished from stress corrosion cracking by the polarity of the metal when corrosion occurs. While stress corrosion cracking is associated with highly anodic metal surfaces, hydrogen embrittlement often occurs due to the presence of cathodic surface metal sites, where H_2 is produced during normal (uniform) corrosion.

Prevention—Hydrogen embrittlement is prevented or minimized by (1) reducing the uniform corrosion rate on a metal surface (by coating/painting the metal surface, for example), to decrease the rate of hydrogen evolution on the metal surface: (2) baking the metal (hydrogen evolution is an

almost reversible process, especially in steels, thus heating the metal to 200°F to 300°F liberates trapped hydrogen), which often restores the mechanical properties of the metal; and/or (3) using alloying agents (e.g., nickel and molybdenum) that are not susceptible to hydrogen embrittlement.

26.8 BATTERIES AND FUEL CELLS

26.8.1 Batteries

Batteries are electrochemical reactors that convert chemical energy into electrical energy. The thermodynamic relationship for this conversion is given by Equation (26.19):

$$E = -\frac{\Delta G}{nF}$$

where E is the electromotive force (voltage) of the battery system, ΔG is the free energy change for the overall battery reaction (the sum of the primary anode and cathode reactions), and n is the number of electrons involved in the battery reactions. The available thermodynamic voltage depends on the chemical reactants. In a battery, reactants for the oxidation and reduction reactions do not meet directly, but are consumed at different sites, the anode and cathode, which causes electrons to flow through an external circuit between the battery terminals. The energy transfer is manifested as a voltage (a measure of the energy difference of electrons at the anode and cathode) and current (the flow of electrons through the external circuit connecting the anode and cathode). All batteries have four common features: (1) the anode and cathode electrodes must be electronically conducting; (2) the electrolyte between the anode and cathode must be ionically conducting; (3) there must be physical separation of the electrodes and the fuel and oxidant reactants; and (4) the available fuel and oxidant materials for the electrode reactions must be contained within the battery itself. Primary batteries [166–170] are designed only for a single discharge, while a secondary battery is expected to be capable of repetitive charge/discharge cycles. The original chemistry of a primary battery cannot be restored by electrical means internal to a cell due to (1) irreversibility in phase changes and chemical interconversion of the electrode active material; (2) isolation, electrically or electronically, of active material; and/or (3) local poor conductivity of electrode materials in the discharged state [169]. In contrast to primary batteries, secondary batteries [168, 171, 172] can be recharged electrically to their original condition many times by passing current through them in the opposite direction to that of the discharge current. Thus, the anode and cathode battery reactions in a secondary battery must be reversible.

26.8.1.1 Battery Performance Characteristics

Battery performance is related to the available voltage and current while the battery is discharging. The terminal voltage of a battery depends on the thermodynamic free-energy change of the anode and cathode reactions, according to Equation (26.19) and by the various activation (kinetic), concentration, and resistance overpotentials that lower the battery's voltage (as discussed in Section 26.3.4):

$$E_{cell} \equiv E^C - E^A = (E^e)^C - (E^e)^A - \left|\Sigma\eta^A\right| - \left|\Sigma\eta^C\right| - \left|\eta_{ohm}\right| \tag{26.165}$$

where the superscripts A and C refer to the anode and cathode, respectively. According to the above equation, one should choose the anode and cathode reactions with a large ($E_e^C - E_e^A$). At the same time, the various overpotentials (primarily the kinetic and resistance overpotentials) must be minimized, by ensuring fast electrode reactions and by designing the battery with a low electrical resistance (e.g., a high-conductivity electrolyte, a small interelectrode gap, and a low-resistance

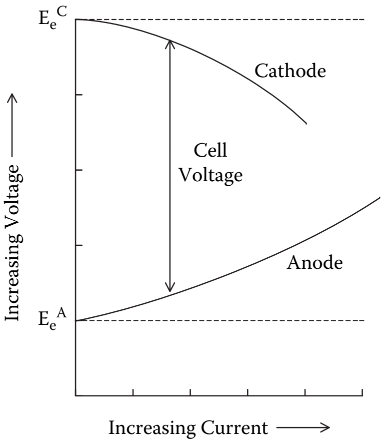

FIGURE 26.37 Cell polarization as a function of current density for the anode and cathode of a battery. The displacement of the electrode potentials from their equilibrium (thermodynamic) potentials is due to the presence of overpotentials.

anode/cathode separator). Unfortunately, these overpotentials increase with increasing current, causing the battery voltage to decrease, as shown schematically in Figure 26.37.

The key components of a primary or secondary battery are: (1) the container, which must possess the necessary mechanical strength and resistance to internal and external corrosion; in some batteries, such as the Lechlanche cell (Table 26.16), the zinc container acts as one of the electrodes; (2) separators, to minimize intermixing of the reactants and products of the anode and cathode reactions (e.g., microporous polyethylene for lead-acid batteries); (3) metal grid or sheet current collectors, which provide mechanical support for and improve the electrical conductivity of the electrodes (the electrodes are often composed of a thick, porous layer of active material with limited mechanical strength and electrical conductivity); (4) the electrolyte, which is determined by the electrode reactions, along with the need for substantial conductivity; and (5) active electrode materials, which are in solid form and in intimate contact with the electrolyte (often the active material structure is a porous electrode paste that is spread on a current collector).

Current is a measure of the rate at which a battery is discharging. As can be seen in Figure 26.37, a battery's current and voltage behaviors are linked. Ideally, one would like the battery to deliver a high current without excessive voltage losses, which means that there must be rapid electron transfer reactions at the two electrodes. Additionally, the electrodes should ideally be designed to ensure an adequate supply of electro-active material near sites where electron transfer reactions are occurring. Battery properties that are dependent on current/voltage behavior are [168]:

1. Capacity. The capacity of a battery depends on how much of the active materials at each electrode are consumed during battery discharge. The theoretical capacity of each electrode, with units of ampere hours, is calculated from Faraday's law, with the weight (w) and molecular weight (MW) of active (reactant) material and the number of electrons involved in the electrode reaction (n):

$$\text{Capacity} = \frac{w \times n \times F}{MW} \tag{26.166}$$

   The capacity of the battery is determined by the electrode of lowest capacity. The actual capacity depends on the discharge current, commonly measured by the decline in the battery voltage with time at a fixed discharge current (see Figure 26.38).

TABLE 26.16
Commercial Primary Battery Systems

Common Name	Overall Cell Reaction	Nominal Voltage	Approximate Power Density (Wh/cm^3)	Comments
Leclanche	$Zn + 2MnO_2 + 2NH_4Cl = Zn(NH_3)_2Cl_2 + H_2O + Mn_2O_3$	1.5	0.20	Low cost; general purpose; wide range of sizes
Zinc chloride	$4Zn + 8MnO_2 + ZnCl_2 + 9H_2O = 8MnOOH + ZnCl_2 \cdot 4ZnO \cdot 5H_2O$	1.5	0.20	Intermediate cost and performance
Alkaline	$2Zn + 3MnO_2 = 2ZnO + Mn_3O_4$	1.5	0.25	Sets standard for cylindrical cells
Silver	$Zn + AgO_2 = 2Ag + ZnO$	1.6	0.50	Good pulse power, higher voltage than Zn/HgO or Zn/Air
Mercury	$Zn + HgO = Hg + ZnO$	1.35	0.50	Sets the standard for button-size cells
Zinc-air	$2Zn + O_2$ (air) $= 2ZnO$	1.4	1.0	Twice the capacity of a mercury battery
Li/CuO	$2Li + CuO = Li_2O + Cu$	1.5	0.60	Potential replacement for leclanche and zinc chloride batteries
Li/FeS	$2Li + FeS = Li_2S + Fe$	1.6	0.40	Replacement for Zn/HgO and Zn/Ag_2O
Li/SO_2	$2Li + 2SO_2 = Li_2S_2O_4$	2.8	0.4	Military battery; low temperature; excellent storage
$Li/SOCl_2$	$Li + SOCl_2 = LiCl + SO_2$	3.6	1.0	High voltage; high-energy density
Li/CF_x	$xLi + CF_x = xLiF + C$	2.7	0.50	High voltage; long shelf-life; wide operating temperature
Li/MnO_2	$Li + MnO_2 = LiMnO_2$	2.8	0.50	High voltage; long shelf-life; wide operating temperature
Li/I_2	$2Li + I_2 = 2LiI$	2.8	0.60	Battery for heart pacemaker

Data from [167–170].

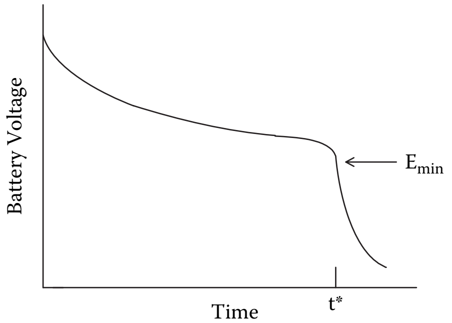

FIGURE 26.38 Voltage vs. time curve during battery discharge at a constant current.

From such data, the capacity is calculated from the product of I (the discharge current) and t^* (the time required for the battery voltage to decrease to a value of E_{min}, below which the battery is no longer useful). The flatness of the discharge curve and the ability of the battery to deliver its expected capacity at increasing currents (i.e., discharge rates) are important battery properties. The real capacity of a battery is usually well below its theoretical value.

2. Theoretical specific energy density. The theoretical specific energy density (with units of kW-hr/kg) is defined as the maximum energy available from a battery ΔG, divided by the anode and cathode reactant masses M_i:

$$\text{Theoretical Energy Density} = \frac{\Delta G}{\Sigma M_i} \tag{26.167}$$

3. Actual specific energy density. The actual specific energy density is determined from the weight of active material w, the discharge current I, the discharge time t^*, and the average battery voltage during discharge E_{av}:

$$\text{Actual Energy Density} = \frac{I \times t^* \times E_{av}}{w} \tag{26.168}$$

4. Storage density. The storage density of a battery is a measure of the charge per unit weight stored in a battery and is given by the capacity per unit weight of the battery. Low-molecular-weight electrode reactants translate into high storage densities, such as lithium, where the electrode reaction $Li \rightarrow Li^+ + e$ produces 1 F (96,487 coulombs) of charge during the consumption of only 7 g of metal.
5. Power density. The power density of a battery is given by the product of the current and battery voltage divided by the battery weight:

$$\text{Power Density} = \frac{I \times E_{cell}}{\text{weight}} \tag{26.169}$$

   As the battery voltage decreases during discharge at a given current, the power density will also decrease.
6. Cycle life. The cycle life of a secondary battery is the number of cycles that are possible before failure occurs. The charging period of a secondary battery's charge/discharge cycle should return the electrodes' active material to a suitable state for further discharge. The active material must have the proper chemical composition, morphology, and distribution in the battery after charging. Since the electrode reactions are not completely reversible, secondary batteries have a finite cycle life (with either a slow decay in performance or a sudden and catastrophic failure). The most common secondary battery failures are: (1) corrosion of the current collector or contacts, (2) shorting due to dendrites of electrically conductive material between electrodes, (3) changes in electrode morphology (so-called shape changes), and (4) shedding of active material from the electrodes.

The anode, cathode, and overall cell reactions during discharge of a lead-acid battery are

Anode (negative electrode): $$Pb + SO_4^{2-} \rightarrow PbSO_4 + 2e^- \tag{26.170}$$

Cathode (positive electrode): $$PbO_2 + 4H^+ + SO_4^{2-} + 2e^- \rightarrow 2H_2O + PbSO_4 \tag{26.171}$$

Overall cell reaction: $$PbO_2 + Pb + 4H^+ + 2SO_4^{2-} \rightarrow 2PbSO_4 + 2H_2O \tag{26.172}$$

In the lead-acid battery, the actual capacity is well below its theoretical value due to the formation during discharge of poorly conducting $PbSO_4$, which forms a barrier between the electroactive PbO_2 and the current collector. Examples of various primary and secondary batteries are listed in Tables 26.16, 26.17, and 26.18.

TABLE 26.17
Commercial Secondary (Rechargeable) Battery Systems

Common Name	Overall Cell Reaction	Nominal Voltage	Approximate Power Density Wh/l	Approximate Power Density Wh/kg	Comments
Lead-Acid	$Pb + PbO_2 + 2H_2SO_4 = 2PbSO_4$	2.10	80	35	Lowest cost; largest sales
Nickel-Cadmium	$Cd + NiOOH + 2H_2O = Cd(OH)_2$	1.30	80	38	High rate; available sealed
Nickel-Iron	$Fe + 2NiOOH + 2H_2O = Fe(OH)_2 + 2Ni(OH)_2$	1.37	90	30	Very long cycle life; almost indestructible; old technology
Nickel-Hydrogen	$H_2 + 2NiOOH = 2Ni(OH)_2$	1.35	90	45	Special space battery; very long cycle life; high self-discharge
Silver-Zinc	$Zn + AgO + H_2O = Zn(OH)_2$ $+Ag_2OZn + Ag_2O + H_2O =$ $Zn(OH)_2 + Ag$	1.86 1.60	200	100	Two-step discharge; limited cycle life; high-energy density
Lithium-MoS_2	$Li + MoS_2 = LiMoS_2$	2.3	150	80	Small sealed cell

Data from [168, 169, 171, 172].

Battery Systems Formerly/Currently in Various Stages of Development

Common Name	Overall Cell Reaction	Nominal Voltage	Approximate Power Density Wh/l	Approximate Power Density Wh/kg	Comments
Nickel-Zinc	$Zn + 2NiOOH + H_2O = Zn(OH)_2 + Ni(OH)_2$	1.65	95	60	Limited cycle life; high rate capability
Zinc-Bromine	$Zn + Br_2 = ZnBr_2$	1.85	75	65	Bromine complexed by quaternary ammonium salt; circulating electrolyte
Lithium-FeS	$Li + FeS = LiFeS$	1.33	90	95	Low cost; high temperature fused salt
Sodium-Sulfur	$2Na + 3S = Na_2S_3$	2.1	120	160	Solid -Al_2O_3 separator; high temperature operation
Aluminum-Air	$4Al + 3O_2 + 2H_2O = 2Al_2O_3 \cdot H_2O$	1.6		300	Circulating electrolyte; low cost; low-energy efficiency
Lithium-TiS_2	$Li + TiS_2 = LiTiS_2$ (intercalate)	2.1		150	Room temperature; organic electrolyte
Solid-State Lithium	$C_6 + LiMO_2 = Li_xC_6 + Li_{1-x}MO_2$	3.4–3.7		90–120	

Data from [169, 173–176].

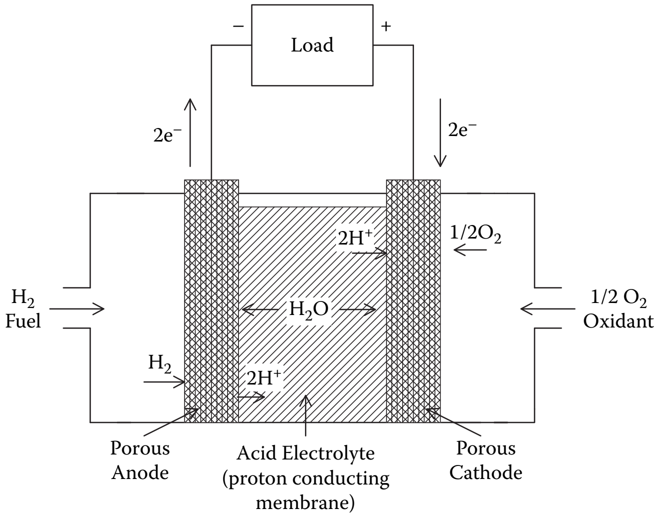

FIGURE 26.39 Principle components in a hydrogen/oxygen fuel cell.

26.8.2 Fuel Cells

A fuel cell is an electrochemical device that converts the chemical energy of a fuel and oxidant directly into low-voltage, direct current electricity. Unlike batteries, the fuel and oxidant are stored externally and are fed to the electrodes as needed. For most terrestrial fuel cells, the oxidant is atmospheric oxygen, whereas the fuel can be H_2 or a low-molecular-weight hydrogen-containing compound such as methanol. For H_2 and O_2 reactants, operation and components of a fuel cell are illustrated in Figure 26.39.

H_2 gas is fed to the anode, where it spontaneously oxidizes to form two protons (H^+) and two electrons. Protons migrate through an acid electrolyte to the anode (under the influence of the electric field), where they react with oxygen and electrons to form water. The electrons that are created at the cathode flow through an external metallic circuit and are consumed at the anode. The electrons provide electrical energy to an external load (e.g., an electric motor) in the circuit. The anode, cathode, and overall reactions for this fuel cell are

Anode: $$H_2 \rightarrow 2H^+ + 2e^- \qquad (26.173)$$

Cathode: $$1/2O_2 + 2H^+ + 2e^- \rightarrow H_2O \qquad (26.174)$$

Overall fuel cell reaction: $$H_2 + 1/2O_2 \rightarrow H_2O \qquad (26.175)$$

The overall reaction is basically the spontaneous cold combustion of hydrogen. In contrast to a combustion process, however, the fuel and oxidant in a fuel cell are kept separate and are never mixed. In the fuel cell, little heat is liberated and instead the free energy is released directly as electrical energy. Hence, the maximum energy efficiency is written as

$$\text{Max. Fuel Cell Eff.} = \frac{\Delta G_T}{\Delta H_o} \qquad (26.176)$$

where ΔG_T is the change in free energy for the overall anode/cathode reaction at the cell operating temperature and ΔH_o is the corresponding enthalpy change. ΔG_T is related to the open circuit

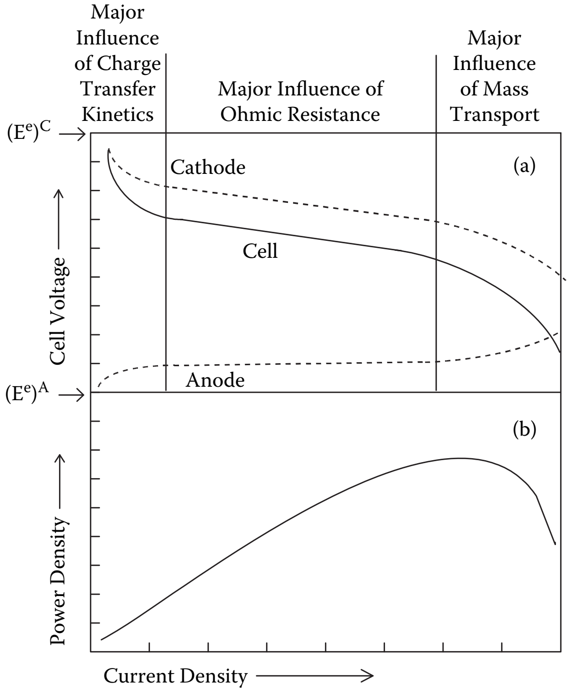

FIGURE 26.40 Typical current density/voltage (a) and current density/power density (b) plots for a fuel cell.

theoretical anode/cathode cell potential, which is about 90% to 95% that of ΔH_o at moderate temperatures. Consequently, the intrinsic maximum energy conversion efficiency of a fuel cell is much greater than that of a heat engine (typically 30% to 40%, as determined by the Carnot efficiency) [177–179]. The actual operational efficiency of a fuel cell is in the range of 30% to 60%) due to activation (kinetic), concentration (mass transfer), and resistance overpotentials, which lower the cell voltage, according to Equation (26.166). The current density regimes where these overpotentials dominate in a typical fuel cell are shown in Figure 26.40a, and the resulting power density vs. current density curve is shown in Figure 26.40b.

26.8.2.1 Fuel Cell Types

A summary of the electrolyte, anode, and cathode gases, operating temperature, and efficiency of different fuel cells is presented in Table 26.19.

Considerable research is currently in progress to find applications for fuel cells. Fuel cells may be useful for large-scale power generation during intermittent peak electricity demand and for load leveling (where electricity is stored in a fuel cell during off-peak hours) [179, 192, 193]. Automobiles equipped with fuel cells are being tested [194–196], but the cost of an automotive fuel cell power plant is too high. Military and space applications of fuel cells are also being explored [177, 179, 192] and portable power applications (replacement for lithium batteries) look promising. Research is in progress to develop cheaper sources of hydrogen gas (the fuel used in most fuel cells) and to find improved methods to store and transport hydrogen.

Molten Carbonate Fuel Cells—The anode fuel is hydrogen, with the following oxidation reaction:

$$H_2 + CO_3^{2-} - 2e^- \rightarrow CO_2 + H_2O \tag{26.177}$$

TABLE 26.19
Types of Fuel Cells

Fuel Cell Type	Electrolyte	Anode Gas	Cathode Gas	Temperature	Efficiency	Refs.
Molten carbonate	Alkali-carbonates	Hydrogen	Atmospheric oxygen	650°C (1200°F)	40%–55%	177, 179, 180
Phosphoric acid	Phosphorous	Hydrogen	Atmospheric oxygen	210°C (400°F)	35%–50%	177, 178, 181, 182
H_2/O_2(air) proton exchange membrane	Solid polymer membrane	Hydrogen	Pure or atmospheric oxygen	75°C (180°F)	35%–60%	178, 183–187
Direct methanol	Solid polymer membrane	Methanol solution in water	Atmospheric oxygen	75°C (180°F)	35%–40%	188–190
Alkaline	Potassium hydroxide	Hydrogen	Pure oxygen	<80°C	50%–70%	177, 181
Solid oxide	Ceramic oxide	Hydrogen, reformed methane	Atmospheric oxygen	800°C–1000°C (1500°F–1800°F)	45%–60%	177, 181, 191

At the cathode, oxygen is reduced in the molten carbonate medium:

$$O_2 + 2CO_2 + 4e^- \rightarrow 2CO_3^{2-} \tag{26.178}$$

Carbon dioxide transfers between the anode, where it is produced, and the cathode, where it is consumed. The anode electrode material is porous nickel or a Ni-Cr alloy, while the cathode is porous NiO. The electrolyte is a mixture of $LiAlO_2$, K_2CO_3, and Li_2CO_3, which is absorbed into a porous inert matrix. These cells operate at about 650°C, where a cell voltage of +0.9 V is obtained at a current density of about 150 mA/cm^2. Systems of 10 kW to 2 MW have been tested for electric utility applications.

Phosphoric Acid Fuel Cells

Hydrogen gas fuel and air (O_2) are fed to anode and cathode Pt catalyst powder layers, respectively. The Pt catalysts is Teflon-bonded to porous carbon sheets to form gas-diffusion electrodes, with a catalyst loading of about 1.0 mg/cm^2. The Pt anode and cathode are separated by a thin inert porous matrix that is filled with concentrated phosphoric acid. The cell operates at 200°C (to improve the electrode kinetics), with a cell voltage of about 0.67 V at a current density of 0.150 A/cm^2. Most voltage losses occur at the air cathode. The hydrogen gas must be pure because sulfur and carbon monoxide poison the Pt anode catalyst. This type of fuel cell is commercially available today, with more than 200 systems installed all over the world in hospitals, hotels, office buildings, and utility power plants.

Proton-Exchange Membrane (PEM) Hydrogen/Oxygen Fuel Cells

This type of fuel cell has received much attention in recent years due to its moderate operating temperature and high-power density. The anode and cathode are Pt-loaded carbon powders. Air is normally used as the source of oxygen for the cathode reaction. Of major importance is the removal/management of product water from the fuel cell. A hydrated cation-exchange membrane separates the anode and cathode.

Direct Methanol PEM Fuel Cells

Liquid methanol has been investigated as the anode fuel in PEM fuel cells, due to ease of handling methanol, its low cost, and widespread availability. The fuel oxidation reaction here is

$$CH_3OH + H_2O \rightarrow 6H^+ + CO_2 + 6e^- \quad (26.179)$$

and the cell operates normally at a temperature of about 80°C. High-temperature operation (120°C to 140°C) with vaporized methanol has also been studied, to improve the oxidation kinetics and minimize anode catalyst poisoning by CO (a by-product of the methanol oxidation reaction). The problem of methanol crossover (leakage) through the solid polymer electrolyte cation-exchange membrane is yet to be solved completely. An alternative approach is to reform methanol and then pump the resulting H_2 gas product to a PEM H_2/O_2 fuel cell.

Alkaline Fuel Cells

This low-temperature fuel cell uses H_2 and O_2 reactants and a highly alkaline aqueous KOH electrolyte. The advantages of this fuel cell are the faster oxygen reduction reaction in the alkaline electrolyte and the possibility of using low-cost, nonprecious metal electrode catalysts, such as Ag-loaded carbon powder. The greatest problem with alkaline fuel cells is that the electrolyte reacts with traces of CO_2 to produce insoluble carbonates.

Solid Oxide Fuel Cells

Such fuel cells operate at high temperatures (~1000°C) and utilize a ceramic oxide material to separate the anode and cathode. At elevated temperatures, the ceramic electrolyte becomes conductive to oxide anions. In these fuel cells, either hydrogen or hydrogen/carbon monoxide mixtures (produced by reforming natural gas) are consumed at the anode and air or oxygen is fed to the cathode. This is a promising fuel cell for large, high-power applications, including industrial and large-scale central electricity generating stations.

NOMENCLATURE

a_i	Activity of species i
a	Electrode area per unit volume (cm^{-1})
A	Area (cm^2)
b_a, b_c	Anodic and cathodic Tafel slopes (V/decade)
C	Concentration (mol/cm^3)
C_∞, c^b	Bulk solution concentration (mol/cm^3)
CE	Current efficiency of an electrode reaction (%)
d	Tube diameter in Equation (26.80) (cm)
D	Diffusion coefficient of the electroyte (cm^2/sec)
D_i	Diffusion coefficient of species i (cm^2/sec)
e	Charge of an electron (1.6021×10^{-19} C)
E	Electromotive force (EMF) (V)
E^e	Equilibrium reduction potential (V)
E°	Standard reduction potential (V)
f_i	molar activity coefficient of species i
$f_\pm$	Mean molar activity coefficient
F	Faradays constant (96487 C/equiv.)
g	Acceleration of gravity (cm/s^2)
G	Gibbs energy (J)
Gr	Grashof number (defined by Equation [26.79d])
H	Enthalpy (J)
i	Current density (A/cm^2)
i_L	Mass-transfer limited current density (A/cm^2)
i_o	Exchange current density in the Butler-Volmer equation (A/cm^2)
I	Current (amps)

I_s	Ionic strength (mol/kg)
k_a, k_c	Chemical kinetic rate constants for the anodic and cathodic directions of an electrode reaction
k_d	Mass transfer coefficient (cm/sec)
L	Characteristic electrode dimension (cm)
m	Molality (mol/kg)
MW	Molecular weight (g/mol)
n	Number of electrons involved in the electrode reaction
N_i	Molar flux of species i (mol/cm^2-s)
P	Pressure (N/cm^2)
q	Total charge passed during an electrolysis (C)
r	Reaction rate in Equation (26.14) (mol/s)
r	Disk radius in Equation (26.81) (cm)
R	Universal gas constant (8.3142 J/mol-K)
R_i	Rate of homogeneous production of species i (mol/cm^3-s)
Re	Reynolds number
Sc	Schmidt number [defined by Equation (26.79c)]
Sh	Sherwood number [defined by Equation (26.79a)]
t	Time
t_i	Transference number of species i
T	Temperature (K)
u_i	Electric mobility of species i (cm^2-mol/J-s)
v	Fluid velocity (cm/s)
V	Volume (cm^3)
V_m	Partial molar volume (cm^3/mol)
w	Weight (g)
Wa	Wagner number, as defined by Equation (26.124)
x	Distance along the electrode surface (cm)
X	Membrane ion-exchange capacity (mol/cm^3)
y	Distance perpendicular from the electrode surface (cm)
z_i	Charge number of species i

Symbols

β	Symmetry factor in the Butler-Volmer equation
γ_i	Molal activity coefficient of species i
$\gamma_\pm$	Mean molal activity coefficient
δ	Actual mass transfer boundary-layer thickness (cm)
δ_e	Effective mass transfer boundary-layer thickness (cm)
ε	Permittivity of the electrolyte solution
η_s	Activation overpotential (V)
η_{ohm}	Ohmic overpotential (V)
η_c	Concentration overpotential (V)
κ	Conductivity (ohm^{-1}-cm^{-1})
λ	Ionic equivalent conductance (cm^2-ohm^{-1}-equiv.$^{-1}$)
μ_i	Chemical potential of species i (J/mol)
$\bar{\mu}_i$	Electrochemical potential of species i (J/mol)
μ	Viscosity (g/cm-sec)
v_+, v_-	Numbers of cations and anions into which a molecule of electrolyte dissociates
v	Kinematic viscosity (cm^2/sec)

ρ Density (g/cm^3)
Φ Electric potential (V)
ω Rotation speed of disk (compare Equation (261.81)) (rad/sec)

27.1 INTRODUCTION

Proprietary engineering technology can be preserved as a corporate or personal asset by patents and trade secrets. In many segments of the chemical process industry, these assets contribute significantly to corporate valuation and the ability to compete. The purpose of this chapter is to set forth the basic elements of patents, trade secrets, and related issues of "intellectual property," as a guide to the chemical engineer. To obtain, maintain, and enforce patent or trade secret rights or to apply these guidelines to specific situations, the engineer is advised to consult with an attorney.

27.2 UNITED STATES PATENTS AND RELATED RIGHTS AND DOCUMENTS

27.2.1 Utility Patent

The most common and well-known type of patent is the "utility patent." Utility patents cover functional features of an invention with utility as a key requirement. Inventions that qualify for utility patents include articles of manufacture, compounds or compositions of matter, manufacturing processes, and methods of using articles, compounds, or compositions.

The term of enforceability of a utility patent extends from its issue date to its expiration date. This is in contrast to certain other countries, where a patent once issued may qualify for enforcement retroactively to a publication date that precedes the issuance of the patent. When originally created by federal law, U.S. patents expired 17 years from the issue date. This was changed in 1995 by federal legislation implementing the GATT (General Agreement on Tariffs and Trade) Treaty for international harmonization of patent laws. Under the 1995 legislation, a utility patent applied for after June 8, 1995, will expire 20 years from the filing date of the earliest United States application that the patent derives benefit from. Thus, a utility patent issuing on an original application filed in the United States Patent and Trademark Office (USPTO) after June 8, 1995, expires 20 years from the filing date of the application; and a utility patent issuing on an application filed either before or after June 8, 1995, as a continuation, continuation-in-part, or division of an application filed before June 8, 1995, expires 20 years from the filing date of the previously filed application regardless of the status of that application. A patent that was either (a) issued prior to June 8, 1995, and had not yet expired by that date, or (b) issued after June 8, 1995, on an application filed before that date expires either 17 years from the issue date or 20 years from the filing date, whichever results in a longer period of time between issuance and expiration. The term of a patent is generally not extendable beyond these expiration dates, except for those patents that were issued as the result of an appeal before the USPTO Board of Patent Appeals and Interferences, and for patents on inventions requiring federal regulatory approval prior to commercialization.

A utility patent bestows on its owner the right to exclude others from making, using, offering to sell, or selling the invention as defined by the scope of the patent claims, within the geographical boundaries of the United States and its territories and possessions. Thus, patents to articles of manufacture, compounds, or compositions of matter are infringed by the unauthorized manufacture, use, offer of sale, or sale of the article, compound, or composition within these boundaries. Patents to methods of use are infringed by the unauthorized practice of the patented method within these boundaries. Patents to manufacturing processes are likewise infringed by the unauthorized practice of the patented process within these boundaries, but are also infringed by the importation into the United States of a product that was produced outside the United States by the patented process, or by the offer of sale, the sale, or the use of such a product in the United States. No patent insulates its owner from potential liability as an infringer of another patent.

27.2.2 Design Patent

Design patents are issued only for articles and cover only the ornamental features of the article rather than functional features. The term of enforceability of a design patent extends from its issue date to an expiration date 14 years from the issue date, and remains unaffected by GATT implementation legislation. Like a utility patent, a design patent bestows on its owner the right to exclude others from making, using, or selling a product that embodies the patented design, within the geographical boundaries of the United States and its territories and possessions.

27.2.3 Provisional Patent Application

A provisional patent application is a document filed in the USPTO as a preliminary step toward applying for a utility patent. The primary advantage of a provisional patent application is the official

recognition by the USPTO of the date of receipt of the document at the USPTO, and the option of transferring that date to a subsequently filed (nonprovisional) application for a utility patent to serve as an effective filing date for the utility application. Further advantages include a lower filing fee than an application for a utility patent and fewer filing requirements in terms of the content and form of the application. Provisional applications find their greatest use when an early filing date is desired with insufficient time to assemble the information needed to accompany an application for a utility patent or to prepare an application that will meet all requirements of a utility patent.

Provisional patent applications are regarded by the USPTO as abandoned 1 year from the application date. Hence, the filing date benefit of a provisional application can only be transferred to an application for a utility patent that is filed before the 1-year anniversary of the provisional application. For any U.S. patent application, whether utility, design, or provisional, the date of mailing to the USPTO with appropriate certification can be recognized as the official filing date. Patent applications can be filed electronically through the USPTO's Electronic Filing System (EFS), details of which are available on the USPTO Web site www.uspto.org.

A provisional application does not confer upon an inventor any ability to exclude others from practicing the invention, nor does it affect the term of any patent issued on a nonprovisional application subsequently filed.

27.2.4 Trademarks

Trademarks confer property rights on names, symbols, or devices that are associated with goods or services. Trademarks reflect such features as the value of name recognition, quality assurance, and good will, and the association of these qualities with the source or origin of the good or service. While the source need not be known to the purchaser, the value of a trademark is a recognition by the purchaser that all goods bearing the trademark originate from a common source and share the value associated with that source. A trademark is infringed when the name, symbol, or device is used on a product or service from a different supplier in a manner that is likely to confuse a purchaser into believing that the product or service is from the same source as products or services sold by the true owner of the trademark.

A trademark becomes a property right simply upon use of the trademark in commerce, and as such is immediately enforceable against infringers. Trademarks can be federally registered with the USPTO, and when so registered are permitted to bear the symbol ®. Federal registration serves as official evidence of the validity of the trademark, the registrant's exclusive right to use the trademark, and the registrant's ownership of the trademark, all of which are considerable advantages to the trademark owner seeking to enforce the trademark against an infringer. Registrations used or renewed prior to Nov. 16, 1989 remain in force for 20 years from the date of issue or renewal, while registrations issued or renewed on or after Nov. 16, 1989 remain in force for 10 years from the date of issue or renewal. In all cases, registrations can be further renewed indefinitely for additional periods of 10 years by supplying evidence toward the end of the 10-year period that the trademark is still in use.

27.2.5 Copyrights

Copyrights confer property rights on original works of authorship that are fixed in a tangible medium of expression. Examples of qualifying works of authorship are literary works, musical works, pictorial and graphic works, sound recordings, audiovisual works, and computer programs. Copyrights do not confer proprietary rights in the underlying ideas, concepts, procedures, principles, or similar component parts, even though these components may be central to the work; instead, the copyright resides only in the form of expression.

The duration of a copyright for a work created after January 1, 1978, is the life of the author (or, for joint works, the last surviving author) plus 50 years. When the author is unknown or is a business entity rather than an individual, the duration is either 75 years from the year of first

publication or 100 years from the year of creation, whichever expires first. Copyrights for works created before January 1, 1978, and still in force on that date have a duration of 28 years from the securement of the copyright, subject to renewal for an additional 47 years.

Copyrights need not be federally registered to be effective, but federal registration is required before suing an infringer, and early registration offers advantages to the copyright owner when enforcing the copyright, particularly in terms of the monetary damages and costs that the successful owner can collect. Copyrights are registered with the United States Copyright Office.

27.3 PATENTS OUTSIDE THE UNITED STATES

As in the United States, patents in countries throughout the world are generally enforceable only in the countries where the patents are issued. There is no global patent; patents must be applied for in each country where patent rights are desired.

Patent treaties between certain groups of countries serve to simplify the process of applying for patents in multiple countries within the groups and to promote consistency in standards for patentability. Included among the multi-country patent treaties are the European Patent Convention (31 countries), the Eurasian Patent Convention (9 countries), the African Regional Industrial Property Organization (ARIPO) (16 countries in western Africa), the African Intellectual Property Organization (OAPI) (16 countries in eastern Africa), the Gulf Cooperation Council (6 countries in the Persian Gulf), and the Patent Cooperation Treaty (PCT) (encompassing the latter 4 conventions plus approximately 60 additional countries including the United States). Each of these treaties offers the establishment of a filing date for a patent application in each of its member countries by filing the application at a single location. In addition, the European Patent Convention, the ARIPO, the OAPI, and the Gulf Cooperation Council each provide a single examination applicable to all of their own member countries.

The oldest and most widely used treaty is the Paris Convention, which permits an application initially filed in a single country to be subsequently filed in other countries with recognition of its original filing date, provided that the subsequent filings are made within a year of the original filing. The Paris Convention has approximately 170 signatory countries worldwide (including the United States). The Paris Convention can be used for foreign filings through any of the other treaties listed above.

The purpose of a patent in any country is to confer a state-recognized property right to an invention. The laws of individual countries differ in such matters as the types of inventions that can be patented, the degree to which an invention must advance the state of the art, the types of prior documents and activities that will defeat patentability, and whether or not the patentee can be required to issue licenses to others and under what conditions, and what constitutes infringement. U.S. patent law, for example, is notable for its difference from the patent laws of certain other countries in the patentability of pharmaceutical compositions and medical procedures (both patentable in the United States), and in cases where competing inventors apply for conflicting patents on the same invention (the United States awards the patent to the first to invent, while most other countries award the patent to the first to file, although, as of the date of publication of this chapter, legislation is pending in the United States to change the standard to first-to-file).

27.4 REQUIREMENTS FOR PATENTABILITY

To qualify for a patent in the United States, an invention must meet the fundamental requirements of novelty, utility, and nonobviousness.

27.4.1 Novelty

Novelty is met by the presence of any element or feature of the invention distinguishing it from the "prior art," the legal term used to designate certain categories of information that are considered

by the patent statute to place the information in the possession of the public. The statute sets forth seven categories of prior art, each with qualifying factors that vary depending on such questions as whether or not the information is reduced to written or printed form or is represented by a use, sale, or offer of sale; if printed, whether or not it was published and to whom it was distributed; if published, the type of publication and when publication or distribution occurred; if a use rather than a publication, the context, degree, and purpose of the use; if a sale or offer of sale, the status or condition of the product being sold or offered. The novelty requirement is met by any distinction, however slight, including the identification of critical parameters not previously recognized in subject matter that is already known but only in a broader context.

27.4.2 Utility

Utility is met by stating that a function is served by the invention and that it has a value, even if the value is only potential. Commercial viability is not a requirement of utility. Nor is the inclusion of laboratory test data, except in inventions where such data are normally considered necessary by "those skilled in the art" (the scientific community) to establish that the invention will serve its stated function.

27.4.3 Nonobviousness

This requirement addresses the type and degree of the difference(s) distinguishing the invention from the prior art. Although originally derived from the conventional meaning of the word "obvious," the term "nonobviousness" has developed into a complex set of legal parameters that vary with both the type of invention and the type of distinction. Establishing nonobviousness in some cases can be achieved by a simple description of the invention, while others require comparative test data, and still others require expert testimony. Secondary factors such as long-felt need and evidence of commercial success are also relevant in many cases.

27.5 PRELIMINARY STEPS FOR THE INVENTOR

27.5.1 Representation before the USPTO

While inventors are legally entitled to represent themselves before the USPTO, it is advisable to use a qualified patent attorney for all communications with the USPTO and for consultation in all preliminary steps. Qualified patent attorneys are registered by the USPTO to represent inventors, and the appropriate patent attorney for any invention is one having a university degree in a technical field in which the invention resides or in a field that enables the attorney to understand the technical nature of the invention. Many patent attorneys handling inventions in chemistry or chemical engineering have advanced degrees in these fields, as well as industry experience as practicing chemists or engineers prior to entering law.

27.5.2 Prior Art Searching

A search of the prior art is often conducted by or for the inventor before applying for a patent. There is no legal requirement that a search be performed, but a search can be of use to an inventor seeking to decide whether or not to apply for a patent. The search can also help the inventor focus the invention or assign the invention an appropriate scope before submitting a patent application to the USPTO. Searches can be performed through computer databases as well as by professional searchers who have direct access to the USPTO records and the assistance of USPTO examiners. Prior art can take the form of published technical papers, oral presentations at technical symposia, news reports, previously issued patents, published patent applications, applications for federal regulatory approval, and in general any form of written or oral presentation throughout the world

that is available to those in the technical field of the invention, or any commercial activity in the United States. The type of search and the manner in which it is conducted will determine what type of prior art is found.

27.5.3 Patents as Prior Art

A form of prior art commonly encountered is previously issued patents. The discovery of a relevant patent cannot only affect the patentability of a subsequent invention, but can also raise the possibility of infringement of the patent by the subsequent inventor. These considerations are often independent and must be addressed separately. The freedom to *patent* a new invention over a prior patent requires scrutiny of everything disclosed in the prior patent. The most relevant portion of the prior patent for this purpose is its specification (the text preceding the patent claims), since the specification often contains description or disclosure that does not appear or is not reflected in the claims, or is peripheral to the invention appearing in the claims. The freedom to *practice* a new invention requires scrutiny of the claims of the prior patent, and is achieved when the new invention avoids fully meeting the recitations in each of the claims.

Free to patent but not to practice. An invention of this type is one that falls within the scope of one of the claims of a prior patent that is still in force, while still offering a patentable distinction over what is disclosed in the patent. This includes such inventions as those representing an improvement in a process or product whose initial discovery is the subject of the prior patent that claims the process or product in a generic manner, and inventions whose use requires the concurrent use of the invention claimed in a prior patent. An example is an invention residing in a new reaction to achieve a particular product, followed by an invention residing in a new catalyst or new reaction conditions to enhance the rate, product yield, or selectivity of the reaction without departing from the reaction itself. For inventions in this category, anyone seeking to practice the second invention will require permission from the owners of both patents. The owner of any one of the two patents will likewise require a license from the owner of the other patent to practice the second invention.

Free to practice but not to patent. This describes an invention that is fully disclosed in a prior patent (that is still in force), although outside the scope of the claims of that patent. This category also includes an invention that is fully disclosed (and possibly claimed) in a prior patent that is either expired, dedicated to the public, or declared invalid.

Free to neither patent nor practice. Inventions of this type are those that are fully disclosed in the specification of a prior patent and fall within the scope of the claims of that patent. The discovery of two patents, two patent applications, or a patent and an application claiming the same invention can lead to an "interference," a procedure that determines which of the two competing parties has priority over the other, usually in terms of the date of invention, and awards the patent to the prevailing party.

Free to patent and to practice. Inventions of this type are those that are distinct from anything disclosed in the prior patent and fall outside the scope of the patent claims.

27.5.4 Record Keeping

The date of conception of an invention can often be used to remove a prior patent or publication from consideration as prior art. Laboratory notebooks or other written records are particularly useful for this purpose, provided they bear a fully contained description of the idea conceived or the work performed, and each page is signed and dated by the inventor. The value of the record as evidence is strengthened when the inventor's signature is supplemented by the signature and date of a witness, and further strengthened when the signatures are notarized.

27.5.5 Minimizing Chances for Invalidation

Those seeking to apply for a patent or to preserve the option to do so can minimize the risk of losing potential patent rights by being aware of actions that defeat patentability or that place a time limit on applying for a patent. Such actions include:

- Publications or public disclosures of the invention
- Sales of the invention or offers to sell the invention (i.e., selling or offering to sell a product or performing on a commercial basis or offering to perform a process, as opposed to selling or offering title or license rights to the invention)
- Uses of the invention in a commercial or public setting

When one or more of these acts is performed by the inventor, the inventor has 1 year from the earliest such act in which to apply for a patent. When the act is performed by anyone other than the inventor, with or without the inventor's knowledge or consent, the inventor has the right to establish conception of the invention prior to the act, but only if the patent was applied for within 1 year from the earliest such act.

Exceptions to these acts are as follows: For publications, neither the date of submission of a manuscript for review prior to publication nor the date of acceptance of the manuscript initiates the 1-year time limit, only the actual publication date. Disclosures of the invention to potential licensees, customers, or users can avoid initiating the time limit if the number of recipients is limited and the disclosure is made on a confidential basis. Confidentiality generally requires a written agreement including provisions requiring that the disclosed information be used only for evaluation of the invention and that neither party disclose the information to outsiders without the prior consent of the other party. An offer for sale of the invention can avoid initiating the time limit if the offer is made before the invention is reduced to a fully workable form. A use of the invention, even in a commercial setting, can avoid initiating the time limit if the use is experimental (i.e., expressly for purposes of evaluation, with direction and monitoring of performance by the inventor or owner).

Patentability can also be jeopardized during the application process by failure to disclose critical items in connection with the invention. One is the "best mode" of the invention, which is the favored embodiment or means of implementing the invention, particularly the one example that functions the best or enables the invention to perform to its utmost advantage, as known to the inventor at the date of applying for the patent. The "best mode" must be included in the text of the patent application, and cannot be reserved as a trade secret. A second disclosure requirement is the disclosure of relevant "prior art" that the inventor is or becomes aware of. This is a continuing requirement that lasts until the issuance of the patent, and encompasses any publications, disclosures, uses, sales or offers, and other acts or documents that qualify as prior art.

When the "best mode" requirement is not violated by maintaining a trade secret, a trade secret can coexist with a patent in a single area of technology. In general, however, a trade secret is an alternative to patent protection.

27.6 TRADE SECRETS

Any information considered proprietary can be a trade secret, regardless of whether the information would also qualify for a patent. Trade secrets are established by the manner in which information is treated, used or disseminated; no application or registration with a government authority is required.

Trade secrets are created and maintained by enforcing secrecy, either by employment agreements or policies or by confidential disclosure agreements. Trade secrets are extinguished by disclosures that are inconsistent with maintaining the secrecy of the information. Violation and extinguishment of a trade secret most often occur when one who is under an obligation to the owner to maintain the secret makes an unauthorized disclosure of the secret. The information in a

patent application can have trade secret status until the application becomes a patent or is published prior to issuance, as often occurs in countries outside the United States. One can thus apply for a patent with the option of maintaining the invention as a trade secret if a patent is not granted.

Unlike patents, there is no limitation on the duration of a trade secret that is not otherwise extinguished by non-secret disclosure.

27.7 INTELLECTUAL PROPERTY BETWEEN THE EMPLOYER AND EMPLOYEE

The obligations of an inventor to the inventor's employer extend to both patents and trade secrets, and to both present and past employers. Issues regarding these obligations often arise when the inventor changes jobs.

27.7.1 Patents—Ownership and Other Rights and Obligations

While patents are by law issued in the name of the inventor, the patent of an employed inventor is most often owned by the employer, the transfer having been made through an assignment executed by the inventor as a requirement of employment. When no assignment has been executed, the employer may still claim ownership through a contract obligating the employee to assign. The contract is often an express contract included in a more general employment contract. If no employment contract has been signed, the contract to assign patent rights can be inferred from statements of policy in such documents as employee handbooks or company memoranda issued by the employer. Whether express or implied, the employer's claim to ownership of patent rights can be challenged on such grounds as a failure of the employer to clearly explain the obligation, an open disagreement and lack of acquiescence by the employee in the obligation, or the claim that an invention did not involve any materials, facilities, or trade secret information of the employer and bore no connection to work performed for the employer. The latter is often supported by state law.

When neither a patent assignment clause in an employment contract or in a policy statement in an internal company document exists, employer ownership of patent rights can be implied for employees who are hired to invent, i.e., those hired either for a specific project or problem or for their expertise in a specific area. If the inventor is an officer or director of a corporation or other business entity, a special obligation to assign may exist as part of the officer's or director's fiduciary duty toward the entity.

When an inventor refuses to sign the documents required to apply for a patent, a present or former employer claiming ownership of the invention can apply for a patent in the inventor's name, provided that an appropriate showing of the respective rights and obligations can be made. The inventor will be informed by the USPTO of the existence of the application, and the USPTO will independently invite the inventor to participate in the application process.

Employers that do not claim ownership in patented inventions may claim a "shop right," which is a nonexclusive, royalty-free (although nontransferable) right to use the invention. Shop rights arise when an inventor has used the employer's resources to conceive the invention, reduce it to practice, perform scale-up, or develop the invention for commercial use. Shop rights can be voided by actions of either the inventor or the employer that are inconsistent with a shop right, or by express agreement or the payment of compensation by the employer to the inventor, the compensation voiding the royalty-free aspect of the shop right.

27.7.2 Trade Secrets—Obligations to Present and Past Employers

Trade secrets are some of the most valuable assets of employers. Present employees are obligated to respect the trade secrets of their employers by maintaining confidentiality of the secrets. Former employees have a greater obligation because they are prohibited from using or disclosing the trade

secrets of their past employers in any new employment situation. This prohibition does not extend to the use of one's general knowledge and skills, but only to information that is specific to the past employer's business and that is truly proprietary to that employer. The risk of violating a trade secret is highest when the new and previous employers are direct competitors and the new employer hires the employee to supervise, design, or work in connection with the same product or service in which the employee had intimate involvement under the previous employer. The risk is lowest when the project assignments under the previous and new employer are unrelated, and when both the employee and the new employer agree to avoid any involvement of the employee in any project that would compete with the previous employer or that would benefit from specific technical knowledge gained by the employee in the previous employment.

27.7.3 Rights and Obligations Created or Eliminated by Express Agreement

All rights and obligations that are implied by the employment situation can be negated or modified by written agreement. Additional rights and obligations that are not otherwise implied can also be created by written agreement. Some of the most common among these are obligations not to compete with a former employer, obligations to cooperate with the former employer, and the rights of a former employer to patents in inventions subsequently developed. Noncompetition provisions are usually limited in scope, either in terms of geographical area or time, and obligations to cooperate are usually directed to assisting in the securement of patent rights when such assistance is needed. In general, pre-employment agreements, employment contracts, and statements of company policy should be studied with care by the employee to identify the rights and obligations of the employee.

> First, controlling language. What matters is insignificant detail. Spelling mistakes, typos, mistakes in idiom, unfashionable usages, all these characterize you as a writer controlled by language rather than controlling it … It is not a question of being clear. These revelations of self don't usually obscure ideas: they obscure you. Worse, they reveal you. They reveal that you have not paid attention to your own writing and invite the reader to respond in kind. They model the history of your mind.
>
> **Richard Lanham (*Revising Prose*. New York: Scribner, 1979, 81)**

28.1 INTRODUCTION

At some point in your work—after you have used all the resources at your disposal, such as this handbook—you will have to write up your results and share them with the world, possibly giving a verbal presentation as well. This moment of communication is the point at which you begin to exist as an engineer or scientist. It is these nontechnical skills, the so-called "soft skills," that set you apart from others in your field. If readers or listeners of your work are constantly distracted or, worse, amused, by how you present yourself in writing or speaking, they may begin to question what you are trying to say. As Professor Lanham notes, these errors reveal you—and in a way that you don't want to be revealed.

Effective writing and editing involves many considerations, and a brief checklist shows how detailed the process can become. In no particular order, each exercise at writing involves the following:

- Coherence and unity
- Transitions
- Subject-verb agreement
- Clarity and logic
- Pacing
- Conciseness
- Sentence patterns
- Sentence variety
- Awkwardness
- Pronoun reference
- Correct modification
- Word choice

Anyone using this guidebook will likely have already been exposed to a large body of written material and probably be an experienced writer. Many of these steps will be handled in the course of writing, and rarely does one person at this level have trouble with all of the above. What's more likely is that he or she may have a blind spot, say, dangling modifiers and conciseness. For that person, it becomes a matter of identifying the problems and working on them. This is where paying attention becomes important.

Tip: Keep a record of the comments made on your writing and look for patterns.

Welcome the information, for it will help you improve. Technical writing is a skill like any other: the more you practice, the better you get. But remember: it is also possible to practice bad habits. Anyone who has ever played golf will know the truth of this. Practice doesn't make perfect—it ingrains. Perfect practice makes perfect.

A complete writing/speaking treatise is beyond the scope of this chapter, but there are some basic areas and problems that, once corrected, can lead to rapid improvement. Certain errors tend to occur often in technical writing and speaking, and these are dealt with first. Some suggestions follow on refinements of style, along with examples.

28.1.1 Some Preliminaries

Audience Analysis. This staple of all communication goes beyond merely thinking about the occupations or titles of your readers/listeners. At some point, the following considerations will come into play as you plan your communication. The more of these you can match, the likelier your message will be received successfully. Clearly, it is unrealistic to expect to match more than, say, the cognitive needs and style, but be aware that your readers will likely be reading you through a lens colored by these variables.

Variables affecting a receiver's (reader/listener) behavior:

- Self-esteem
- Anxiety
- Authoritarianism
- Open/close-mindedness
- Cognitive needs
- Cognitive style
- Commitment

Pay Attention. Getting in the habit of seeing what is actually written on the paper, instead of hastily scanning what you thought you had written, will get you off in the right direction. For example, look at the following sentences (all from students' final reports) with comments in brackets:

> Viscosity is determined by combing Equations 6 and 13.
>
> *[With a fine-toothed comb?]*
>
> The water flew through heat exchanger 1 to 2 when the inlet valve was opened.
>
> *[On wings of....?]*
>
> It was necessary to calibrate the flow meters in conjunction with the gasses interested in running the mass spec.
>
> *[Gases were interested in running a mass spec?]*

It takes little knowledge of grammar, mechanics, or style to figure out that something is amiss here.

Give the Draft Time to Cool Down. Errors somehow manage to slip in between the brain and the keyboard, between intent and pen. In revising or proofreading, we tend to review the script that unscrolled in our brains as we composed. Often we don't "see" what is actually on the page, reading only what we expect to be there. The less time we wait after writing, the clearer that script is, and the less likely we are to see the words on paper as simply that—words on paper. That's why it is so easy to spot errors in someone else's writing: we have no script to follow, so we only look at what's written. Putting a draft aside for a while lets us objectify what we've written, remove it from that familiar script in our heads, and get a fresh perspective. Letting someone else read the draft can accomplish the same, but then you're at the mercy of that person's "error-spotting" ability. If time is unavailable, then proceed to proactive editing below.

Read the Draft Aloud. Hear the rhythms. Hear the omissions. Get a feel for the lengths of sentences.

Be a Proactive Editor (Using the paramedic method described below, for example.). Look for particular problems (as well as strengths—it's okay to appreciate your own work and to pat yourself on the back for a well-turned phrase). Too often in looking over a draft we actually overlook it—hoping something will jump out at us. When nothing does, we are later surprised that someone else, usually a supervisor or higher, has returned the draft awash in red ink. Most writers tend to make the same mistakes in each document, or have similar problems in each writing. Ideally, you'll find out what your areas for improvement are—by working with an editor, for example. Failing that, you can work off the list provided below of common problems often arising in technical writing.

28.2 PRINCIPLES OF GOOD EDITING

Richard Lanham's "paramedic method" (*Revising Prose*, 34) is a direct and simple approach that focuses on aspects of writing that often occur in technical prose. This section also deals with an

important aspect of style—the use of sentence combining—and concludes with some thoughts about the prevailing practice of avoiding the use of the first person.

28.2.1 Paramedic Method

Although there are five steps to the method, they are not sequential. For example, number 4 may be considered a first step; numbers 1 to 3 can be done at the same time; and number 5 acts as a final check. According to this method,

1. Circle the prepositions.
2. Circle the "is" forms (be, am, is, are, was, were).
3. Put the action where it belongs—in a simple active verb.
4. Start fast—no mindless "zero-content" openings.
5. Read your draft aloud and listen for sound patterns.

Circle the Prepositions. Prepositional phrases act as adjectives or adverbs, adding qualifying detail. Used properly, they do their little jobs quite effectively, but in technical writing they often march along in a parade of details—an ineffective catalog because all details are treated the same way without regard to levels of importance. Consider the following example (from T.P. Johnson. *Effective Communication for Engineers*, 6), which contains eight prepositional phrases.

Before

> The unlikelihood **of** meeting orders **from** the majority **of** its new customers is **of** concern **to** the company, due **to** tardiness **in** the installation **of** its new manufacturing line.

Written in this way, all the details are equally weighted—nothing is more important than anything else. Read aloud, the sentence also lacks any life. The two- or three-word phrases all tramp along in the same rhythm. This is a poetic device (of two unstressed syllables and a stressed) that poets use to slow down the movement of the verse. Rarely is that a goal of technical writing. After a few such sentences, it is not surprising that readers find themselves nodding off.

The sentence gains new energy with the use of dependent clauses that subordinate details with respect to their importance.

After

> The company does not know whether it can meet most new-customer orders, because its new manufacturing line is not yet installed.

This revision has zero prepositional phrases and two dependent clauses. It also exemplifies steps 2 and 3 in the paramedic method. See Section 28.2.2 for more about dependent clauses. Prepositional phrases are, of course, an integral part of writing and are not to be avoided. It is only their excessive use and without thought to what is being said that creates problems. The lack of such phrases in this sentence is only coincidental.

Circle the "Is" Forms (be, am, is, are, was, were). The "to be" verbs are important, but by their nature they make existence statements rather than action statements. When overworked, they rob a sentence of energy. For example,

Before

> The calibration of the thermocouple **was** accomplished by the technician.

The intended action of this statement is the act of calibrating, but it is buried in the subject of the sentence, not in the action word, the verb, where it belongs, as in the "After" example below.

Put the Action Where It Belongs—in a Simple Active Verb. The section on smothered verbs (Section 28.3, Common Grammar Problems) shows how pervasive this problem can be. The sentence that expressed no action now becomes an active statement.

After

The technician **calibrated** the thermocouple.

Start Fast—No Mindless "Zero-Content" Openings. If a section heading is "Results," why make the first sentence: "This section contains the results of the experiment."

Read Your Draft Aloud and Listen for Sound Patterns. The rhythm of your writing will become apparent when you read aloud. Reread example 1 above and listen to the effect of the preposition parade. For example, you may also discover that all your sentences are basically "This is the house that Jack built" sentences—all beginning with "the" and all verbs lacking any force. Reading aloud will make this painfully clear. It will also tell you if your sentences are too long or too short.

28.2.2 Style: Dependent Clauses and Sentence Combining

(*See Also Section 28.3.3.*)

Becoming a good stylist in one's writing isn't always a matter of genes or nurture, but simply of paying attention, which the writer of the following two sentences clearly was not doing:

The attic tank is used as the water supply for the system. This tank is located in the attic.

The strings of prepositional phrases, mentioned above, are also often a signal that we haven't been paying attention. The solution is to emphasize the important details, such as by using dependent clauses to subordinate details with respect to their importance.

Recognizing a Dependent Clause.

- It is not a complete statement.
- It must have an introductory conjunction (if, when, which, that, because, since, etc.) or relative pronoun.
- It must have a subject and a verb, though not be independent.

Dependent clauses also act as adjectives and adverbs, and as nouns.

Noun: I saw **what you did**. (Object of the verb "saw")

Adjective: The car **(that) he owns** is very fast. (Modifies the noun "car")

Adverb: She sings **when she takes a shower**. (Modifies the verb "sings")

Dependent clauses make sentences more informative.

- They analyze detail, highlighting what is important (and tell me "when," "if," "because," "who," and so forth that help the reader interpret what is being described).
- They force the writer to break up the equating of detail (preposition parade).
- They make writing sound more natural.

Sentence Combining. Look for short sentences, especially if related by information, and combine them. Common sense has to prevail here. The goal is not just to write long sentences. Balance is important, but usually a series of short statements indicates undeveloped ideas or ideas lacking proper emphasis. The use of dependent clauses is at the heart of improving style by sentence combining. The following sentences illustrate what is involved.

Before

> Before starting experiments each day, the spectrophotometer was calibrated. This was accomplished by determining the absorbance of a standard solution of dye.

After

> We first calibrated the spectrophotometer by determining the absorbance of a standard solution of dye.

Before (The following example contains undifferentiated statements.)

> The temperature difference is the driving force in a heat exchanger. The temperature difference can be the difference between the temperatures of the steam and the water.

After

> The temperature difference, which is the driving force in a heat exchanger, is the difference, for example, between the temperatures of the steam and the water.

or, depending on the emphasis

> The temperature difference, which is the difference between the temperatures of the steam and the water, is the driving force in a heat exchanger.

Before (This example contains an awkward shift from active to passive.)

> To begin the experiment, we adjusted the water flow rate to the desired value. The exit stream valve was then opened and the other steam exit valves were closed.

After

> To begin the experiment, we adjusted the water flow rate to the desired value, opened the exit stream valve, and closed the other steam exit valves.

28.2.3 Avoidance of First Person?

One of the ironies of writing in the engineering profession is the disappearance of the author. At every stage of the work, the engineer is the chief actor in the drama. From the birth of the idea to the presentation of the results to the world, he or she is the central figure. Yet, when it comes time to tell the world, the writer has to disappear. By being forced to drop the use of the word "I," the writer adopts the third person, which leads to more pronouns and passive verbs, and this in turn leads to all the problems with dangling and misplaced modifiers.

A workable compromise might be the use of the first person in moderation. For example, in certain sections of a report it makes sense to let the author's voice come through. A description of apparatus, for example, rightly focuses on the devices themselves, unless the writer wants to

emphasize his or her use of the equipment. A description of procedure, however, is a record of that person's work; as such, the use of first person not only improves the style but also makes the writing more accurate, especially if legal questions arise later. A discussion of results also warrants a stronger authorial presence, whereas a treatment of method or theory reads better with an emphasis on the ideas themselves. And because teamwork is usually involved in a great deal of engineering work, the first person "we" doesn't carry as much of a stigma as "I."

28.2.4 Verb Tense

The choice of verb tense is usually a matter of common sense: if the report deals with a completed project, the appropriate choice is past tense. However, there are some confusing gray areas, such as the use of the "historical present" or a universal truth. For example, there is a large difference in implication between the following two statements:

Newton's law **states** that.....

Newton's law **stated** that….

The implication in the second is that the law has possibly been superseded. Even though it's several hundred years old, we use the present tense with Newton's law because the law still holds true. However, of the phlogiston theory we would probably write: "The phlogiston theory maintained that…."

Use past tense for stating the problem and describing the procedure. For example (with the words emphasized in boldface):

The objective of this work **was** to….

The unit **was** brought to a steady state….

Present tense is appropriate for theory and for discussing results, since the theory holds true and the results still stand. For example:

The theory **is** based on the conservation of….

Table 1 **shows** that….

The values for Run 1 **are** consistent with….

Use past tense to refer to what happened in the actual work:

The significant difference in output shows that the pump **was** not working….

28.2.5 A Final Word

Crafting a cabinet, refining a golf swing, or writing clear prose—all require effort. The rewards in all three begin with satisfaction and end with a product that speaks well of your effort. Begin by paying attention to what you have put on the page. Look at the words as words and the relationships between them. How do they connect? Which direction do they point? Who is doing what to whom? Does the verb do for the noun what it should be doing? Or is it pointing to some other word later in the sentence? And so on. Much can be inferred even if grammatical categories escape you. Read what is on the paper, not what you think you have written.

28.3 GRAMMATICAL PROBLEMS COMMON TO ENGINEERING WRITING

Handbooks, textbooks, usage manuals, and any number of general works are filled with the problems common to technical writing. Improvement in these typical areas will immediately improve your writing overall.

28.3.1 Agreement

Problems in subject-verb and noun-pronoun agreement in technical writing often arise because the verb is separated from the subject by one or more clauses that often contain a plural element. In the following examples, the writers allowed themselves to be misled by the plurals in the intervening words:

> The **kerosene hold-up** in the column at agitator speeds of 200, 250, and 300 rpm **are** shown in Figure 5.

> **Interstage eddy flow** at the two agitator speeds also **confirm** the above prediction.

28.3.2 Agreement and Ambiguity

The following sentence illustrates a number of problems:

> The exit temperature of the water and the water flow rate was observed to give an approximation of how the constants functioned.

In this example, the writer creates several problems. First, it appears that the water flow rate also has a temperature! The order of the first two statements implies that the preposition "of" applies to both items. Writing "water flow rate" first would remove that problem and make it clear that the verb should be "were." Were observed to give what? That is, a dangling modifier (infinitive, see below) is next. Here's what must have been the original meaning:

> To give an approximation of how the constants functioned, we observed the water flow rate and the exit temperature of the water.

28.3.3 Conciseness—or, Wordiness from Insecurity

First, conciseness is not the same as brevity. Clarity is the goal. Sometimes, a sentence with 40 words may be more concise than one with half that many. Wordiness is almost always the sign of an early draft. In an early draft, one's main concern is to get the ideas down; revision is for later.

An effective way of achieving conciseness is through subordination of sentences (see also Section 28.2.2). Another step is to write confidently. The following are examples of degrees of authorial insecurity: "I feel that," "It should be noted," and "The reason is that." If something should be noted, then do so. The note itself is sufficient. To preface it by saying "It should be noted that" or "It is worthy to note that" is to show your insecurity in your own words.

> I feel that the approach will not work under these conditions.

> If you trust yourself and your work, be bold:

> The approach will not work under these conditions.

> It should be noted that the average value does fall within the range of literature values for a fouled system.

The average value falls within the range of literature values for a fouled system.

The reason a high uncertainty is associated with the Wilson plots is most likely due to random error coupled with the inapplicability of the Wilson equation.

The high uncertainty associated with the Wilson plots is most likely due to random error coupled with the inapplicability of the Wilson equation.

In each of these examples the revision reads with more conviction.

28.3.4 Dangling Modifiers—"Using"

Words point to words when we write, but the connections between and among them often become confused. Consider the following statement:

Using this equation, we calculated the area.

Who is doing the using? Clearly, it is the subject of the sentence: "we." However, engineers are often told not to use first person. Their first instinct is to convert the sentence to passive voice:

When this equation was used, the area was calculated.

But this revision sounds awkward, so they then convert only half the sentence to passive voice:

Using this equation, the area was calculated.

That appears to sound better, but is it? "Using" (a verb used as an adjective, called a participle) must modify the subject of the main clause, which was originally "we," but instead it is left dangling without a sensible subject. Another way to look at it is to consider that an action is being indicated at the beginning of the sentence. Does a logical agent of the action follow? In the original sentence it makes sense that "we" were using; in the most recent revision, the area is now using the equation! The restriction on first person has pushed the writer into this corner of writing something that "sounds good" but makes no sense. "Ah," you might say, "but I know what the writer means." Yes, but why waste your time doing what was the writer's responsibility? Take the time you spend reading all the literature you are required to read—not including all that's out there in the professional literature that you'd always hoped to keep up with—and then add to that the time you spend rewriting what you are reading. This kind of writing wastes your time.

The same problem occurs if the clause comes later in the sentence:

The area was calculated using this equation.

This is a very common expression in technical writing; in fact, writers tend to make "using" into an all-purpose preposition. For example,

The permeability of a pure gas can be found using the pressure in both the shell and the permeate and the molar flow rate of the permeate.

Models were developed using linear regression.

Permeabilities were calculated using the numerical integration technique.

Four runs were made using the co-current flow pattern at two conditions.

The error and the humor can be seen by considering the following sentences:

> The rabbits were seen using binoculars.

> The skeleton was discovered while digging for gold.

Just as the rabbits are holding binoculars and Mr. Bones is digging here, in the previous sentences the permeability is using pressure, models are using linear regression, and runs are using flow patterns! Sometimes the absurdity is immediately evident:

> After drying in the sun for a few days, the workers finished the roadway.

And if attention is not paid, a dangling modifier can strain common sense:

> After exiting the first exchanger, the water temperature was measured again by another thermocouple.

> The inoculum was prepared a period of time before arriving in the laboratory.

28.3.5 Smothered Verb

A smothered verb is also referred to as nominalization. A sure-fire way to make writing sound impressive, or so think ineffective writers, is to convert a verb into a noun and then add another weak verb to the sentence. This is guaranteed to add more words to your text. Consider the following sentence:

> The experimental engineer calibrated the thermocouple.

Simple and straightforward but not very "impressive." What you will often find in student writing is the following version:

> The calibration of the thermocouple was accomplished by the technician.

The main action of the sentence is contained in the act of calibrating. The verb has been *nominalized*—turned into a noun; two prepositional phrases have been added ("of the thermocouple" and "by the experimental engineer"); and another verb created ("was accomplished").

Another example:

> We compared the permeabilities during co- and countercurrent flow by graphing the permeability versus run number.

With the onus on the use of first person, this sentence quite easily becomes

> The comparison of the permeabilities during co- and countercurrent flow was done by graphing the permeability versus run number.

But it could just as easily have been written

> The permeabilities during co- and countercurrent flow were compared by graphing the permeability versus run number.

With no gain in clarity or meaning, the writers of these sentences have taken a perfectly good concise sentence and larded it with fat! Whenever possible, keep the main action of the sentence in the main verb.

28.3.6 Weak (or Strange) Predication

Predication relates to the part of the sentence that expresses what is said of the subject; it consists of the verb plus any modifiers or complements. Weak predication arises when the main action of the sentence is not in the verb or when a weak verb is used. The following examples usually have a number of problems as a result.

Sentences 1a and 1b take on different meanings when considered in conjunction with this example:

1. Karen was waiting for the system to come to equilibrium.

1a. The final step was plugging in the vacuum pump.

1b. The hazard in the laboratory was climbing a ladder.

Of course it is possible that the final step and the hazard did the plugging and climbing on their own initiative, but what the writer intended was more likely the following:

1c. The final step involved plugging in the vacuum pump.

1d. Climbing the ladder was hazardous.

Other problems arise with “is when” and “is where” sentences. Often used in defining terms, they fail to include a category and are indirect. They equate (“is”) a noun (the subject of the sentence) with an adverb of time (“when”) or place (“where”).

2. This limit is when the gas flow holds up the liquid flow.

2a. This limit is the point at which the gas flow holds up the liquid flow.

2b. This limit occurs when the gas flow holds up the liquid flow.

28.4 FORMATS

Formats are either organization or discipline specific. In general, though, they will contain some or all of the following sections.

Abstract/Executive Summary. The abstract is a mini-report independent of the main body. Placed before each report, the abstract distills the essence of the report. It abbreviates a longer text without changing any aspect of it and includes nothing that is not in the original. It is specific, includes key numbers, and clearly states the main conclusions but generally does not have tables and figures, unless their production was the main goal of the work. An executive summary is traditionally longer and more detailed than an abstract, often written for individuals who will read nothing else of the report.

The abstract must

- Reduce principal matters to the fewest words and eliminate details.
- Give a general view of the overall situation.
- Separate cause from effect.
- Retain a sense of substance and quality.

The main types of abstracts are the descriptive and the informative. A *descriptive* abstract tells what the report discusses but does not reveal its conclusions. It says more about the report than

about the work. An *informative* abstract, however, contains information from the report, including the facts on which the conclusions are based, the conclusions themselves, and any recommendations made. Basically, it is a miniature report or distillation of an entire report.

Table of Contents. Keep the reader in mind and include everything that will make the work accessible to the reader. Remember to include figures and tables in a separate listing.

Introduction. The importance and relevance of the project and the objectives of the work are presented here. The level of detail depends on the type of report or the intended audience. A proposal or memorandum will require a different opening than a formal report, laboratory report, or technical manual. In any case, you should state your subject and purpose for writing and include some idea of the scope of the work. Again, the level of detail and size of the report/project will determine how much detail is needed in the introduction. For a technical manual, most of the detail should be left to the body of the report, with the introduction doing just that: introducing.

Method/Theoretical Information. Ideas, principles, theories, and techniques as well as relevant equations that apply to the project are included here. Derivations, calibrations, and other ancillary material are usually put in an appendix. Be careful not to turn this section into a list of equations. Provide enough information, both as introductory material and as transitions, to demystify the equations. In short, keep readers' needs in mind as you write.

Apparatus and Procedure. Describe the main features of the apparatus including schematics as well as major pieces of equipment. Use the past tense if reporting on work already completed. Use present tense when describing an apparatus or procedure in general.

Results and Discussion. In general, use plots (figures) rather than tables to discuss your results. Describe what is shown in the figures and tables and tell what it means. Do not make the reader figure it out. For tables and figures in the main body, describe each in a caption and refer to each in the text. Do not put all your figures and tables in the Results and Discussion section; show examples of some plots and discuss the general results. Present results of your statistical work, including regression, propagation of error, and analysis of variance. It is acceptable to refer to the appendix for some details.

Conclusions and Recommendations. Results and Discussion have led to concrete conclusions. Discuss those here as short sentences in a numbered list that must be supported by the data and the theory. Relate your conclusions to the objectives presented in the introduction and add the recommendations supported by the results of your project.

Notation. List symbols used in alphabetical order, English first and Greek in a second list. (Be sure to also introduce them in the report the first time they are used, in an indented table.)

References. List books and articles referred to in the report (see Section 28.4.5).

Appendices. Appendices contain details needed to support your results and to be used by people who may continue your work. Make it easy for them by organizing the material under subtitles or sub-appendices listed in the table of contents. Use enough words in appendices to define units and manipulations, but do not worry about smooth text with introductions and transitions. Include data sheets, sample calculations including error propagation, tables of intermediate variables in the calculations, working plots, calibration curves, and all the figures and tables that you did not include in the main body.

28.4.1 Related Format Matters: Equations, Tables, Figures, References

Equations. State the nature or origin of each equation that you use (definition, balance, kinetic expression, or empirical correlation) to take the mystery out of your development. For example,

The rate of heat transfer in a heat exchanger is frequently reported as follows:

$$q = UA\Delta T \tag{44.6}$$

where

q = heat transfer between hot and cold fluids in exchanger

A = area over which heat is transferred

ΔT = average temperature difference between hot and cold fluids in the exchanger

Equations should appear on separate lines from the text. Definitions of symbols should appear in an indented section also separate from the text. All of this material must be at hand for those interested in following the details, but all of it must be carefully separated so that a busy reader can get the sense quickly from the text. Even interested engineers are likely to read all the text first to find out where you are going and then go back and read the equations.

All definitions of symbols can be included in a nomenclature section at the end of the report or article, or right after the equation, as in the example above.

Tables and Figures. Tables are organized collections of numbers or words. Figures include plots, drawings, and photographs. Tables and figures are numbered consecutively in the order of their appearance in the report.

Refer in the text to each table and figure that appears in the main body, giving the table or figure number, and state the nature of its contents. Call attention in the text to trends or other features shown in the table or figure important to your development; never assume it is obvious to the reader. For example:

> In Figure 3 on page 8, the Nusselt number is plotted against the Reynolds number for each of the four exchangers. The prediction of the Dittus-Boelter equation is also shown. For each exchanger, the Nusselt number increases with the Reynolds number at a rate not significantly different from that of the prediction, but the 95% confidence intervals show that the Nusselt numbers for all exchangers are significantly different from the predicted values.

Labeling Tables and Figures. In general, table labels appear above the table and consist of a number and title, and frequently a line under the title giving more specification. (When any footnotes are used, they appear below the table.) For example

> Table 1. Heat-Transfer Coefficients
>
> *3 in. ID Exchanger*

Figure labels usually appear below the figure, and consist of a number, title, and usually a caption, which is needed to specify the content. For example

> Figure 2. Heat-transfer coefficients as a function of Reynolds number. Runs made after replacing the pressure gage., 0.5-in. tube; —, 1-in. tube;, 3-in. tube.

References to the Literature. Direct quotations and equations taken from the literature must be acknowledged. Special methods may also be acknowledged, but methods in general use need not be. As in most format matters, convention often rules, whether it be industrial or professional society prescribed. The guiding principle in whatever form you are involved with is to keep the reader in mind. And as a reader, what kind of information would you like to have as you read? Few things are as frustrating as trying to locate a reference that is poorly made.

In the main text show numbers in parentheses that are the numbers in your list of references. Show a page number also, if it is pertinent. For example

These results agree with those in Jones and McLaughlin (4, 77).

The derivation below follows that in Bird, Stewart, and Lightfoot (2, 255).

Hardcastle et al. (6, 215) showed that this method is incorrect.

The style of reference lists varies widely from one discipline to another, from one journal to another, and from one corporation to another. Professional societies often have a style that is used in all their journals. See Section 28.6 for lists of professional and general style guides.

Several types of references are needed. The following examples cover general usage:

28.5 BASIC PRINCIPLES OF ORAL REPORTING IN THE WORKPLACE

An oral report is simply a conversation—with attention to some constraints imposed by the situation. If, as you are walking down the hall, the boss asks, "How's the project coming?", your response is basically an oral report. Rather than have, say, a dozen such strolls—to talk with everyone who might have an interest or a stake in your work, it is more practical to talk to all of them at once. So why is this situation so much more fraught with terror than the former? It need not be. What is different about it? For one, with more people in the room you have to make eye contact with more than one person. Because they are further away from you, you have to speak louder. And since sound waves dampen rather quickly, you need to enunciate clearly so that even the last row will understand you. You also may not know the expectations or biases of all of your listeners, so it is best to err on the side of caution and to dress formally and maybe speak a little more formally than in everyday conversation. And the same holds true for the level of formality and quality of visuals or other materials. But these are all practical accommodations dictated by the situation.

For some reason we develop this fear of "The Formal Presentation." Not confident in ourselves or our speaking style, we adopt a "false formal" style that quickly sounds like the worst nineteenth-century legalese. See Section 28.5.2 for some tips on dealing with anxiety.

Oral presentations come in all types and lengths—from the stroll down the hall to a professional conference or major policy address. Though dramatically different, they all share some common features.

Target the audience: What is obvious to you may not be so to them. Consider their:

- Background
- Familiarity with the subject
- Information needs

Connect with the audience personally:

- Look at them
- Smile
- Talk to, not at, the audience
- Use movement to relax yourself and the audience

Use graphics to explain and connect. Make them

- Relevant
- Easy to read
- Interesting (color, clip art, etc.)

28.5.1 Considerations of Delivery

Delivery Method. The following are the four most common delivery methods for oral reporting:

1. **"Off the cuff"**: Too risky for a technical report where accuracy is important.
2. **Reading** (or manuscript speech): Acceptable as a last resort, but it is easy to lose touch with the audience.
3. **Memorization**: Very hard to do well, as memory lapse may unsettle the speech. Speaker thinks in words, not thoughts. Voice and body actions become stylized; lack spontaneity.
4. **Extemporaneous** (best choice): The speech is not written out, only outlined with any vital facts and figures that must be presented accurately (to guard against lapses of memory). It is practiced several times, but no attempt is made to memorize. The advantages are

- Better eye contact (only occasional glances at notes needed)
- Greater flexibility (you work from blocks of thought, not of words)
- Greater spontaneity (because you are not bound to words)

Ideally, you will know the material so well that all you will need are your visual aids.

Posture. Stand naturally and try to convey the impression of calm control. The audience seldom sees your knees shaking.

Quirks. Beware of jingling coins, waving a pointer, swaying, playing with your hair, and so on. These actions will so fascinate your listeners that they will be more interested in watching the show you are presenting than listening to what you have to say.

> "uh…um…er…like…you know…"

Speakers often say "um" before they launch into their subject, and these "prefatory" um's are not too distracting. Pause-filling noises can be very annoying, though, and should be avoided. Don't be afraid to be silent. Your listeners will welcome the pause as an opportunity to reflect on your wisdom.

Eye Contact. Look at the audience as much as possible. Move your eyes slowly around the room, giving the back rows equal time. Learn to glance quickly at notes and to take in a block of

information (which will be easy if you have practiced the talk). Also, practice "dropping" the eyes instead of bending down to look at notes. This motion is not as large as a movement of the head and is not as noticeable. Look back at the screen only for as long as it takes you to orient yourself.

Voice. Why should the audience show any enthusiasm if you do not? Enunciate clearly—sloppiness here may signal a lack of preparation. Worse yet, the audience may see it as a sign of disrespect, which is a sure way to lose their sympathy. You will also have to speak up if the room is fairly large. Have a friend signal to you if you are not making yourself heard. If talking too fast is your habit, focus on enunciating clearly. Consonants take time to form and doing so will give you the slowdown you need. There's no excuse, in a formal presentation, for "wanna," "gonna," and so on. Mispronouncing technical terms is especially bad practice. Like a performer in a one-person show on Broadway, you are in control of your material.

> **Tip:** Always give yourself positive cues. A basketball player who thinks, "Don't miss this freethrow!" is in trouble already. He or she has given the muscles no positive action to perform. Focusing on what is in one's control is important. That player should be focusing on technique, not outcome. In the same way, focusing on enunciating clearly will accomplish more than telling yourself, "Don't talk too fast" or "Slow down"—both of which detract from your concentration.

Accent. Don't worry about any accent you may have or think you have. Accents vary in all countries from region to region, but there's no excuse for sloppy pronunciation. Look up the pronunciation of words that give you trouble.

Movement. Don't be afraid to gesture when speaking, if it is natural for you to do so. Purposeful movement (gestures also) can help in several ways:

- Uses nervous energy and puts it to work
- Attracts attention; emphasizes points
- Adds confidence; keeps speaker and audience awake
- Refreshes the visual scene for the audience

Speakers on the radio gesture emphatically even though they are out of sight of the audience. Use normal descriptive gestures that everyone uses in conversation to indicate length, height, speed, roundness, and so forth.

Notes. They should be unobtrusive. Avoid holding an 8.5 x 11 sheet of paper. Make notes very brief, using key words or phrases.

Timing. Clearly, the most important element for your professional audience will be your explanation of your results. In planning your talk, do this part first; then, with the time available, fill in the other sections.

Visuals. Time limitations and volume of material to cover make it necessary that you use an overhead projector, slide projector, or some computer-aided variation. Quality is very important here. If your lettering is too small or sloppy, your audience will not only have trouble reading what you have written but will likely form a negative opinion about the quality of your work or effort. In general:

- Print, using large lettering
- Use brief action statements, not complete sentences
- Put only one equation on a slide (unless they are very brief)
- Draw a neat schematic of the apparatus, highlighting the main features
- Label axes of graphs; include data points and confidence intervals

28.5.2 Coping with Anxiety

1. **Expect it.** Anxiety is a fact of life. World-class athletes and performers experience it. You might as well anticipate it and prepare for it, realizing that for a few minutes, most likely at the beginning, you are going to be a little shaky. On the other hand, this same nervous energy can be a creative force, helping you to be alert and focused. Focused nervousness equals creative tension. So, literally follow step 2.
2. **Plan for it.** Ignoring or suppressing it is not going to make it go away. As you outline your preparations, just add "will be nervous" to the list, thereby reducing it to just another aspect of the talk needing a little attention, not the sole attention given it otherwise.
3. **Focus on the audience's needs,** not on your own success or failure. Ask yourself continually: "What can I do to help them understand….?" Your main goal is to communicate a message to the audience, not to perform. If you are caught up in your own success or failure, then any little mistake can loom large. If you are focused on the audience, then you will do what it takes to help them understand.

It may help you to remember that the audience is on your side. Have you ever noticed your reaction to a speaker who is struggling? Generally you sympathize with the person. Your listeners will feel the same sympathy, and even empathy, for you.

28.5.3 Six Signals All Audiences Want to Hear

One author suggests that you make sure the audience gets the following signals (Hoff, 1992; see also Section 28.6.6):

1. I will not waste your time.
2. I know who you are.
3. I am well organized.
4. I know my subject.
5. Here is my most important point.
6. I am finished.

28.6 TOOLS AND RESOURCES FOR EFFECTIVE WRITING

28.6.1 Online Guides

http://owl.english.purdue.edu (excellent resource for all kinds of writing help)
http://www.bucknell.edu/x3393.xmL (resources for writers)

29.2.5 Case of Reactor That May Run Away 1862
29.2.6 Competing Researchers...1863
29.2.7 Questionable Company Ethics 1863

29.1 INTRODUCTION

Engineers will almost certainly be tempted to do something that is either unethical, if not illegal, on more than one occasion. Selecting a course of action that is ethical is not always easy and often requires careful planning.

In general, an engineer signs a legal contract with his employer to protect propriety information for at least several years. The engineer also needs to consider how to maintain good relations with his associates and the public. As an analogy, ethics in many ways is like a stool with three or four legs. The rights of the employer (or client), the public, industrial associates, plus the engineer, all need to be considered and balanced.

First, ethics and legal matters are not equivalent. A course of action may be on occasion legal, but not necessarily ethical. How is ethics defined? As defined here, and by many, ethics is the code adapted by a group, profession, and a country. For example, offering money to a political official is generally considered in the United States as a bribe. Hence, it would often be considered not only unethical but also illegal. Yet in certain countries, providing a gift to a key government official might be considered as a way of life and a method of taxation. The old saying was, "When in Rome, do as the Romans do." Since industry is rapidly becoming more internationalized, many engineers will have experiences with individuals from other cultures. Hence, another complication is added to maintaining high ethical standards.

The American Institute of Chemical Engineers plus other professional societies have adapted, as guidelines, codes of ethics. The engineers should serve with fidelity the employer and the public. At all times, the engineer uses his skills to advance human efforts, to increase his technical competence, and to increase the prestige of the engineering profession. Based on personal experience, nothing, and let me repeat nothing, can tarnish one's reputation in the eyes of his colleagues more than to be thought to act unethically.

Several areas in which disagreements can occur between an employer and an employee are as follows:

1. Confidential information: What is confidential information? Incidences have occurred in which an employer claims that specific information is confidential. Yet the company has permitted the information to be published in the open technical literature. Often the engineer is not certain just what is and what is not confidential.
2. What information can an employee take from one company to a second? Often details on the manufacture of a new catalyst are considered proprietary; yet if the employee developed a new method of designing a heat exchanger, the information might not be considered proprietary. An engineer supposedly improves and becomes more of an expert while he is with the first employer.
3. Assuming an engineer becomes convinced that a process or certain equipment has serious safety problems, but the employer insists that the current set-up is safe. What course of action should the engineer follow? With current laws, an engineer can be held liable for suppressing information on potential hazards. At the very least, it is recommended that the engineer address written correspondence on this matter to the top management of his company.
4. Stolen information: Situations have occurred in which an individual leaving one company fills his briefcase with confidential reports. When an employee at either the first or second company learns of this, what action should he take?
5. Technical reports have been published in which incorrect or misleading information has been published on a competitor's process.

Many industries and individuals find that they need to consult to an increased extent with attorneys in planning their actions and programs.

29.2 CASE STUDIES

The following case examples have been used by the author in numerous talks to engineers, students, and others throughout the United States. Several examples were published in the magazine *Chemical Engineering* (September 2, 1963, 87–90; December 9, 1963, 177–184; September 22, 1980, 177–184; September 2, 1987, 40–43; and September 28, 1987, 108–120). The author has, on occasion, modified the original. In some cases, he has used personal experiences. The questions raised in these talks are first reported. The answers received during these presentations are summarized.

29.2.1 Case of the Eager Applicant

Mr. A of ABC Chemical Co. interviews engineer X of XYZ Chemical Co. for an opening in ABC. ABC and XYZ are competitors. As engineer X explains his capabilities, he discloses confidential information about XYZ. Such information is of value to ABC.

Engineer X is obviously a top-notch engineer and he would be able to do the required engineering for ABC.

Questions

(a) Is it ethical for Mr. A to pass on the confidential information to the engineers of ABC? The information was volunteered freely by engineer X.
(b) If the information was passed on, is it ethical for engineers in ABC to use the information if they recognize how it was obtained?
(c) Should ABC hire engineer X?
(d) Should ABC inform XYZ that engineer X talks too much?

Comments

About 50% of engineers vote yes to both (a) and (b). Older engineers sometimes vote affirmably more than younger engineers. Of interest, the ethics of engineer A can be questioned. Did he in any way pump engineer X? Most engineers agree that engineer X acted unethically. Most engineers indicate that ABC Chemical should not hire engineer X since he is too talkative. I personally am aware of a real-life experience similar to this.

29.2.2 Case of the Hospitality Suite

Engineer B is working on a rush project for Supreme Chemical Co. Company X has already commercialized the specific product. Company X has a hospitality suite at an AIChE convention. It was advertised in the lobby.

Engineer B goes to the hospitality suite and starts talking with a tipsy sales representative; he is not asked his company affiliation and he does not volunteer it. He guides the conversation into an area relative to his rush project. The sales representative reports on sales projections for the product, which will be of value to Supreme.

Questions

(a) Was it ethical for engineer B to go to the hospitality suite of the competitor?
(b) Although not requested, should engineer B have made his affiliation known?
(c) Did engineer B act ethically in getting information from the company X sales representative?
(d) Assuming the sales representative was not really tipsy and he recognized engineer B, is it ethical for him to feed engineer B "misinformation"?

Comments

Most engineers agree that they can go to hospitality suites of competitors to get free refreshments. Most believe that engineer B should have identified himself, but also that company X representatives should have asked for identification. Also, engineer B should not have have tried to pump the company X representative. But then company X representatives were apparently not truly vigilant. So both engineer B and company X representatives seem to be at fault. One can also question the ethics of the company X representative in spreading "misinformation." That, too, is not really ethical!

29.2.3 Case of the Super Super Heat Exchanger

Ken initially works for Superbouncy Rubber Co. He has signed a secrecy agreement not to divulge information that Superbouncy considers proprietary. While there, he makes an important improvement on a heat exchanger for a highly viscous elastomeric solution. The company decides to keep the new equipment as a trade secret.

Ken leaves Superbouncy and goes to work for Yum Yum Candy Co. The improved heat exchanger would result in a substantial savings in operating expenses for fudge stream. Superbouncy and Yum Yum are not direct competitors. Ken should do which of the following?

(a) Not report the improved heat exchanger to Yum Yum.
(b) Suggest a development program to Yum Yum that will lead to a heat exchanger similar to the one used by Superbouncy.
(c) Recommend an improved heat exchanger that, based on his calculations, would be essentially identical to the one that he developed for Superbouncy.
(d) Other.

Comments

Most engineers consider this as a grey area. I agree. Is this new heat exchanger truly proprietary? Ken has had courses on heat exchangers in college. Is this new exchanger based on a truly new and unexpected concept?

Ken needs to report to Yum Yum that an improved exchange is possible but also to report possible legal problems. If Ken believes that the new exchanger is really his idea and that it is a logical extension of his scientific growth, then he should receive a favorable legal report first. If there is any question on the ethics, Yum Yum should inform Superbouncy, who would likely license at a rather low cost.

29.2.4 Spy in Sky

Engineer Z of Super Plastics, Inc. is to estimate production costs of a new type of polyethylene produced by a competitor. She reviews the literature and her analysis indicates that the design and size of reactor are of key importance. She needs more information on the size of the reactor. Driving by the plant gives her a good idea on auxiliary equipment but not of the reactor. She is convinced that aerial photography would provide important information.

Questions

(a) Are photos taken from the road ethical?
(b) Are photos taken from an airplane ethical?
(c) Are photos taken from a helicopter ethical?

Comments

Most engineers and students agree by a large majority to a yes answer for question (a). Less than 50% vote affirmatively to question (b) and almost none to question (c). Yet, if the competitor really has information that should be hid, that company could either hide it by placing siding around the reactor or by building dummy reactors.

Engineers do not like the idea of snooping on a competitor by aerial photography. Yet a U.S. government agency is known to have used it on at least one occasion. In another case, I have been told that one company aerially spied on another.

29.2.5 Case of Reactor That May Run Away

Engineer L works for KO Acid Co. and has just been assigned a new supervisor (engineer M). Engineer L is asked to make laboratory batch runs of a process described in a memo from Alpine Chemical Co. Rumor is that this memo arrived with the new supervisor, who had a job with Alpine Chemical 30 days ago. If batch laboratory runs are satisfactory, plant runs will be started shortly with engineer L in charge. Batch runs are conducted. Three runs result in major boilover of strong acid, including two on the day before the first plant run is to be made.

Questions

(a) Should engineer L ask about the ethics of the situation from the new supervisor, who seems unfriendly?
(b) Should engineer L perform the batch runs as requested if circumstantial evidence indicates that the memo was taken without permission from Alpine?
(c) Should engineer L perform the plant runs as requested? Take any action relative to ethics before making the plant runs?
(d) If engineer L resigns from KO Acid, does he have any responsibilities to other employees who may be endangered if there is a "runway"?

Note: This case is based to a considerable extent on an incident in which more than one person was killed when the plant reactor blew up.

Comments

Engineer L needs to be assured that safety, ethical, and legal matters are above board. Both the EPA and OSHA potentially can become involved later. Possibly at the very least, engineer L should put his concerns in writing with a letter addressed to the top management of his company.

29.2.6 Competing Researchers

Twenty-four months ago Prof. Q of the University of Some Excellence (USE) submitted a research proposal to Supreme, Inc. Shortly thereafter Supreme sent a check to support the first year of research and indicated they expected to support a second and third year of research as well. No formal contract was signed, but the possibility of a patent was discussed between them.

Two Supreme personnel visited Prof. Q about 20 months ago, and the proposed research was discussed in considerable detail. Prof. Q also telephoned or wrote Supreme personnel on several occasions to discuss the proposed research. Supreme decided after reading Prof. Q's proposal to start their own in-house research, but did not at the time inform Prof. Q. When Prof. Q started, after several months, his research, he was told that the Supreme had started research and already knew some of the results to be expected from the first-year program. After research was started at USE, it was "suggested" that Prof. Q modify his first-year program and was requested not to publish research results already obtained until at least Supreme's patent application on the subject was acted upon.

(a) Should Supreme have informed Prof. Q or USE that they planned to do research in this area in their own laboratories?
(b) Should Supreme have tried to hire Prof. Q as a consultant for this project?
(c) Prof. Q and his research associate obtained much information in their first several months of research, which was sent as a progress report to Supreme. They asked Prof. Q not to publish, especially until a patent was granted; they did not want to inform their competition. Should Prof. Q agree to this request?
(d) Prof. Q had proposed industrial applications, and he believes that he should be listed as an inventor. Supreme disagrees but fails to provide any information pertaining to their specific claims on the patent application. Based on ethical considerations only, what action, if any, would you recommend to Prof. Q?

Note: Based on an actual example of several years ago.

29.2.7 Questionable Company Ethics

Company A: Company A placed advertisements in local newspapers in their search for new employees. Company A was clearly seeking individuals who were employees of a competitor and who were privy to highly confidential information. This incident was repeated for employees of two different competitors of company A.

Company B: Several companies who licensed a process of company B became concerned about the safety of the process, which used a liquid catalyst known to be highly hazardous.

(a) Several users of company B's process were sufficiently concerned that they decided to test the safety of the process. Company B declined to become involved (and declined to contribute to the costs). *The test proved the process and catalyst of company B were even more dangerous* in at least one respect than expected.
(b) Company B, 2 years later, distributed to their potential customers a report suggesting a competing process *using a very different catalyst* was equally as dangerous as the catalyst

used by company B; company B reported no specific experimental evidence on the dangers of the other catalyst. *They merely postulated on the dangers.* Many people did not agree that this other catalyst was that dangerous.

(c) As a result of the report distributed by company B, several companies felt obligated to test the hypothesis publicized by company B. These other companies asked company B to be a participant and pay their share of the costs of the testing. Company B declined.

(d) Tests indicated that company B's postulate was incorrect.

Comments

If you were an engineer of either company A or company B, what action if any should you take when you learned of your company's actions?

Appendix: Conversion Factors

The following table gives conversion factors from various units of measure to SI units. It is reproduced from NIST Special Publication 811, *Guide for the Use of the International System of Units (SI)*. The table gives the factor by which a quantity expressed in a non-SI unit should be multiplied in order to calculate its value in the SI. The SI values are expressed in terms of the base, supplementary, and derived units of SI in order to provide a coherent presentation of the conversion factors and facilitate computations (see the table "International System of Units" in this section). If desired, powers of ten can be avoided by using SI prefixes and shifting the decimal point if necessary.

Conversion from a non-SI unit to a different non-SI unit may be carried out by using this table in two stages, e.g.,

$$1\ \text{cal}_{\text{th}} = 4.184\ \text{J}$$

$$1\ \text{Btu}_{\text{IT}} = 1.055056\ \text{E+03 J}$$

Thus,

$$1\ \text{Btu}_{\text{IT}} = (1.055056\ \text{E+03} \div 4.184)\ \text{cal}_{\text{th}} = 252.164\ \text{cal}_{\text{th}}$$

Conversion factors are presented for ready adaptation to computer readout and electronic data transmission. The factors are written as a number equal to or greater than one and less than ten with six or fewer decimal places. This number is followed by the letter E (for exponent), a plus or a minus sign, and two digits that indicate the power of 10 by which the number must be multiplied to obtain the correct value. For example:

$$3.523\,907\ \text{E-02 is } 3.523\,907 \times 10^{-2}$$

or

$$0.035\,239\,07$$

Similarly:

$$3.386\,389\ \text{E+03 is } 3.386\,389 \times 10^{3}$$

or

$$3\,386.389$$

A factor in boldface is exact; i.e., all subsequent digits are zero. All other conversion factors have been rounded to the figures given in accordance with accepted practice. Where less than six digits after the decimal point are shown, more precision is not warranted.

It is often desirable to round a number obtained from a conversion of units in order to retain information on the precision of the value. The following rounding rules may be followed:

1. If the digits to be discarded begin with a digit less than 5, the digit preceding the first discarded digit is not changed.

Example: 6.974 951 5 rounded to 3 digits is 6.97

2. If the digits to be discarded begin with a digit greater than 5, the digit preceding the first discarded digit is increased by one.

Example: 6.974 951 5 rounded to 4 digits is 6.975

3. If the digits to be discarded begin with a 5 and at least one of the following digits is greater than 0, the digit preceding the 5 is increased by 1.

Example: 6.974 851 rounded to 5 digits is 6.974 9

4. If the digits to be discarded begin with a 5 and all of the following digits are 0, the digit preceding the 5 is unchanged if it is even and increased by one if it is odd. (Note that this means that the final digit is always even.)

Examples:
6.974 951 5 rounded to 7 digits is 6.974 952
6.974 950 5 rounded to 7 digits is 6.974 950

[9] The U.S. survey foot equals (1200/3937) m. 1 international foot = 0.999998 survey foot.

[10] One technical atmosphere equals one kilogram-force per square centimeter (1 at = 1 kgf/cm^2).

[11] The Fifth International Conference on the Properties of Steam (London, uly 1956) defined the International Table calorie as 4.1868 J. Therefore the exact conversion factor for the International Table Btu is 1.055 055 852 62 kJ. Note that the notation for the International Table used in this listing is subscript "IT." Similarly, the notation for thermochemical is subscript "th." Further, the thermochemical Btu, Btu_{th}, is based on the thermochemical calorie, cal_{th}, where cal_{th} = 4.184 J exactly.

[12] The kilogram calorie or "large calorie" is an obsolete term used for the kilocalorie, which is the calorie used to express the energy content of foods. However, in practice, the prefix "kilo" is usually omitted.

[13] Conversion factors for mercury manometer pressure units are calculated using the standard value for the acceleration of gravity and the density of mercury at the stated temperature. Additional digits are not justified because the definitions of the units do not take into account the compressibility of mercury or the change in density caused by the revised practical temperature scale, ITS-90. Similar comments also apply to water manometer pressure units. Conversion factors for conventional mercury and water manometer pressure units are based on ISO 31-3.

[14] The exact conversion factor is 1.638 706 4 E–05.

[15] The darcy is a unit for expressing the permeability of porous solids, not area.

[16] The centigrade temperature scale is obsolete; the degree centigrade is only approximately equal to the degree Celsius.

[17] This is a unit for the quantity second moment of area, which is sometimes called the "moment of section" or "area moment of inertia" of a plane section about a specified axis.

[18] The exact conversion factor is $10^4/\pi$.

[19] This conversion factor is based on 1 d = 86 400 s; and 1 Julian century = 36 525 d. (See *The Astronomical Almanac for the Year 1995,* page K6, U.S. Government Printing Office, Washington, DC, 1994).

[20] In 1964 the General Conference on Weights and Measures reestablished the name "liter" as a special name for the cubic decimeter. Between 1901 and 1964 the liter was slightly larger (1.000 028 dm^3); when one uses high-accuracy volume data of that time, this fact must be kept in mind.

[21] The value of this unit, 1 nautical mole = 1852 m, was adopted by the First International Extraordinary Hydrographic Conference, Monaco, 1929, under the name "International nautical mile."

[22] For converting fuel economy, as used in the U.S., to fuel consumption.

[23] The exact conversion factor is 4.535 923 E–01. All units that contain the pound refer to the avoirdupois pound unless otherwise specified.

[24] If the local value of the acceleration of free fall is taken as g_n = 9.806 65 m/s^2 (the standard value), the exact conversion factor if 4.448 221 615 260 5 E+00.

[25] The term (EC) is legally defined in the Council Directive of 20 December 1979, Council of the European Communities (now the European Union, EU). The therm (U.S.) is legally defined in the Federal Register of July 27, 1968. Although the therm (EC), which is based on the International Table Btu, is frequently used by engineers in the United States, the therm (U.S.) is the legal unit used by the U.S. natural gas industry.

[26] Defined (not measured) value.

Foaming systems, capacity discount factors for, 1018
Fokker-Planck equation, 167, 168
FOPDT model, *see* First-order plus deadtime model
Forced convection, correlations for common geometries in, 507–520
flow across circular cylinder, 512–513
flow across tube banks, 513–519
heat transfer in packed and fluidized beds, 519–520
inside annular channels, 510–511
inside round tubes, 507–510
internally enhanced tubes, 510
Fourier transform, 122, 157–160
application, 158–160
application of Fourier cosine transform, 160
application of Fourier sine transform, 159–160
application of Fourier transform, 158
convolution property, 157
Fractionation Research, Inc. (FRI), 1065
Fredholm equations, 42, 140
Fredholm equations, methods of solution for, 136–142
degenerate kernels, 136–137
method of Fredholm resolvent kernels, 137–138
method of iterated kernels, 138–139
method of regularization, 142
numerical solution of nonhomogeneous Fredholm equation of second kind, 139–140
solution of ill-posed Fredholm equations of first kind, 140–142
symmetric kernels, 139
Fredholm integral equations, 136
Fredholm resolvent kernels, 137
FRI, *see* Fractionation Research, Inc.
Froth regime, 1043
Fryer–Potter model, 891
Fuel cells, 1816–1824
Fugacity, definition of, 321

G

Galerkin finite element equation, 114
Garcia–Fair model, 1053
Gas(es)
-foil impellers, 842
holdup expression, 667
-inducing impellers, 846
properties of, 440
superficial velocities of, 1357
Gas chromatograph (GC), 1193
Gas-liquid critical state, 285
Gas-liquid mass transfer, interfacial area for, 929
Gas-liquid mixing, 660–671
equipment and its function, 662–63
gas residence time, 668–669
impeller characteristics, 663–665
mass transfer, 661–662
mass transfer and gas holdup, 666–668
scale-up, 669–671
scope, 660–661
Gas-liquid reaction(s)
absorption of NO_x gases for manufacture of nitric acid (system with multiple complexities), 917–918
effect of various parameters, 917–918
lesson, 918
nomenclature, 917
optimum design, 918
problem, 917
air oxidation of sodium sulfide (simple reaction with typical problems of gas-liquid reactions), 900–916
bubble column, 902
external-loop air-lift reactor, 907–908
horizontal sparged contactor, 908–909
lesson, 916
nomenclature, 900–901
packed column, 913–916
pipeline contactor, 910–913
problem, 901–902
sectionalized bubble column, 905–906
solution, 902
industrially important, 786

Gas-liquid-solid (catalytic) reaction, hydrogenation of organic compound, 934–943
nomenclature, 934–935
solved example, 938–939
stepwise procedure, 939–943
Gas-liquid-solid (noncatalytic) reaction
carbonation of lime, 925–934
data, 927
gas flow rate, 928–934
nomenclature, 925–927
problem, 927
reaction mechanism, 927
solution, 927–928
oxydesulfurization of coal in slurry reactor, 919–925
data, 920
design, 923
design of three-phase sparged reactor, 921–923
determination of rate-controlling step, 920–921
lesson, 925
nomenclature, 919
problem, 919
typical procedure, 923–925
Gas-solid (catalytic) reaction(s), 753–770, 870–878
Bayesian discrimination, 875—876
catalysis by solids, 753–756
discriminatory criterion, 876
effects of various factors on catalyst effectiveness, 764–765
experimental rate data, 872
fixed-bed NINA and adiabatic reactors, 878–883
extension to adiabatic operation, 881–882
lesson, 883
nomenclature, 878–879
solution, 880–883
kinetics of reactions on solid surfaces, 756–759
laboratory reactors for accurate kinetic data, 765–770
lesson, 878
method of parameter estimation, 873–874
models, 872–873
nomenclature, 870–871
problem, 871–878
relative roles of internal and external diffusion, 764
role of diffusion within pellet (internal diffusion), 759–763
role of external diffusion, 763–764
sequential design strategy, 874—875
sequential discrimination algorithm, 876–878
Gas-solid noncatalytic reaction(s), 770–785
development of solid sorbent for cleaning coal gas followed by modeling of reaction and conceptual reactor design, 893–900
lesson, 899–900
modeling of sulfidation step, 895–896
practical moving-bed design, 897–899
reactor design, 896–897
sorbent development, 893–895
extensions to basic models, 781–782
general model reduced to specific ones, 785
modeling of gas-solid reactions, 770–781
models accounting for structural variations, 782–784
Gas-solid reaction, solid reaction followed by, manufacture of methylchlorosilanes, 943–954
chloromethane reactor, 951
continuous reactor, 949–951
fluidized-bed reactor, 949
general conversion equations, 951
kinetics of η-phase formation, 945–949
lesson, 954
models with varying gas-phase concentrations, 951–954
nomenclature, 943–944
systems definition, 944–945
GC, *see* Gas chromatograph
Gibbs-Duhem equation, 281, 283
Gibbs-Duhem relation, 280–284
Gibbs energy, 12, 318
Gibbs free energy, 1739
Gibbs phase rule, 385
Gradientless reactors, 739
Graetz number, 506
Granular and powder materials, dry screening of, 1717–1728
equipment selection criteria, 1725–1727
factors affecting screening performance, 1717–1722
fundamentals, 1717
operations and maintenance, 1727–1728
screen motion and configuration, 1722–1723
specifying screener performance, 1724–1725

microstructural terms, 1546–1547

normalizing, 1543
pearlite, 1547
preheat, 1543
quench and temper, 1545–1546
stainless steel, 1554–1558
stress relief/postweld heat treatment, 1544–1545
Mathematics in chemical engineering, 35–197
activities related to mathematics, 41
Adams-Bashforth methods, 99
Adams-Moulton rule, 100
algebraic equations, 40, 81–92
nonlinear equations, 85–92
system of linear equations, 81–85
arithmatic-geometric means inequality, 59
asymptotic approximations and expansions, 170–173
boundary-value problem, 41, 108, 113, 152, 154
branch cut, 147
breakage kernel, 50
Buckingham's -theorem, 78
Budan's rule of signs, 86
calculus of variations, 163–166
application, 165
Euler-Lagrange differential equation, 163–164
Euler-Lagrange equations for functional involving *n*-order derivative, 165
Euler-Lagrange equations for functional of *n*-dependent variables, 164–165
Euler-Lagrange equations for functional of two independent variables, 165
Cardano's formula, 87
Cauchy integral formula, 148
Cauchy-Riemann equations, 146
Cauchy-Schwartz inequality, 58
chaotic problems, 40
Chebyshev's inequality, 59
complex variables, 143–155
analytic functions, 144–149
argument principle and Rouché theorem, 151–152
conformal mapping, 152–155
properties of complex numbers, 143–144
residue theorem, 149–151
computational fluid dynamics, 131
Cramer's rule, 84
d'Alembert's solution, 124
degenerate kernels, 136
Descartes's rule of signs, 86
diagonal matrix, 82
difference equations, 92–100
method of solution for homogeneous equations, 92
method of solution for inhomogeneous equations, 92–94
numerical solutions to ordinary differential equations, 94–100
difference kernel, 133
differential and integral calculus, 60–66
derivative, 61–62
functions, limits, and continuity, 60
implicit function theorem, 64
integrals, 64–66
L'Hôspital's rule, 63–64
mean value theorem, 62–63
dimensional analysis, 78–81
applications, 79–81
theory, 78
dimensional matrix, 78
dimensions of commonly used physical quantities, 79
Dirac delta function, 184
Dirichlet problem, 118
drag coefficient, 80
Duhamel's principle, 120, 121
elliptic equations, 118
empiricism, 39
entire function, 146
equations, 40–53
difference equations, 42–44
integral equations, 50–52
integrodifferential equations, 52
linear equations, 44–45
nonlinear equations, 45–47
ordinary differential equations, 47–48
partial differential equations, 48–50
stochastic differential equations, 52–53
Euler-Lagrange equation, 163, 164
evolution equations, 118
Fokker-Planck equation, 167, 168
Fourier transforms, 122
Fredholm equations, 42
Fredholm integral equations, 136
Fredholm resolvent kernels, 137
Galerkin finite element equation, 114
gauge functions, 171
Green's function, 108, 110, 130, 136
harmonic function, 146
Hölder inequality, 59
identity matrix, 82
imaginary number, 143
inflection point, 61
initial-value problems, 41
integral equations, 42, 131–143
Fredholm integral equations, 136
methods of solution for Fredholm equations, 136–142
methods of solution for Volterra equations, 132–136
Volterra integral equations, 131–132
integral transforms, 155–163
Fourier transform, 157–160
Hankel transform, 162–163
Laplace transform, 156–157
Mellin transform, 160–161
integrodifferential equations, 42
iterated kernels, 138
Îto stochastic equation, 53
Jacobian matrix, 90
kernels for different transforms and integration limits, 155
Kronecker delta, 120
Laplace equation, 128
Laurent series, 149
linear partial differential equation, 115
linear stability analysis, 179
Lyapunov's function, 179, 180, 181
Markov process, 167

matching strategy, 172
mathematical software, 182–183
MatLab, 81
Minkowski's inequality, 59
modulus of complex number, 143
modulus inequality, 59
multiplicity, 178
natural boundary conditions, 164
Neumann problem, 118
Newton-Raphson iteration, 91
number system, 53–60
algebraic inequalities, 58–59
binomial theorem, 58
comparison test, 56–57
integral inequalities, 59–60
integral test, 55–56
limit comparison test, 57
ratio test, 56
real number system, 53–54
root test, 56
sequences and series, 54–55
Taylor series, 57
tests for convergence of sequence and series, 55–57
ordinary differential equations, 47, 101–115
linear first-order differential equation, 101
linear higher-order differential equations, 111–115
nonlinear first-order differential equation, 101–105
second-order differential equations, 106–111
overlap region, 172
overrelaxation method, 84
partial differential equations, 115–131
classification of second-order equations, 118–119
computational fluid mechanics, 131
elliptic equations, 128–131
first-order partial differential equations, 115–118
hyperbolic equations, 124–128
parabolic equations, 119–124
Poisson equation, 128, 130
population balance equations, 52
quasilinear partial differential equation, 115
regular asymptotic expansion, 172
regularization, 140, 142
resolvent kernels, 134
Reynolds number, 80
Robin boundary condition, 129
Robin problem, 118
Routh-Hurwitz criterion, 85
rules of differentiation for real functions, 145–146
Runge-Kutta method, 96
scalar difference equations, 42
Simpson's rule, 99
singular expansions, 172
singularity theory, 176, 177
square matrix, 82
steady-state multiplicity and stability, 173–181
analysis of multiplicity by singularity theory, 176–179
stability of steady-state solution, 179–181
stochastic differential equations, 42, 166–170
connection between Fokker-Planck equation and, 167–168
differential Chapman-Kolmogorov equation, 167
Îto stochastic integral, 168–170
stochastic integral, 168
symmetric kernels, 139
tables of integral transforms, 185–191
Fourier cosine transforms, 189
Fourier sine transforms, 188
Fourier transforms, 186–187
Hankel transforms, 191
Laplace transforms, 185–186
Mellin transforms, 190
Taylor series expansion, 147
trapezoidal rule, 99
vector analysis, 66–78
gradients of sum and product, 77–78
orthogonal curvilinear coordinate systems, 69–76
vector algebra, 66–68
vector calculus, 68
vector integral theorems, 76–77
vector difference equations, 43
Volterra equations, 42, 132, 136
weak formulation of governing differential equation, 114
white noise, 53
Wicke-Kallenbach experiment, 50
Maxwell–Stefan diffusional equations, 1054
McCabe–Thiele diagrams, 986–987
Mechanically agitated contactor (MAC), 938
Mellin transform, 160–161
application, 161
convolution property, 160
Metallurgy, basic, 1542–1561
alloy designations, 1549
heat treatments, 1542–1546
annealing, 1542–1543
normalizing, 1543
preheat, 1543
quench and temper, 1545–1546
stress relief/postweld heat treatment, 1544–1545
manufacturing of metals and alloys, 1549–1550
metallurgical terms, 1547–1549
metals and alloys, 1550–1561
alloy steel, 1553–1554
carbon steel, 1552–1553
cast iron, 1550–1552
common alloys and metals, 1558–1561
stainless steel, 1554–1558
microstructural terms, 1546–1547
austenite, 1546
ferrite, 1546
martensite, 1546–1547
pearlite, 1547
Metal passivation, 1811
Methylchlorosilanes, manufacture of, 943–954
MFR, *see* Mixed-flow reactor
Microbial cells, 1504–1506
bacteria, 1505
culture media, 1506
fungi, 1505–1506
microbial nomenclature, 1505
Mie scattering theory, 586

MIMO process, *see* Multiple-input/multiple-output process
MIMO process control, 1242–1246
  SISO controllers and (c, y) pairings, 1242–1245
  tuning decentralized controllers, 1245–1246
Minimum approach temperature (MAT), 1343
Mixed-flow model, 885
Mixed-flow reactor (MFR), 751
Mixer settlers, 726
Mix point, 722
Mixtures, phase behavior of, 291–294
  gas-gas equilibrium, 294
  gas-liquid equilibrium, 291–293
  liquid-liquid equilibrium, 293–294
Miyauchi model, 889, 890
Model(s)
  activity-coefficient, 329–343
    complete local-composition equation, 339–341
    Flory-Huggins equation, 334–336
    nonrandom two-liquids equation, 338–339
    Redlich–Kister equation, 330
    regular solutions, 332–334
    UNIQUAC equation, 341–343
    van Laar equation, 330–332
    Wilson's local-composition equation, 336–338
  AIChE efficiency, 1050
  Bingham plastic, 426

NRTL equation, *see* Nonrandom two-liquids equation
Nuclear power generation, 1496–1497
Chernobyl, 1496–1497
hazardous waste disposal, 1496
Three-Mile Island, 1496–1497
VHTR reactors, 1497
Nucleate boiling, 532
Number system, 53–60
algebraic inequalities, 58–59
binomial theorem, 58
comparison test, 56–57
integral inequalities, 59–60
integral test, 55–56
limit comparison test, 57
ratio test, 56
real number system, 53–54
root test, 56
sequences and series, 54–55
Taylor series, 57
tests for convergence of sequence and series, 55–57
Nusselt number, 505, 764

O

Ohm's law, 1755, 1798
Ordinary differential equations, 47, 101–115
linear first-order differential equation, 101
linear higher-order differential equations, 111–115
application of higher-order equations, 112–114
finite element method, 114–115
homogeneous equation, 111–112
inhomogeneous equation, 112
nonlinear first-order differential equation, 101–105
autonomous nonlinear equation, 101
Bernoulli equation, 103–104
exact differential equations, 104
homogeneous equations, 104–105
implicit equation, 101–102
Lagrange equation, 102–103
Ricatti equations, 105
separable equation, 103
numerical solutions to, 94–100
Adams-Bashforth methods, 99
Adams-Moulton methods, 100
explicit methods, 96–99
implicit methods, 99–100
Runge-Kutta methods, 96–98
trapezoidal, Simpson, and Runge-Kutta, 99–100
processes governed by, 47–48
dynamics of continuous stirred tank reactor, 47
steady state of tubular reactor, 48
second-order differential equations, 106–111
Green's function, 108–110
Green's function by eigenfunction (Mercer's) expansions, 110–111
homogeneous linear equations with constant coefficients, 106
inhomogeneous linear differential equations with constant coefficients, 107–108
Organic compound, hydrogenation of, 934–943
Organic electrochemical reactions, examples of, 1779–1780
Orifice meter, 455–462
applications, 462
compressible flow, 460–461
incompressible flow, 455–460
loss coefficient, 462
Orthogonal curvilinear coordinate systems, 69–76
bispherical coordinates, 76
circular cylindrical coordinates, 71
conical coordinates, 74
differential operators in curvilinear coordinate system, 70–71
ellipsoidal coordinates, 75
elliptic cylindrical coordinates, 72
oblate spheroidal coordinates, 73
parabolic coordinates, 74
parabolic cylinder coordinates, 73–74
paraboloidal coordinates, 75–76
prolate spheroidal coordinates, 72–73
scale factors and metric tensors, 69–70
spherical coordinates, 71–72
toroidal coordinates, 76
OSHA listed chemicals, 1470, 1471–1477
OSHA listed hazardous materials, fire-hazard properties of, 1478
Overpotentials, 1764
Oxydesulfurization of coal, 919
Ozone, oxidation of NO using, 869–870

P

Partial differential equations, 115–131
classification of second-order equations, 118–119
computational fluid mechanics, 131
elliptic equations, 128–131
Green's function, 130–131
Poisson integral formula, 129–130
first-order partial differential equations, 115–118
hyperbolic equations, 124–128
d'Alembert's solution, 124–126
separation of variables, 126–128
parabolic equations, 119–124
inhomogeneous boundary conditions, 122
inhomogeneous equation, Duhamel's principle, 120–121
inhomogeneous equation in infinite domain, 123–124
separation of variables, 119–120
similarity solutions, 122–123
processes governed by, 48–50
dynamics of chromatography, 49–50
dynamics of tubular reactor, 48–49
Patents and intellectual property, 1831–1839
intellectual property between employer and employee, 1838–1839
patents, 1838
rights and obligations created or eliminated by express agreement, 1839
trade secrets, 1838–1839
patents outside United States, 1834
preliminary steps for inventor, 1835–1837
minimizing chances for invalidation, 1837
patents as prior art, 1836
prior art searching, 1835–1836
record keeping, 1836
representation before USPTO, 1835
requirements for patentability, 1834–1835
nonobviousness, 1835
novelty, 1834–1835
utility, 1835
trade secrets, 1837–1838
United States patents and related rights and documents, 1832–1834
copyrights, 1833–1834
design patent, 1832
provisional patent application, 1832–1833
trademarks, 1833
utility patent, 1832

activity coefficient, 363
activity-coefficient models, 329–343
Gibbs energy models of liquid solutions, 347–350
group contribution methods, 343–346
ideal and excess solution properties, 328–329

ideal and real solutions, 325–328
mechanical instability, 274
model dumbbell rotator, 302
nonstoichiometric formulation, 375
normal fluids, 288
packing fraction, 300, 306
perturbed hard-chain theory, 301
polymer chain-of-rotator equation, 306
Poynting correction factor, 325
Prigogine–Flory–Patterson theory of polymer liquids, 302
principles of thermodynamics, 256–284
equilibrium energy functions, 268–270
first law of thermodynamics and internal energy, 258–264
open system and chemical potential, 277–280
partial molar quantities and Gibbs-Duhem relation, 280–284
second law of thermodynamics and entropy, 264–268
temperature and ideal gas, 257–258
process, 257
Raoult's law, 325
reduced dipole moment, 311
residual functions, 258
retrograde condensation, 292
saturated liquid state, 355
state of equilibrium phase, 257
statistical-associated fluid theory, 308
stoichiometric formulation, 376
sublimation equilibrium, 372
sublimation pressure, 284, 372
sublimation pressure curve, 296
supercritical extraction, 372, 374
surroundings, 256
system, 256
thermodynamic temperature, 265
throttle, 262
UNIQUAC equation, 343, 369
upper critical solution temperature, 294
van der Waals one-fluid mixing rules, 297
vapor pressure curve, 286
volumetric and thermodynamic properties, 284–324
energy functions of ideal gases and mixtures, 313–316
equations of state, 295–313
fugacity, 321–324
phase behavior of mixtures, 291–294
phase rule, 290–291
pressure–volume–temperature relationship, 284–287
principle of corresponding states, 287–290
residual functions and energy functions from equations of state, 317–321
work expansion of steam, 272
Thiele–Geddes model, 993
Three-Mile Island, 1496–1497
TNS, *see* The Natural Step
Tortuosity factor, 599

VOCs, *see* Volatile organic compounds
Vogel–Tammann–Fulcher equation, 15
Volatile organic compounds (VOCs), 1076
Volterra equation, 42, 132, 136
Volterra equations, methods of solution for, 132–136
degenerate (finite rank) kernels, 133
difference kernels, 133–134
generalized Abel integral equation, 135
kernel as function of dependent variable, 132–133
method of resolvent kernels, 134
numerical solution of Volterra integral equations of second kind, 135–136
separable kernels, 133

Volterra integral equations, 131–132
Volume reaction model, 776
VTPR, 12

W

Weber number, 674, 689
Wegstein acceleration, 1339
Wet corrosion, 1805
Weymouth equation, 440
Wheeler–Robell equation, 1146
White noise, 53
Wien's displacement law, 570
Wilson's local-composition equation, 336–338

Z

Zeigler–Nichols tuning, 1246
Zeolites, 1131

Chemical Engineering

ALBRIGHT'S CHEMICAL ENGINEERING HANDBOOK

Taking greater advantage of powerful computing capabilities over the last several years, the development of fundamental information and new models has led to major advances in nearly every aspect of chemical engineering. **Albright's Chemical Engineering Handbook** is a reliable source of updated methods, applications, and fundamental concepts that will continue to play a significant role in driving new research as well as improving plant design and operations.

Well-rounded, concise, and practical by design, this handbook collects valuable insight from an exceptional diversity of leaders in their respective specialties. Each chapter provides a clear review of basic information, case examples, and references to additional, more in-depth information. The book explains essential principles, calculations, and issues relating to topics including reaction engineering, process control and design, waste disposal, and electrochemical and biochemical engineering. The final chapters cover aspects of patents and intellectual property, practical communication, and ethical considerations that are most relevant to engineers.

From fundamentals to plant operations, **Albright's Chemical Engineering Handbook** offers a thorough, yet succinct guide to day-to-day methods and calculations used in chemical engineering applications.
